
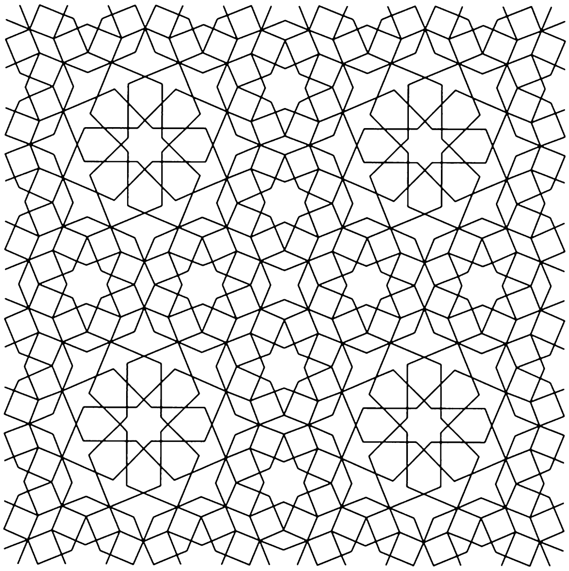
6.5.2 Tessellations

The term *tessellate* means fit together exactly a number of identical shapes, leaving no spaces , as in the making of a mosaic. For example, we may tessellate the Euclidean plane using rectangles of a given size in several ways, and we may tessellate it in other ways as well as illustrated below. In these examples, we may move a given occurrence of any shape onto any other occurrence by a Euclidean transformation, and so by a combination of Euclidean reflections.

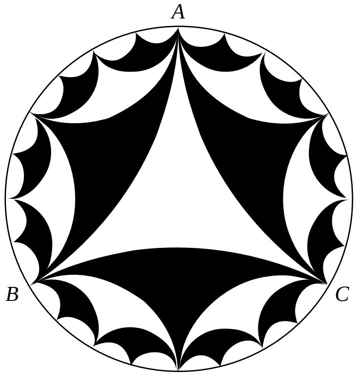
You saw in Theorem 2 of Subsection 5.2.1 that every Euclidean transformation is a composite of reflections.



Euclidean tessellations using a single figure are sometimes called wallpaper patterns , for obvious reasons! With each such figure we can associate its group of symmetries; it is an interesting piece of mathematics that there are only 17 different wallpaper patterns, in the sense that the symmetry group of any wallpaper pattern is isomorphic to one of only 17 non-isomorphic groups.

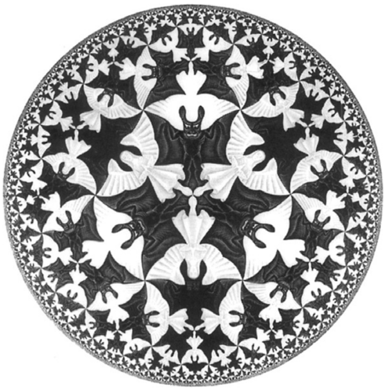
Patterns like those in the figure above are found among the tilings of the Alhambra Palace in Granada (Spain), and elsewhere in Moorish art.

Tessellations occur in hyperbolic geometry also. For example, we may start with a symmetric figure, a symmetric d-triangle ABC, in D bounded by three d-lines (as in the following figure), reflect ABC in each d-line in turn to obtain 3 copies each d-congruent to ABC, and so on. This produces a hyperbolic tessellation of D, as shown in the figure below; for clarity we have shaded all the copies that can be obtained from ABC by direct hyperbolic transformations. All the copies are d-congruent to each other, even though to a Euclidean eye they seem to be of various different shapes and sizes!



Another tessellation of D was suggested to the graphic artist M. C. Escher by the geometer H. S. M. Coxeter, and resulted in the picture below, *Circle Limit IV*. The angels and devils rest on a tessellation of D by d-triangles.

Harold Scott MacDonald Coxeter (1907–2003) was born in London, guided towards mathematics by Bertrand Russell, and spent most of his life in Canada. His work on regular polytopes led to the discovery of Carbon 60, and to the famous geodesic dome of Buckminster Fuller.



Maurits Cornelis Escher (1898–1972) received his graphic art training in Arnhem and Haarlem, and worked in Italy, Switzerland, Belgium and Holland.

6.5.3 Kaleidoscopes

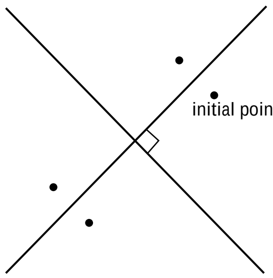
We now explore the ideas underlying the (Euclidean) kaleidoscope, and explain how hyperbolic tessellations can be constructed.

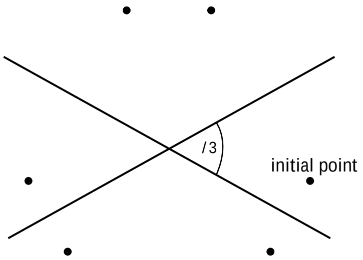
A kaleidoscope is a machine that produces wallpaper patterns using reflections in mirrors.

A Euclidean Kaleidoscope

If two mirrors meet at right angles, an angle of $/2$, any point between the mirrors has an image in each mirror; then, each image itself has an image in the mirrors giving a total of four points in all, lying on a circle centred at the vertex where the mirrors meet.

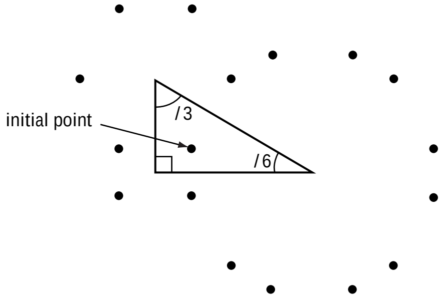
If the mirrors meet at an angle of $/3$, there are 6 points in all; and, in general, if the mirrors meet at an angle $/k$ there are $2k$ points in all.

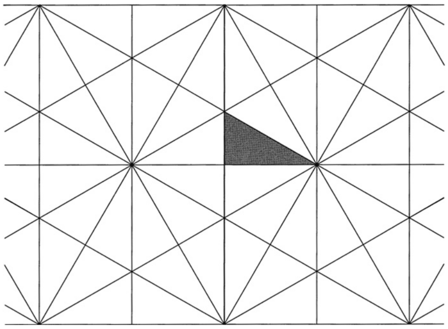




A real kaleidoscope has three mirrors, each pair meeting at an angle $/k$, where k is some integer. For example, consider the case where the mirrors meet at angles of $/2$, $/3$ and $/6$. Corresponding to these vertices there are 4 points, 6 points and 12 points making a total (in the first instance) of 17 points. But each of these points in turn has images in the mirrors, and so on . . .. The whole pattern of images spreads through the plane!

The total number is 17 rather than 22, since some of them are repeated.





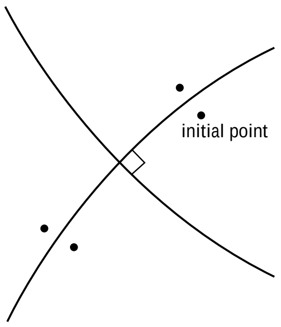
Since reflection is a Euclidean isometry, the process of reflections fills the whole plane with congruent shapes.

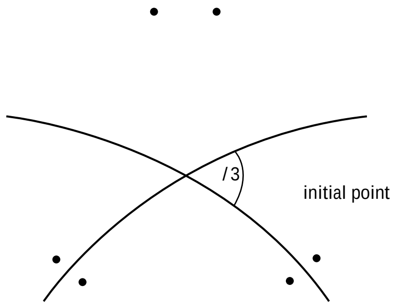
A ‘Hyperbolic Kaleidoscope’

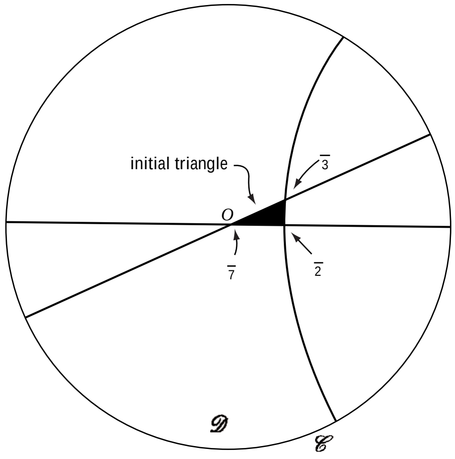
Hyperbolic reflections and transformations are hyperbolic isometries; that is, they map figures without altering the hyperbolic distances between their points even though the images may look (to a Euclidean eye) very different in size and shape from the originals. In particular, they map d-triangles to d-congruent d-triangles.

If two mirrors along d-lines meet at an angle of $/2$, any point between the mirrors has an image under hyperbolic reflection in each mirror; then, each image itself has an image in the mirrors. Again, we obtain a total of four points in all, lying on a hyperbolic circle centred at the vertex.

Similarly, if the mirrors along d-lines meet at an angle of $/3$, there are 6 points in all; and, in general, if the mirrors meet at an angle of $/k$, there are $2k$ points in all.







Now construct a hyperbolic analogue of the Euclidean kaleidoscope, with three mirrors along d-lines in D: two of them lying along d-lines through the origin that meet at O at an angle of $\pi/7$, and the third lying along a d-line that meets the first two at angles of $\pi/2$ and $\pi/3$. We reflect the triangle in each side in turn (using hyperbolic reflections), and continue to reflect indefinitely in the three d-lines.

It is not hard to verify that such a d-line must exist.

Note that $\frac{\pi}{7} + \frac{\pi}{2} + \frac{\pi}{3} < \pi$.

Since hyperbolic reflection is a hyperbolic isometry, the process of reflections fills the whole unit disc with d-congruent d-triangles. The figure that we end up with is just the design on the front of the book and in Subsection 6.4.1.

6.6 Hyperbolic Geometry: the Half-Plane Model

In previous sections we described the disc model of hyperbolic geometry, in which the unit disc $\mathbb{D}$ is the space of points, and the transformations of this space as being of the form

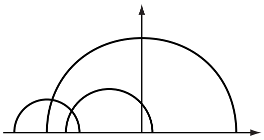
$$z \mapsto M(z) = \frac{az + b}{\bar{b}z + \bar{a}} \quad \text{or} \quad z \mapsto M(\bar{z}) = \frac{a\bar{z} + b}{\bar{b}\bar{z} + \bar{a}}, \quad \text{where } |b| < |a|.$$

However there is a completely *equivalent* hyperbolic geometry, in which the space (the set of points) is the upper half-plane

$$H = \{z : z \in \mathbb{C}, \quad \operatorname{Im} z > 0\},$$

That is, there is a one–one correspondence between points of the two spaces and the transformations in the two geometries.

and the h-lines in H (the analogues of d-lines in $\mathbb{D}$) are the restriction to H of vertical lines in the plane together with the restriction to H of circles with centre on the real axis in $\mathbb{C}$. Notice that the h-lines are all arcs of generalized circles that meet the boundary of H at right angles, just as d-lines are all arcs of generalized circles that meet the boundary $\mathbb{C}$ of $\mathbb{D}$ at right angles.



The Möbius transformation $z \mapsto i\frac{1+z}{1-z}$ maps $\mathbb{D}$ one–one onto H, and provides a convenient method for 'transferring' the geometric properties in $\mathbb{D}$ to corresponding properties in H. For example, it maps the d-lines in $\mathbb{D}$ to the h-lines in H.

The hyperbolic transformations in H are the mappings of H to itself given by

$$z \mapsto M(z) = \frac{az + b}{cz + d} \quad \text{or} \quad z \mapsto M(-\bar{z}) = \frac{a(-\bar{z}) + b}{c(-\bar{z}) + d},$$

where a, b, c and d are real, and $ad - bc > 0$. These are the composites of reflections in h-lines, which are just inversions in the Euclidean circles of which the h-lines form a part.

The geometry in H has many properties similar to those in $\mathbb{D}$:

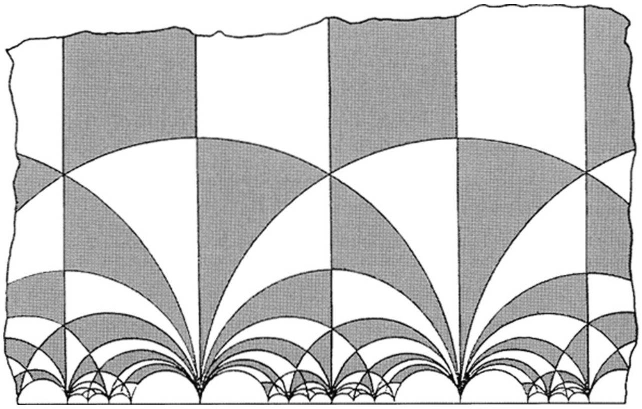
the sum of the angles of an h-triangle is less than π;
two h-triangles are h-congruent if their angles are equal in pairs;
the area of an h-triangle with angles α, β, γ is $K(\pi - (\alpha + \beta + \gamma))$, for some $K > 0$;
h-circles are Euclidean circles in H, and vice-versa.

Generally we take $K = 1$, as in Subsection 6.5.1.

Infinitesimal hyperbolic distances ds in H are related to their Euclidean lengths by the formula $ds = \frac{|dz|}{y}$, from which it can be shown that geodesics in H are the h-lines.

Recall that a *geodesic* is the curve of shortest length joining two points in the space.

Finally, we comment that the hyperbolic geometry of H turns out to be of great importance in many unexpected branches of mathematics such as Number Theory, in which tessellations of H such as the following occur naturally.



6.7 Exercises

Section 6.1

1. Sketch the following d-lines:

$$_1 = \{(x, y) : x + y = 0\} \quad D;$$

$$_2 = \{(x, y) : x^2 + y^2 + 2\ \overline{2}y + 1 = 0\} \quad D;$$

$$_3 = \{(x, y) : x^2 + y^2 \quad \overline{5}y + 1 = 0\} \quad D;$$

$$_4 = \{(x, y) : x^2 + y^2 \quad 3x + 1 = 0\} \quad D.$$

Hence decide which of the d-lines intersect, which are parallel and which are ultra-parallel.

2. Sketch three d-lines $_1$, $_2$ and $_3$ with the following properties: $_1$ and $_3$ are parallel, $_2$ intersects $_1$ and $_3$, and the angles at which $_2$ crosses $_1$ and $_3$ are not equal.

(This shows that the *Corresponding Angles Theorem* in Euclidean geometry does not hold in hyperbolic geometry.)

3. Verify that the points $\frac{1}{\overline{2}}, \frac{1}{2}$ and $\frac{1}{\overline{2}}, \frac{1}{2}$ lie on the circle C with equation

$$x^2 + y^2 + 2\ \overline{2}x + 1 = 0.$$

Hence write down the equations of the diameters of $\mathbb{D}$ which are parallel to the d-line which is part of C.

4. Use the Origin Lemma to show that, given two d-lines meeting at right angles, there is a hyperbolic reflection mapping them to two perpendicular diameters of $\mathbb{D}$.
5. Let $_1$, $_2$ and $_3$ be any three d-lines such that hyperbolic reflection in any one exchanges the other two.
   (a) Prove that there is some point P of $\mathbb{D}$ which lies on each of the three d-lines.
   (b) Use the Origin Lemma to prove that the acute angle between any two of the d-lines is $\frac{}{3}$.
6. Verify that the following equations are the equations of generalized circles of which d-lines are a part, and sketch the corresponding d-lines.
   (a) $x^2 + y^2 + 4x + 1 = 0$
   (b) $x^2 + y^2 + 2x \quad 2y + 1 = 0$
7. Use the fact that the circle with radius a and centre $(1, a)$, where $a > 0$, touches the x-axis to write down the equation of a d-line through the point $\frac{1}{2}i$ that is parallel to the d-line with equation $y = 0$.

Section 6.2

1. Determine the general form of the direct hyperbolic transformations that map 0 to 0 and the diameter $y = x$ of $\mathbb{D}$ to the diameter $y = 0$ of $\mathbb{D}$.
2. (a) Determine the general form of the direct hyperbolic transformations that map each of the following points to 0:

$$\tfrac{1}{2}, \quad \tfrac{1}{2} \quad \tfrac{1}{2}i.$$

   (b) Determine a direct hyperbolic transformation that maps $\tfrac{1}{2}$ to $\tfrac{1}{2} \quad \tfrac{1}{2}i$.
   (c) Determine the general form of the direct hyperbolic transformation that maps $\tfrac{1}{2} \quad \tfrac{1}{2}i$ to $\tfrac{1}{2}$.
3. By drawing a sketch, or in some other way, decide whether the effect of successive hyperbolic reflections in d-lines $_1$ and then $_2$ given by the following equations is a (hyperbolic) rotation, a limit rotation or a translation.
   (a) $_1 : x^2 + y^2 \quad 2x \quad 2y + 1 = 0;$ $_2 : x^2 + y^2 + 2x + 2y + 1 = 0.$
   (b) $_1 : x^2 + y^2 \quad 2x \quad 2y + 1 = 0;$ $_2 : x^2 + y^2 \quad 2x + 2y + 1 = 0.$
4. Let M be a direct hyperbolic transformation mapping the point p in $\mathbb{D}$ to the point q. Let M_q be a direct hyperbolic transformation mapping the point q to 0.
   (a) Show that the composite transformation $M = M_q \quad M$ maps p to 0.
   (b) Deduce that M is the composite of a hyperbolic transformation mapping p to 0 followed by a hyperbolic transformation mapping 0 to q.

5. (a) Prove that the set of all direct hyperbolic transformations forms a group under the operation of composition of functions.
   (b) Prove that the set of all hyperbolic transformations forms a group under the operation of composition of functions.

Section 6.3

1. Determine $d \quad \frac{1}{5}i, 0$ and $d(0.9, 0.99)$.
2. Determine the positive number a for which $d(0, a) = 2$, and the negative number b for which $d(0, b) = 10$.
3. Determined $d \quad \frac{1}{2}, \frac{1}{2}i$.
4. (a) Determine the hyperbolic midpoints of the d-line segments $[0.1, 0.9]$ and $[\quad 0.1, 0.9]$.
   (b) Determine the hyperbolic centre and radius of the circle $C = \{z : |z \quad 0.5| = 0.4\}$.
   (c) Determine the equation of the hyperbolic perpendicular bisector of $[0.1, 0.9]$.
5. Determine the Euclidean centre and radius of the hyperbolic circle $C = \quad z : d \quad \frac{1}{2}, z \quad = 1$.
6. Let $0 < a < b < 1$, and let the d-line with equation $x^2 + y^2 \quad 2cx + 1 = 0$, where $c > 1$, intersect the radius $[0, 1)$ between $A(a, 0)$ and $B(b, 0)$.
   (a) Prove that intersects AB at the point $c \quad \overline{c^2 \quad 1}, 0$.

   Now assume that is the hyperbolic perpendicular bisector of AB.

   (b) Use the Reflection Lemma to prove that

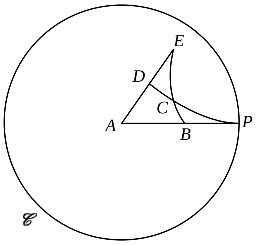
$$c = \frac{1 + ab}{a + b}.$$

   (c) Deduce from parts (a) and (b) that the hyperbolic midpoint of AB is

$$\frac{1 + ab \qquad \overline{(1 \quad a^2)(1 \quad b^2)}}{a + b}, 0 \quad .$$

7. Let be a d-line that is not a diameter of D and whose endpoints on C subtend an angle , $0 < \quad <$, at the centre of D. Prove that the hyperbolic length of the d-line segment from the origin to that is perpendicular to is $\tanh^{\quad 1} \quad \cot \frac{1}{4}(\quad + \quad)$.

Section 6.4



1. $ABCD$ is a d-quadrilateral. The d-lines through A and B and through D and C are parallel, with a common boundary point P on C; the d-lines through D and A and through C and B meet at a point E in D, as in the figure in the margin (in which A is at the origin).
   (a) Prove that it is impossible that $EAB = \quad EDC$.
   Hint: Consider the Euclidean triangle ADP.

(b) Prove that it is impossible that $EBA = ECD$.
Hint: Consider the Euclidean triangle PBC, with B at the centre of D.

(c) Prove that the following combination is impossible:

$$EAB = ECD \quad \text{and} \quad EBA = EDC.$$

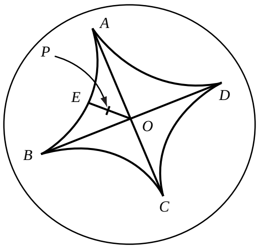
(d) Prove that the following combination is impossible:

$$EAB = EBA \quad \text{and} \quad EDC = ECD.$$

2. Let $_1$ and $_2$ be a pair of perpendicular diameters of D. Sketch $_1$ and $_2$, and some of the ultra-parallels to $_1$ for which $_2$ is their common perpendicular with $_1$.
3. $ABCD$ is a d-quadrilateral such that the hyperbolic length of each side is 1. The d-line segments AC and BD are of equal hyperbolic length and intersect at right angles at the origin O, their common midpoint, and OE is an altitude of the d-triangle OAB. Also, P is the hyperbolic midpoint of OE.

   Determine the hyperbolic length of OE, the Euclidean length of OP, the angle ABC, the hyperbolic length of OB, the Euclidean length of BD, and the angle between PE and either d-line through P that is parallel to the d-line through A and B.

ABCD is a hyperbolic square of side-length 1.



Proof of the Sine Formula (Subsection 6.4.3, Theorem 10).

4. Let ABC be a d-triangle with $ABC = /3$, and let the sides BA and BC have the same hyperbolic length c. Let BD be the altitude from B to the side AC. Show that the hyperbolic length b of AC is greater than c.
Hint: Apply the Sine Formula to triangle BDA.
5. Show that if ABC is a d-triangle right-angled at C, then

$$\sin A = \frac{\sinh 2a}{\sinh 2c},$$

   where a and c are the hyperbolic lengths of the sides BC and AB.
Hint: If $\tan \ = t$, then $\sin^2 \ = \frac{t^2}{1+t^2}$.
6. Determine the hyperbolic lengths of the sides of the d-triangle with angles $\frac{}{2}$, $\frac{}{6}$ and $\frac{}{6}$.

Section 6.5

1. Determine the hyperbolic area of the d-triangle ABC with vertices at the points $A(0,0)$, $B\ \frac{1}{2}, 0$ and $C\ 0, \frac{1}{2}$.
2. Let A, B, C and D be the points (0,0), (1,0), (0,1) and $(\ 1, 0)$, respectively, and let be the d-line BC.

(a) Determine the vertices of the d-triangle that is the image of the d-triangle ABC under hyperbolic reflection in .

(b) Determine the vertices of the d-triangle that is the image of the d-triangle ACD under hyperbolic reflection in .

(c) Sketch the d-triangles ABC and ACD, and their images under hyperbolic reflection in .

(d) Determine the areas of the d-triangles ABC and ACD, and of their images under hyperbolic reflection in .

Hint: You may assume that Theorem 4 of Subsection 6.5.1 holds for asymptotic triangles, with $K = 1$.

Summary of Chapter 6

Introduction

1. **The (Euclidean) Parallel Postulate** Given any line and a point P not on , there is a unique line m in the same plane as P and which passes through P and does not meet .
2. **The (Elliptic) Parallel Postulate** Given any line and a point P not on , all lines through P meet . (That is, there are no lines through P that are parallel to .)
3. **The (Hyperbolic) Parallel Postulate** Given any line and a point P not on , there are at least two lines m through P that do not meet . (That is, there are at least two lines through P that are parallel to .)

Section 6.1: Hyperbolic Geometry: the Disc Model

1. In (Poincarø s model of) hyperbolic geometry, **points** (or ***d*-points**, where d stands for disc) consists of the points in the unit disc $\mathbb{D} = \{z : |z| < 1\} = \{(x, y) : x^2 + y^2 < 1\}$.

   The points on the boundary $\mathbb{C} = \{z : |z| = 1\} = \{(x, y) : x^2 + y^2 = 1\}$ of $\mathbb{D}$ are not points that belong to the geometry.
2. A ***d*-line** (or **line in hyperbolic geometry**) is that part of a (Euclidean) generalized circle which meets $\mathbb{C}$ at right angles and which lies in $\mathbb{D}$. A d-line may be an arc of a (Euclidean) circle or a Euclidean line segment that is a diameter of $\mathbb{D}$. The points where the corresponding generalised circle meets $\mathbb{C}$ are called the **boundary points** of the d-line.

   d-lines that are arcs of Euclidean circles all lie in one-half of the disc $\mathbb{D}$, and all curve away from the diameter bounding the half-disc.

   The equation of a d-line is of the form $ax + by = 0$, where a and b are not both zero, or $x^2 + y^2 + fx + gy + 1 = 0$, where $f^2 + g^2 > 4$.
3. Two d-lines that do not meet in $\mathbb{D}$ are **parallel** if the generalized Euclidean circles of which they are parts meet at a point on $\mathbb{C}$, or **ultra-parallel** if the generalized Euclidean circles of which they are parts do not meet on $\mathbb{C}$.

   Corresponding to any given d-line and any point P in $\mathbb{D}$ that is not on , there exist exactly two d-lines through P that are parallel to , and infinitely many d-lines through P that are ultra-parallel to .
4. Let be a d-line that is part of a Euclidean circle C. Then inversion in C maps $\mathbb{C}$ onto $\mathbb{C}$, and $\mathbb{D}$ onto $\mathbb{D}$.

5. A **hyperbolic reflection** in a d-line is the restriction to D of the inversion in the generalized circle C of which is part.

   The centre of such a circle C is the point of intersection of the tangents to C where C and C intersect.
6. **Hyperbolic transformations** are the composites of a finite number of hyperbolic reflections, and form a group called the **hyperbolic group**, G_{D}, under the operation of composition of functions.

   Hyperbolic geometry consists of the unit disc D together with the group G_{D} of hyperbolic transformations.
7. The (**hyperbolic**) **angle between two curves** through a given point A in D is the Euclidean angle between their (Euclidean) tangents at A.
8. Hyperbolic transformations map d-lines onto d-lines, and preserve the magnitudes of angles.
9. **Origin Lemma** Let A be a point of D other than the origin O. Then there exists a d-line such that hyperbolic reflection in maps A to O.
10. Let A be a point of D. Then there exist infinitely many d-lines through A.

    Let A and B be two distinct points of D. Then there exists a unique d-line through A and B.
11. Let A_1 and A_2 be any two points of D, and let $_1$ and $_2$ be d-lines through A_1 and A_2, respectively. Then there is a hyperbolic transformation which maps A_1 to A_2 and $_1$ to $_2$.
12. Let A, B D be inverse points with respect to the d-line , and let A , B and be the images of A, B and under hyperbolic reflection in another d-line . Then A and B are inverse points with respect to inversion in .

Section 6.2: Hyperbolic Transformations

1. Hyperbolic reflection in the d-line which is part of a Euclidean circle C with centre is given by the formula

   $$(z) = \frac{\overline{z} \quad 1}{\overline{z} \quad \overline{}}, \; z \quad \mathsf{D}.$$

   Hyperbolic reflection is self-inverse.

   Hyperbolic reflection in the diameter of D on which $y = x \tan$ is given by the formula $(z) = {}^2\overline{z}$, z D, where $= \cos + i \sin$.
2. The composite of the hyperbolic reflections $(z) = \frac{\overline{z} \; 1}{\overline{z} \; \overline{}}$ and $(z) = \frac{\overline{z} \; 1}{\overline{z} \; \overline{}}$ is $(\quad)(z) = \frac{(\overline{} \quad 1)\overline{z} +}{(\overline{} \quad \overline{})\overline{z} + \quad \overline{} \quad 1}$.
3. The restriction to D of every Möbius transformation of the form $M(z) = \frac{az+b}{\overline{b}z+\overline{a}}$, with $|b| < |a|$, is a composite of two hyperbolic reflections, and is therefore a hyperbolic transformation.
4. Every hyperbolic transformation can be expressed as a composite of at most three hyperbolic reflections.
5. The composition of an even number of hyperbolic reflections does not change the orientation of the unit disc, and is called a **direct** hyperbolic

transformation. A direct hyperbolic transformation can be expressed as a composite of at most two hyperbolic reflections.

Any direct hyperbolic transformation is given by $z \mapsto M(z) = \frac{az+b}{\overline{b}z+\overline{a}}$, $z \in \mathbb{D}$, for some a, b with $|b| < |a|$.

The composition of an odd number of hyperbolic reflections changes the orientation of the unit disc, and is called an **indirect** hyperbolic transformation.

Any indirect hyperbolic transformation is given by $z \mapsto M(\overline{z})$, where $M(z) = \frac{az+b}{\overline{b}z+\overline{a}}$, $z \in \mathbb{D}$, for some a,b with $|b| < |a|$.

6. The composite of hyperbolic reflections in d-lines ℓ_1 and ℓ_2 that intersect at a point in $\mathbb{D}$ is called a (**hyperbolic**) **rotation** and has exactly one fixed point in $\mathbb{D}$.

   The composite of hyperbolic reflections in d-lines ℓ_1 and ℓ_2 that do not meet in $\mathbb{D}$ but do meet at a point on $\mathbb{C}$ is called a (**hyperbolic**) **limit rotation**, and has no fixed points in $\mathbb{D}$ but leaves one point of $\mathbb{C}$ fixed.

   The composite of hyperbolic reflections in d-lines ℓ_1 and ℓ_2 that do not meet in $\mathbb{D}$ or on $\mathbb{C}$ is called a (**hyperbolic**) **translation**, and has no fixed points in $\mathbb{D}$ or on $\mathbb{C}$.

   The composite of two hyperbolic translations may depend on the order in which they are applied.

7. A direct hyperbolic transformation M can be written in the (canonical) form $M(z) = K\frac{z-m}{1-\overline{m}z}$, where K and m are complex numbers with $|K| = 1$ and $m \in \mathbb{D}$.

   Conversely, every direct hyperbolic transformation M that maps a point m of $\mathbb{D}$ to the origin is of this form.

   A direct hyperbolic transformation M that maps the diameter $(-1,1)$ onto itself is of the form $M(z) = \pm\frac{z-m}{1-mz}$, where $m \in (-1,1)$.

   An indirect hyperbolic transformation M can be written in the (canonical) form $z \mapsto K\frac{\overline{z}-m}{1-\overline{m}\overline{z}}$, where $|K| = 1$ and $m \in \mathbb{D}$.

8. **Strategy** To determine the general form of the direct hyperbolic transformation that maps one point p in $\mathbb{D}$ to another point q in $\mathbb{D}$:
   1. write down the general form of the direct hyperbolic transformation M_1 that maps p to 0, and a matrix $\mathbf{A}_1$ associated with M_1;
   2. write down a direct hyperbolic transformation M_2 that maps q to 0, and a matrix $\mathbf{A}_2$ associated with M_2;
   3. form the matrix product $\mathbf{A}_2^{-1}\mathbf{A}_1$ associated with the direct transformation $M_2^{-1} \circ M_1$, and hence write down the general form of the transformation.

Section 6.3: Distance in Hyperbolic Geometry

1. **Properties of a Distance Function d**
   1. $d(z_1, z_2) \geq 0$ for all z_1 and z_2;
      $d(z_1, z_2) = 0$ if and only if $z_1 = z_2$.
   2. $d(z_1, z_2) = d(z_2, z_1)$ for all z_1 and z_2.

3. $d(z_1, z_3) + d(z_3, z_2) \geq d(z_1, z_2)$ for all z_1, z_2 and z_3. (Triangle Inequality)
4. $d(z_1, z_3) + d(z_3, z_2) = d(z_1, z_2)$ if and only if z_1, z_2 and z_3 lie in this order on a line.

Additional Properties of the Distance Function *d* in Hyperbolic Geometry

5. $d(z_1, z_2) = d(\overline{z_1}, \overline{z_2})$ for all z_1 and z_2 in $\mathbb{D}$.
6. $d(z_1, z_2) = d(M(z_1), M(z_2))$ for all z_1 and z_2 in $\mathbb{D}$ and all direct hyperbolic transformations M in $G_{\mathbb{D}}$.

2. The **hyperbolic distance** $d(0, z)$ between the origin and any point $z \in \mathbb{D}$ is given by $d(0, z) = \tanh^{-1}(|z|) = \frac{1}{2}\log_e\left(\frac{1+|z|}{1-|z|}\right)$. Also, $|z| = \left(e^{2d(0,z)} - 1\right) / \left(e^{2d(0,z)} + 1\right)$.

   In general, the hyperbolic distance between two arbitrary points z_1 and z_2 in $\mathbb{D}$ is given by $d(z_1, z_2) = \tanh^{-1}\left(\left|\frac{z_2 - z_1}{1 - \overline{z_1}z_2}\right|\right)$.
3. For small z, $d(0, z) \simeq |z|$; as $|z| \to 1$, $d(0, z) \to +\infty$; for $z \neq 0$, $d(0, z) > |z|$.
4. A point m in $\mathbb{D}$ is the **hyperbolic midpoint** of the hyperbolic line segment joining a and b in $\mathbb{D}$ if m lies on this segment and $d(a, m) = d(m, b) = \frac{1}{2}d(a, b)$.
5. **Strategy** To find the hyperbolic midpoint of a hyperbolic line segment joining two points p, q on a diameter of $\mathbb{D}$, where $|p| > |q|$:
   1. calculate $d(0, p)$ and $d(0, q)$;
   2. if p and q lie on opposite sides of O, then calculate $d = \frac{1}{2}(d(0, p) - d(0, q))$; otherwise calculate $d = \frac{1}{2}(d(0, p) + d(0, q))$;
   3. then the hyperbolic midpoint is the point m on the radius through O and p at a Euclidean distance $\tanh(d)$ from O.
6. The **hyperbolic circle** with **hyperbolic radius** r and **hyperbolic centre** c is the set $\{z : d(c, z) = r,\ z \in \mathbb{D}\}$.
7. Every hyperbolic circle in $\mathbb{D}$ is a Euclidean circle, and vice versa.

   Strategy To find the Euclidean centre and radius of a hyperbolic circle C with hyperbolic centre m:
   1. find the points a, b where Om meets C;
   2. the Euclidean centre of C is the Euclidean mid-point of ab;
   3. the Euclidean radius of C is $\frac{1}{2}|a - b|$.

   Strategy To find the hyperbolic centre and radius of a Euclidean circle K with Euclidean centre p:
   1. find the points a, b where Op meets K;
   2. the hyperbolic centre of K is the hyperbolic mid-point of ab;
   3. the hyperbolic radius of K is $\frac{1}{2}d(a, b)$.
8. Let A and A' be points in the unit disc $\mathbb{D}$ that are images of each other under reflection in a d-line ℓ. Then ℓ is the (hyperbolic) perpendicular bisector of the hyperbolic line segment AA'.
9. **Reflection Lemma** Let p and q be points of $\mathbb{D}$. If $|p| \neq |q|$, then the hyperbolic reflection that maps p and q onto each other is given by

$$M(z) = (\ \bar{z} \quad 1) \quad (\bar{z} \quad \bar{\ }), \text{ where}$$

$$= (p \quad q + pq(\bar{p} \quad \bar{q})) \quad (p\bar{p} \quad q\bar{q}).$$

The *d*-line in which this reflection takes place has equation

$$x^2 + y^2 \quad 2ax \quad 2by + 1 = 0, \text{ where } \quad = a + ib.$$

If $|p| = |q|$, then the reflection that maps p and q onto each other is reflection in the diameter of D that bisects the angle pOq.

Section 6.4: Geometrical theorems

1. A ***d*-triangle** consists of three points in the unit disc D that do not lie on a single *d*-line, together with the segments of the three *d*-lines joining them.
2. The sum of the angles of a *d*-triangle is less than .

   Each external angle of a *d*-triangle is greater than the sum of the opposite two internal angles.

   Small triangles have angle sums close to (but less than) , and triangles with large areas have angle sums close to zero.
3. A ***d*-quadrilateral** *ABCD* consists of four points A, B, C, D in D (no three of which lie on a single *d*-line), together with the segments *AB*, *BC*, *CD* and *DA* of the four *d*-lines joining them. We also require that no two of these segments meet except at one of the points A, B, C or D.

   The sum of the angles of a *d*-quadrilateral is less than 2 .
4. In a *d*-triangle *ABC* the angles *ABC* and *ACB* are equal if and only if the sides *AB* and *AC* are of equal (hyperbolic) length.
5. Two figures in the unit disc D are ***d*-congruent** if there is a hyperbolic transformation that maps one onto the other.

   Similar *d*-triangles (that is, *d*-triangles with corresponding angles equal) are *d*-congruent.
6. An **asymptotic triangle** is a *d*-triangle, except that one or more of its vertices lie on C rather than in D. Simply asymptotic, doubly asymptotic and trebly asymptotic triangles have 1, 2 and 3 vertices on C, respectively.

   The angle sum of an asymptotic triangle is less than . The angle sum of a trebly asymptotic triangle is zero.
7. Let and be two *d*-lines, and suppose that there exist points *A* on and *A* on such that the *d*-line segment *AA* meets and at right angles. Then *AA* is a **common perpendicular** to and .

   Common Perpendiculars Theorem Two *d*-lines have a common perpendicular if and only if they are ultra-parallel. This common perpendicular is unique.
8. Through any point *P* of D not on a *d*-line , there is a unique *d*-line that meets at right angles.

   Let be a *d*-line which passes through one vertex *A* of a *d*-triangle *ABC* and which is perpendicular to the side *BC* at the point *D*. The *d*-line segment *AD* is an **altitude** of the triangle *ABC*.

   Altitude Theorem Let the sides *AB* and *AC* of a *d*-triangle *ABC* be of equal hyperbolic length, and let the angle at *A* be . Then the hyperbolic length of the altitude through A of the triangle is less than some number that depends only on .

9. **Pythagoras' Theorem** Let ABC be a d-triangle in which the angle at C is a right angle. If a, b and c are the hyperbolic lengths of BC, CA and AB, then $\cosh 2c = \cosh 2a \times \cosh 2b$.
10. **Lobachevskii's Formula** Let the d-triangle ABC have a right angle at C, and let the hyperbolic lengths of AC and BC be b and a, respectively. Then $\tan A = \tanh 2a \quad \sinh 2b$.
11. **Angle of Parallelism** Let be a d-line, and P a point of $\mathbb{D}$ that does not lie on . Then the angle between the perpendicular from P to (of hyperbolic length p) and either d-line through P that is parallel to is given by $\tan \quad = 1 \quad \sinh 2p$.
12. **Sine Formula** Let ABC be a d-triangle right-angled at C. Let a and c be the hyperbolic lengths of BC and AB, respectively. Then $\sin A = \sinh 2a \quad \sinh 2c$.
13. Let be a d-line that ends at points A and B on $\mathbb{C}$, and let be that part in $\mathbb{D}$ of a (Euclidean) circle through A and B, and let be the angle (in $\mathbb{D}$) between and . Then all points on are the same distance $\frac{1}{2}\log_e \ \tan \ \frac{}{2} + \frac{}{4}$ from .
14. For $x \quad (\ 1, 1)$, the following are all equal to $\tanh \ ^1 x$: $\frac{1}{2}\log_e \frac{1+x}{1 \ x}$, $\frac{1}{2}\sinh \ ^1 \frac{2x}{1 \ x^2}$, $\frac{1}{2}\cosh \ ^1 \frac{1+x^2}{1 \ x^2}$.

Section 6.5: Area

1. **Area** in hyperbolic geometry has the following properties:
    the area of a d-triangle is non-negative, and is zero only if its Euclidean area is zero;
    d-congruent d-triangles (and d-congruent asymptotic d-triangles) have the same area;
    if one d-triangle can be fitted inside another, it has a smaller area;
    area is additive.
2. All trebly asymptotic d-triangles are d-congruent to each other.
3. Let ABC be a d-triangle. Then there exists a trebly asymptotic d-triangle DEF that contains ABC.
4. All trebly asymptotic d-triangles have the same (hyperbolic) area, and this is a finite number.
5. The area of a d-triangle with angles , , is given by $K(\quad (\ + \ + \ ))$, where K is the same constant for all d-triangles. It is usual to take $K = 1$, so that the area of a d-triangle is its **angular defect**.
    Let , , be positive real numbers with $0 < \quad + \quad + \quad < \quad$. Then there is a d-triangle in $\mathbb{D}$ with angles , , .
6. Let P be a point on a d-line of $\mathbb{D}$, and let $0 < \quad < \frac{}{2}$. Then there are exactly two d-lines through P that make an acute angle with , and each is a (hyperbolic) reflection of the other in .

7. **Tessellate** means fit together exactly a number of identical shapes, leaving no spaces .

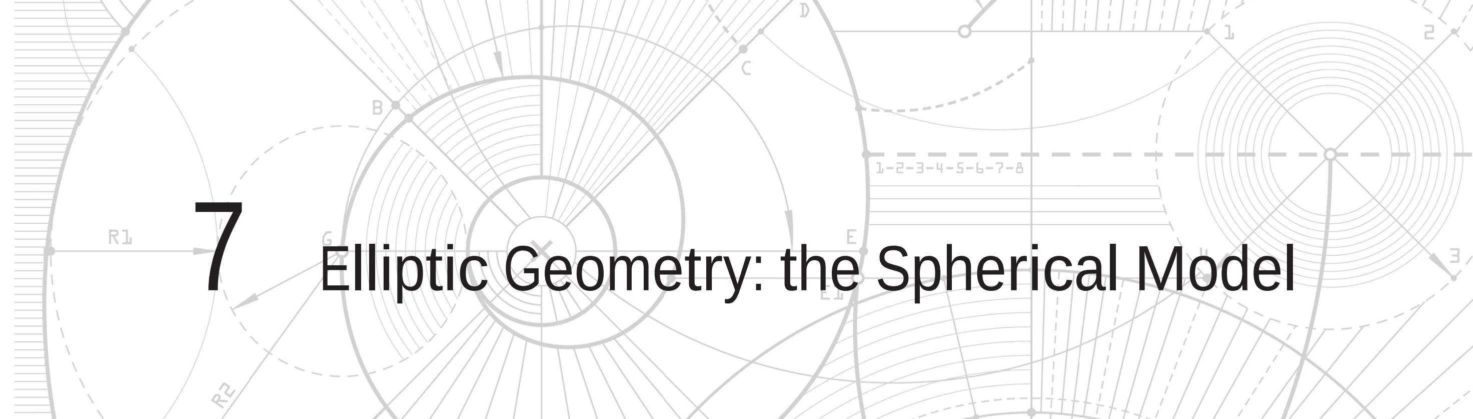
   Tessellations of the Euclidean plane using a single figure are sometimes called **wallpaper patterns**. There are only 17 different wallpaper patterns, in the sense that the symmetry group of any wallpaper pattern is isomorphic to one of only 17 non-isomorphic groups.
8. A **kaleidoscope** is a machine that produces wallpaper patterns using reflections in mirrors.

   Successive reflections of a point in two plane mirrors that meet at an angle π/k give $2k$ points in all.

   Successive (hyperbolic) reflections of a point in two mirrors along d-lines in $\mathbb{D}$ that meet at an angle π/k give $2k$ points in all. We may obtain a **hyperbolic tessellation** of $\mathbb{D}$ (with d-congruent d-triangles) by successive hyperbolic reflections starting from a d-triangle in $\mathbb{D}$ formed by three mirrors along d-lines at angles of $\pi/7$ (at the origin), $\pi/2$ and $\pi/3$.

Section 6.6: Hyperbolic Geometry: the Half-Plane Model

1. In the half-plane model, the set of points is the upper half-plane $H = \{z : z \in \mathbb{C}, \operatorname{Im} z > 0\}$; h-lines are the restriction to H of vertical lines in the plane together with the restriction to H of circles with centre on the real axis in $\mathbb{C}$; and the hyperbolic transformations are the mappings of H to itself given by $z \mapsto (az + b)/(cz + d)$ or $z \mapsto (-a\bar{z} + b)/(-c\bar{z} + d)$, where a, b, c, d are real and $ad - bc > 0$.



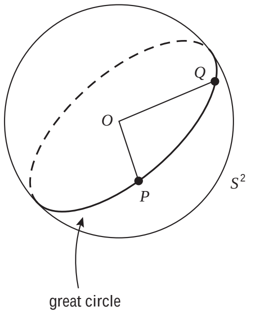
7 Elliptic Geometry: the Spherical Model

In the introduction to Chapter 6, we saw that in Elliptic Geometry all the postulates of Euclidean Geometry hold except that the Euclidean Parallel Postulate is replaced by the following.

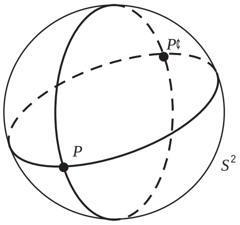
We usually take the sphere to have radius 1.

The (Elliptic) Parallel Postulate Given any line and a point P not on , all lines through P meet . (That is, there are no lines through P that are parallel to .)

In this chapter we study the geometry of the sphere (which we call S^2), such as the surface of the Earth, as a model of elliptic geometry.



A line joining two points P and Q on the surface of a sphere is the curve of shortest length (that is, a *geodesic*) on the sphere between the points: it is actually the *great circle* (that is, the intersection of the plane through the centre O of the sphere with the surface of the sphere) through the two points. Any two distinct great circles meet in two (diametrically opposite) points, so any two lines in spherical geometry meet in two points.



The group of transformations in spherical geometry is the group of isometries of the sphere. Clearly a rotation of the sphere is an isometry, and we shall see that the group of isometries is composed of rotations of the sphere together with reflections in great circles. It turns out that any orientation-preserving isometry of the sphere is in fact a single rotation.

Recall that an *isometry* is a one one mapping that preserves distances.

In Section 7.1, we establish a system of coordinates for the sphere; these are essentially the familiar coordinates of *latitude* and *longitude*. Then, in Section 7.2, we obtain matrix representations for the isometries of the sphere: every isometry can be written as a 3 × 3 matrix.

Next, in Section 7.3, we define a *triangle* on the sphere, find a formula expressing its area in terms of the sum of its angles, and show that every spherical triangle has a *dual triangle* whose sides and angles have the magnitudes of the angles and sides, respectively, of the original triangle.

There is an attractive formula for the distance between two points on the sphere in terms of their coordinates. There is also an attractive generalization of Pythagoras Theorem in spherical geometry, and in proving it we are led to the trigonometric formulas connecting the sides and angles of a spherical triangle. These establish that of the six measurements that describe a spherical triangle (three side lengths, three angles) any set of three determines the other three. This is not the case in Euclidean geometry (where similar, non-congruent figures exist), but it is also true in hyperbolic geometry. Indeed, there are closer analogies between spherical geometry and hyperbolic geometry than there are between either geometry and Euclidean geometry.

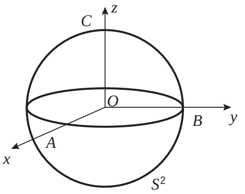
Many aspects of spherical geometry may be studied more easily if we first map the sphere onto a plane. This can be done in many ways, although, none of the mappings (or *projections*) is an isometry of the sphere onto the plane. In Section 7.4, we revisit *stereographic projection*, which maps the sphere onto the plane in a way that preserves angles and generalized circles. We also show how to obtain the group of isometries of the stereographic image of the sphere on the plane; and revisit coaxal circles. Finally, in Section 7.5, we look briefly at the problem of mapping the spherical Earth onto a flat map.

7.1 Spherical Space

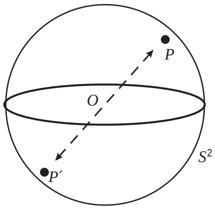
7.1.1 Spherical Geometry

Spherical geometry is the study of geometry on the surface of a sphere. It is simplest to choose this sphere to have unit radius; we therefore concentrate on what we call the *unit sphere* in Euclidean 3-dimensional space $\mathbb{R}^3$, namely the sphere whose centre is at the origin and which has radius 1. In terms of the usual x-, y-, z-Cartesian coordinates in $\mathbb{R}^3$ with origin O at the centre of the sphere, the unit sphere has the equation $x^2 + y^2 + z^2 = 1$. We shall denote it by the symbol S^2.

It is usually straightforward to modify our results to the case of a sphere of arbitrary radius, R say.



The positive x-, y-, z-axes meet the sphere S^2 at the points $A(1,0,0)$, $B(0, 1, 0)$, $C(0, 0, 1)$, respectively. For obvious reasons the point C is sometimes called the *North Pole* of the sphere, and denoted by N. Every point (x,y,z) on the sphere S^2 has a diametrically opposite or *antipodal* point $(-x, -y, -z)$; for example, the antipodal point to the North Pole is the *South Pole* $S(0,0,-1)$. The plane through O perpendicular to the line ON cuts the sphere in a circle called the *equator*.



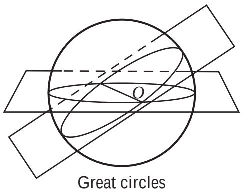
Antipodal points

Example 1 Prove that any plane that cuts the sphere S^2 in more than one point cuts it in a circle.

Solution Let OT be a radius of the sphere perpendicular to the given plane. A rotation of the sphere about this axis maps the plane to itself, and the sphere to itself; so it maps their intersection to itself. Each point on the intersection traces out a circle (of the same radius and centre) under the rotation, so the intersection is a circle. □

The analogue in spherical geometry of a straight line in the plane is a curve on S^2 called a great circle.

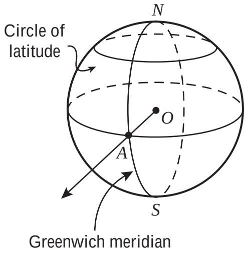
Definition A **great circle** is the circle cut out on the sphere S^2 by a plane through the centre of the sphere.



Great circles

Note that, by Example 1, a great circle is indeed a circle. Moreover, it is a circle of maximal radius 1 on the sphere, which gives rise to the name great circle.

Definitions Any great circle through N is called a **circle of longitude**. The part of the circle of longitude through $A(1,0,0)$ which has positive x-coordinates we call the **Greenwich Meridian**. The curve of intersection of S^2 with a plane parallel to the equator is a circle called a **circle of latitude**. The curve of intersection of S^2 with a plane that is not a great circle is called a **little circle**.



The equator is a circle of latitude; circles of latitude other than the equator are little circles.

We define distance in spherical geometry (on S^2) in the natural way.

Definitions Let P and Q be any two points on S^2, and C a great circle through P and Q. Then either arc with endpoints P and Q is said to be a **line** on S^2 joining P and Q, or a **line** PQ. The **length** of a given line on S^2 is defined to be the Euclidean length of the corresponding circular arc; the **distance** (or **spherical distance**) between two points P and Q on S^2 is the length of the shorter of the two lines PQ, and is often denoted simply as PQ.

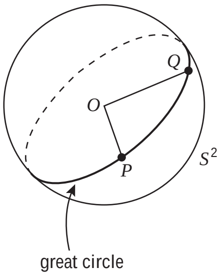
Let P, Q and R be any three points on S^2 that do not lie on a single great circle. Then a line PQ, a line QR and a line RP form a **triangle** PQR.

Thus the line PQ is not unique.

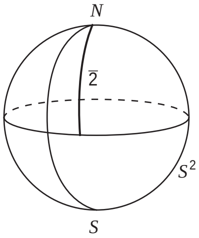
Thus there are several triangles PQR.

A property of great circles that we state without proof is that *great circles are geodesics on* S^2; that is, curves of shortest length between any of their points. This is intuitively clear for the circles of longitude from the North Pole, for instance. Note that little circles are not geodesics on S^2.

The distance between any two points on S^2 is a portion of a great circle through the points. This circle has radius 1, and so has circumference 2 the same as the angle that the great circle subtends at its center (the centre of the sphere). It follows, by proportion, that the distance between any two points on S^2 is equal to the angle that they subtend at the centre of S^2.

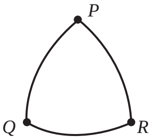


Theorem 1 The distance between any two points P and Q on S^2 is equal to the angle that they subtend at the centre of S^2.



Thus, for example, the distance from the North Pole to any point on the equator is $\pi/2$, and the distance from the North Pole to the South Pole is π.

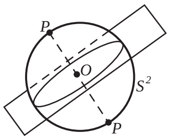
With the above definition, spherical distance possesses all the "natural" properties that a distance function should possess. (We listed these in Subsection 6.3.1.)



For example, it satisfies the Triangle Inequality; that is, if P, Q and R are any three points on S^2, then the side lengths of the triangle $\triangle PQR$ satisfy the inequality $PQ + QR \geq PR$. This can be proved in a similar way to the Triangle Inequality in hyperbolic geometry (Theorem 2, Subsection 6.3.3).

Great circles in spherical geometry play many of the roles that lines play in Euclidean plane geometry. There is always a great circle joining any two points on S^2, because there is always a plane passing through them and the origin. The plane and the corresponding great circle are unique unless the points are diametrically opposite, in which case there are infinitely many great circles joining the points.

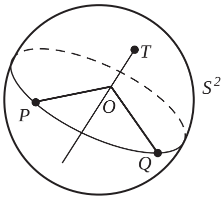
However, one way in which spherical geometry differs markedly from Euclidean plane geometry comes from observing that any two great circles meet not in one, but in two (diametrically opposite) points. They do so because the planes that define them have a common point, the origin, and therefore a common line in $\mathbb{R}^3$, which cuts S^2 in the given points. So although great circles are analogous to the straight lines of the plane, the analogy breaks down almost at once. There are certainly no "parallel lines" on the sphere, because any two great circles meet in two points.



The antipodal points P and P' have a common equator

It is sometimes helpful to observe that corresponding to each point P on S^2 there is a unique great circle of points $\pi/2$ distant from P, which plays the role of the equator with P as a "pole". We shall call this great circle the **great circle associated with the point** P. Conversely, given any great circle there are two points of S^2 which play the role of its "poles".

Example 2 Let P and Q be any two points on S^2. Show that there is a rotation of S^2 that maps P to Q.

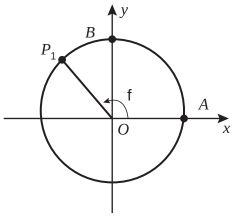


Solution Consider the great circle through P and Q, and let T be one of its poles. The rotation of S^2 about the axis OT and through the angle $\angle POQ$ (in the appropriate direction) sends P to Q, as required. □

Problem 1 Determine whether rotations of S^2 exist with the following properties.

(a) $(1,0,0) \to (0,-1,0)$
(b) $(1,0,0) \to (0,1,0)$ and $(0,1,0) \to (0,0,1)$
(c) $(1,0,0) \to (0,-1,0)$ and $(0,0,1) \to (0,1,0)$

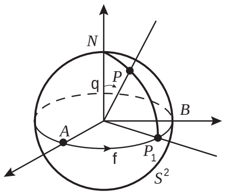
7.1.2 Coordinates on S^2



Equatorial plane of S^2

We now set up a system of *spherical polar coordinates* on S^2. We start by defining the direction along the equator from $A(1,0,0)$ to $B(0,1,0)$ to be the positive direction on the equator. Then for any point P_1 on the equator let ϕ be the angle $\angle AOP_1$ measured in the positive direction along the equator; then we assign the coordinates $(\cos\phi, \sin\phi, 0)$ to P_1, where $0 \le \phi < 2\pi$.

Next, let P be any point on S^2 (other than the North and South Poles) that does not lie on the equator. Let P_1 be the point on the equator that lies on the arc NS of the great circle through N and P.



P has spherical coordinates $(\cos\phi\sin\theta, \sin\phi\sin\theta, \cos\theta)$.

Then let ϕ be the angle $\angle AOP_1$ measured in the positive direction along the equator $(0 \le \phi < 2\pi)$, and let θ be the angle $\angle NOP$ $(0 < \theta < \pi)$; we assign the coordinates $(\cos\phi\sin\theta, \sin\phi\sin\theta, \cos\theta)$ to P.

For example, the point of S^2 with spherical polar coordinates $\left(\cos\frac{\pi}{3}\sin\frac{\pi}{4}, \sin\frac{\pi}{3}\sin\frac{\pi}{4}, \cos\frac{\pi}{4}\right)$ is the point $\left(\frac{1}{2\sqrt{2}}, \frac{\sqrt{3}}{2\sqrt{2}}, \frac{1}{\sqrt{2}}\right)$.

Problem 2 Determine the angles ϕ and θ in the spherical polar representation $(\cos\phi\sin\theta, \sin\phi\sin\theta, \cos\theta)$ of the points $\left(0, -\frac{\sqrt{3}}{2}, \frac{1}{2}\right)$ and $\left(-\frac{1}{\sqrt{14}}, -\frac{\sqrt{2}}{\sqrt{14}}, -\frac{3}{\sqrt{14}}\right)$.

In this way every point on S^2 other than the North and South Poles has been given spherical polar coordinates involving appropriate values of ϕ and θ. At the North Pole we take θ to be zero and let ϕ take any value in the interval $[0, 2\pi)$, and at the South Pole we take θ to be π and let ϕ take any value in the interval $[0, 2\pi)$; the non-uniqueness of coordinates at the Poles will cause us no problems.

Definitions Let P be a point on S^2 with spherical polar coordinates $(\cos\phi\sin\theta, \sin\phi\sin\theta, \cos\theta)$, where $0 \le \phi < 2\pi$ and $0 \le \theta \le \pi$. The angle θ of P is called its **colatitude**; the quantity $\lambda = \frac{\pi}{2} - \theta$ is called its **latitude** (note that $-\frac{\pi}{2} \le \lambda \le \frac{\pi}{2}$). The angle ϕ of P is called its **longitude**.

Sometimes we shall find it convenient to regard ϕ as being defined on $\mathbb{R}$ rather than on $[0, 2\pi)$, as a periodic function with period 2π.

Notice, for example, that the distance of a point P with colatitude θ on S^2 from the North Pole is simply θ.

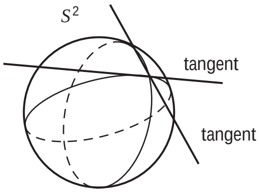
Problem 3 Determine the latitude, colatitude and longitude of the point $\left(\frac{1}{2\sqrt{2}}, \frac{\sqrt{3}}{2\sqrt{2}}, \frac{1}{\sqrt{2}}\right)$ on S^2.
Hint: You met this point just before Problem 2 above.

Problem 4 Determine the spherical polar coordinates of the point 45° W of the Greenwich meridian on S^2 and 30° S.

Note that 30° S means '30° below the equatorial plane'. Also, sometimes we take the phrase 'of the Greenwich meridian' as understood when describing longitude.

Notice also that the set of points on the sphere with a common colatitude θ forms a circle, C_θ say; this is a little circle if $\theta \neq \pi/2$, and a great circle (the equator) if $\theta = \pi/2$. Since θ measures the distance of each point of the circle C_θ from the North Pole N, we shall say that C_θ is a *circle on the sphere* *with centre N*. Since any point on S^2 may be chosen as the North Pole (with a suitable choice of coordinate axes), it follows that a circle on S^2, defined as the set of points equidistant from a given point, is either a great circle or a little circle.

Problem 5 Show that, given any two great circles on S^2, there are two great circles bisecting the angles between them, each at right angles to the other.
Hint: The angle between two curves on S^2 at one of their points of intersection is the angle between their tangents at that point.



7.2 Spherical Transformations

7.2.1 Isometries of S^2

An isometry of S^2 is a mapping of the unit sphere to itself that preserves distances between points. In fact the isometries of a sphere form a group, since

the composition of two isometries is also an isometry;
the identity mapping is an isometry, and it is the identity element of the group;
the inverse of any isometry is an isometry;
the composition of isometries is associative, since the composition of functions is always associative.

We have therefore established the following theorem.

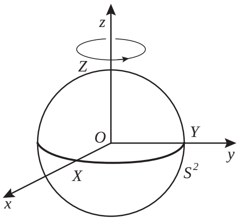
Theorem 1 The isometries of S^2 form a group.

We call this group the *group of spherical isometries*, and denote it by the symbol $S(2)$.

We shall see at the end of this section that the rotations of S^2 form a group, which is identical to the group of direct isometries of the sphere. A reflection of S^2 in a plane through the centre of the unit sphere is not a direct isometry of S^2, but every composition of an even number of such reflections is a direct isometry of S^2.

A transformation is *direct* if it preserves the *orientation* of angles, and *indirect* if it reverses them.

We now consider the three *elementary rotations* of S^2 (that is, its rotations about the coordinates axes) and their composites.



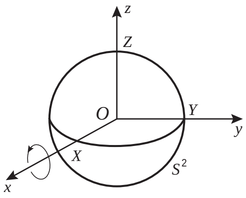
The elementary rotation about OZ leaves the z-axis fixed, and rotates the (x, y)-plane. The positive direction of this rotation is anticlockwise as seen from above (that is, as viewed from a point of the positive z-axis), from the positive x-axis towards the positive y-axis. So a rotation of S^2 about OZ through an angle , which we denote by $R(Z, \ )$, is given by

$$R(Z, \ ): S^2 \quad S^2$$
$$\mathbf{x} \quad \mathbf{Ax}$$

where $\mathbf{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix}$ and $\mathbf{A}$ is the matrix $\begin{pmatrix} \cos & \sin & 0 \\ \sin & \cos & 0 \\ 0 & 0 & 1 \end{pmatrix}$.

We say that **A** is the matrix *associated with* (or *of*) the elementary rotation $R(Z, \ )$.

Next, the elementary rotation about OX leaves the x-axis fixed, and rotates the (y, z)-plane. The positive direction of this rotation is taken to be anticlockwise as seen from above (that is, as viewed from a point of the positive x-axis), from the positive y-axis towards the positive z-axis. So a rotation of S^2 about OX through an angle , which we denote by $R(X, \ )$, is given by

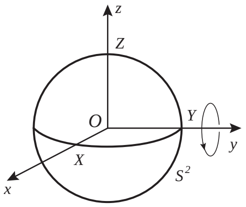


$$R(x, \ ): S^2 \quad S^2$$
$$\mathbf{x} \quad \mathbf{Ax}$$

where $\mathbf{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix}$ and $\mathbf{A}$ is the matrix $\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos & \sin \\ 0 & \sin & \cos \end{pmatrix}$.

Here **A** is the matrix *associated with* (or *of*) the elementary rotation $R(X, \ )$.

Finally, the elementary rotation about OY leaves the y-axis fixed, and rotates the (x, z)-plane. The positive direction of this rotation is taken to be anticlockwise as seen from above (that is, as viewed from a point of the positive y-axis), from the positive z-axis towards the positive x-axis. So a rotation of S^2 about OY through an angle , which we denote by $R(Y, \ )$, is given by



$$R(Y, \ ): S^2 \quad S^2$$
$$\mathbf{x} \quad \mathbf{Ax}$$

where $\mathbf{x} = \begin{pmatrix} x \\ y \\ z \end{pmatrix}$ and $\mathbf{A}$ is the matrix $\begin{pmatrix} \cos & 0 & \sin \\ 0 & 1 & 0 \\ \sin & 0 & \cos \end{pmatrix}$.

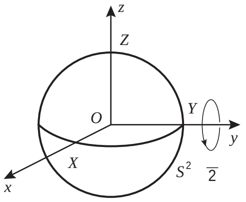
Here **A** is the matrix *associated with* (or *of*) the elementary rotation $R(y, \ )$.

It is easy to verify that the determinants of the elementary rotations $R(X, \ )$, $R(Y, \ )$ and $R(Z, \ )$ are all equal to 1. Since any rotation can be expressed as a finite composition of these rotations, it follows that the determinant of the matrix of any rotation of S^2 also has determinant 1.

We will prove this fact in Theorem 7, Subsection 7.2.3.

Problem 1 Determine the images of the points $(1, 0, 0)$, $(0, 1, 0)$, $(0, 0, 1)$ and $\frac{1}{14}, \ \frac{2}{14}, \frac{3}{14}$ under the transformation $R \ \ Y, \frac{}{4}$.

Notice that the simple cases of these rotations when , or $=$ $/2$ correspond to rotations of one axis onto another. For example,



$$R \ \ Y, \frac{}{2} = \begin{pmatrix} \cos\frac{}{2} & 0 & \sin\frac{}{2} \\ 0 & 1 & 0 \\ \sin\frac{}{2} & 0 & \cos\frac{}{2} \end{pmatrix} = \begin{pmatrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{pmatrix};$$

under this mapping, $(1, 0, 0) \quad (0, 0, \ 1)$, $(0, 1, 0) \quad (0, 1, 0)$ and $(0, 0, 1) \quad (1, 0, 0)$.

Example 1 Show that $R\ \ X, \frac{}{2} \ \bullet R\ \ Y, \frac{}{2} \ = R\ \ Y, \frac{}{2} \ \bullet R\ \ X, \frac{}{2}$.

This shows that multiplication of the matrices of elementary rotations (and hence composition of elementary rotations) is not commutative.

Solution Here

$$R\ \ X, \frac{}{2} \ \bullet R\ \ Y, \frac{}{2} \ = \begin{matrix} 1 & 0 & 0 \\ 0 & \cos\frac{}{2} & \sin\frac{}{2} \\ 0 & \sin\frac{}{2} & \cos\frac{}{2} \end{matrix}$$

$$\times \begin{matrix} \cos\frac{}{2} & 0 & \sin\frac{}{2} \\ 0 & 1 & 0 \\ \sin\frac{}{2} & 0 & \cos\frac{}{2} \end{matrix}$$

$$= \begin{matrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{matrix} \quad \begin{matrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{matrix}$$

$$= \begin{matrix} 0 & 0 & 1 \\ 1 & 0 & 0 \\ 0 & 1 & 0 \end{matrix} \ ,$$

and

$$R\ \ Y, \frac{}{2} \ \bullet R\ \ X, \frac{}{2} \ = \begin{matrix} \cos\frac{}{2} & 0 & \sin\frac{}{2} \\ 0 & 1 & 0 \\ \sin\frac{}{2} & 0 & \cos\frac{}{2} \end{matrix}$$

$$\times \begin{matrix} 1 & 0 & 0 \\ 0 & \cos\frac{}{2} & \sin\frac{}{2} \\ 0 & \sin\frac{}{2} & \cos\frac{}{2} \end{matrix}$$

$$= \begin{matrix} 0 & 0 & 1 \\ 0 & 1 & 0 \\ 1 & 0 & 0 \end{matrix} \quad \begin{matrix} 1 & 0 & 0 \\ 0 & 0 & 1 \\ 0 & 1 & 0 \end{matrix}$$

$$= \begin{matrix} 0 & 1 & 0 \\ 0 & 0 & 1 \\ 1 & 0 & 0 \end{matrix} \ .$$

Thus $R\ \ X, \frac{}{2} \ \bullet R\ \ Y, \frac{}{2} \ = R\ \ Y, \frac{}{2} \ \bullet R\ \ X, \frac{}{2}$, as required. □

Problem 2 Calculate $R(Z,\ ) \bullet R(Y,\ )$ and $R(Y,\ ) \bullet R(Z,\ )$.

Problem 3 For the elementary rotation $R(X,\ )$, verify that the transpose of its matrix is equal to the matrix of the elementary rotation $R(X,\quad)$. State and prove the corresponding results for the elementary rotations $R(Y,\ )$ and $R(Z,\ )$.

Notice that the inverse of an elementary rotation through a given angle is an elementary rotation through the same angle but in the opposite direction;

that is,

$$R(X,\ )^{\ 1} = R(X,\ \ ),$$
$$R(Y,\ )^{\ 1} = R(Y,\ \ )$$
$$\text{and}\qquad R(Z,\ )^{\ 1} = R(Z,\ \ ).$$

Combining this observation with the result of Problem 3, we obtain the agreeable consequence that the inverse of a matrix representing an elementary rotation is equal to the transpose of that matrix. For example the matrix **A** of the elementary rotation $R(Y,\ )$ is

$$\mathbf{A} = \begin{matrix} \cos & 0 & \sin \\ 0 & 1 & 0 \\ \sin & 0 & \cos \end{matrix}\ ;$$

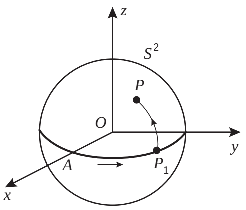
then $\mathbf{A}^{\ 1} = \mathbf{A}^T$.

Recall that any square matrix **A** with the property that $\mathbf{A}^{\ 1} = \mathbf{A}^T$ or $\mathbf{A}\mathbf{A}^T = \mathbf{I}$ is an *orthogonal* matrix.

We saw earlier that we can rotate S^2 in such a way as to map any particular point onto any other. We now see how we can determine the matrix of such a rotation explicitly.

Subsection 7.1.1, Example 2

First, we see how to rotate S^2 so as to send the point $A(1,0,0)$ to any point $P(\cos\ \ \sin\ ,\sin\ \ \sin\ ,\cos\ )$ of S^2. First we rotate S^2 to send A to the point $P_1(\cos\ ,\sin\ ,0)$; then we rotate S^2 to send P_1 to P.



From A to P_1, and from P_1 to P by rotations

The first rotation is the elementary rotation $R(Z,\ )$; but what is the second rotation? It is a rotation of S^2 towards the North Pole through an angle $\ = \frac{}{2}\ \ $, so it is something like $R(Y,\ \ \ )$ or $R\ \ Y,\ \ \ \frac{}{2}$. But it is not a rotation about the y-axis; instead, it is a rotation of S^2 about the direction where the first rotation sent the y-axis. We may perform such a rotation in several stages: rotate the sphere first by the reverse transformation $R(Z,\ \ )$, then by the elementary rotation $R\ \ Y,\ \ \ \frac{}{2}$, and then finally by the transformation $R(Z,\ )$.

For $\ = \frac{}{2}\ \ $, and $R(Z,\ )^{\ 1} = R(Z,\ \ )$.

Thus the second rotation is the composition mapping

$$R(Z,\ )R(Y,\ \ \ )R(Z,\ \ \ ) = R(Z,\ )R(Y,\ \ \ )R(Z,\ )^{\ 1}.$$

It follows that the final transformation that sends A to P is given by

$$R(Z,\ )R(Y,\ \ \ )R(Z,\ )^{\ 1}\ \ R(Z,\ ) = R(Z,\ )R(Y,\ \ \ ).$$

Theorem 2 A rotation of S^2 that maps $A(1,0,0)$ to $P(\cos\ \ \sin\ ,$ $\sin\ \ \sin\ ,\cos\ )$ is given by the composition $R(Z,\ )R(Y,\ \ \ )$, where $\ = \frac{}{2}\ \ \ $.

Note that there are many such rotations. *Any* composition of this particular rotation with a subsequent rotation about OP has the required properties.

Problem 4 Determine the matrix **A** of a rotation **x** $\ \ $ **Ax** of S^2 that maps $A(1,0,0)$ to $P\ \ \frac{1}{2\ 2}, \frac{3}{2\ 2}, \frac{1}{2}\ \ $. Verify your answer by direct calculation.

Hint: You met this point P in Problem 3 of Subsection 7.1.2.

Example 2 Determine a rotation that maps the point $P(\cos\ \ \sin\ \ ,$ $\sin\ \ \sin\ \ , \cos\ \ )$ of S^2 to $N(0,0,1)$, in terms of elementary rotations.

Solution By Theorem 2, one rotation that sends A to P is given by the composition $R(Z,\ \ )R(Y,\ \ \ \ )$, where $\ \ = \overline{\ \ 2}\ \ \ \ $. It follows that the mapping

$$R(Z,\ \ )R(Y,\ \ \ \ )^{\ 1} = R(Y,\ \ \ \ )^{\ 1}R(Z,\ \ )^{\ 1}$$
$$= R(Y,\ \ )R(Z,\ \ \ \ )$$

sends P to A.

Now at the North Pole $\ \ = 0$ and $\ \ = 0$, so that $\ \ = \overline{\ \ 2}$. Hence one rotation that sends A to N is $R\ \ Y,\ \ \overline{\ \ 2}\ \ $. It follows that one rotation that sends P to N is

$$R\ \ Y,\ \ \frac{\ \ }{2}\ \ \ \ R\ \ Y,\ \ \ \ R(Z,\ \ \ \ )$$
$$= R\ \ Y,\ \ \ \ \ \ \frac{\ \ }{2}\ \ R(Z,\ \ \ \ )$$
$$= R(Y,\ \ \ \ )R(Z,\ \ \ \ ).$$ □

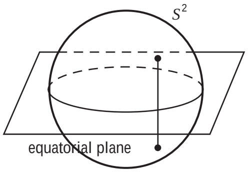
For
$R(Y,\ \ _1)R(Y,\ \ _2)$
$= R(Y,\ \ _1 +\ \ _2)$,
for any angles $\ _1,\ \ _2$.

Problem 5 Determine the matrix **A** of a rotation **x** $\ \ \ \ $ **Ax** of S^2 that maps $P\ \ \frac{1}{2\ \overline{2}}, \frac{\overline{3}}{2\ \overline{2}}, \frac{1}{\overline{2}}\ \ $ to N. Verify your answer by direct calculation.
Hint: You met this point P in Problem 4.

Problem 6 Determine the matrix **A** of a rotation **x** $\ \ \ \ $ **Ax** of S^2 that maps $Q\ \ \frac{1}{2},\ \ \frac{1}{2},\ \ \ \frac{1}{\overline{2}}$ to $P\ \ \frac{1}{2\ \overline{2}}, \frac{\overline{3}}{2\ \overline{2}}, \frac{1}{\overline{2}}\ \ $. Verify your answer by direct calculation.

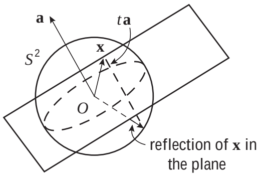
7.2.2 Reflections in Great Circles

Reflection in the *equatorial plane* of S^2 (that is, in the plane $z = 0$ that contains the equator of S^2) is the mapping **x** $\ \ \ \ $ **Ax** that sends the point $\mathbf{x} = (x,y,z)$ to the point $(x,y,\ \ z)$, so $\mathbf{A} = \begin{matrix} 1 & 0 & \ \ 0 \\ 0 & 1 & \ \ 0 \\ 0 & 0 & \ \ 1 \end{matrix}$. Each point lies vertically above or below its image, unless it lies in the equatorial plane in which case it coincides with its image.



Problem 7 Evaluate the determinant of the above matrix **A**.

Next, let $\ \ $ be any plane that passes through the centre O of the sphere S^2. The equation of $\ \ $ must be of the form $ax + by + cz = 0$, since it passes through O; if we define the vectors **a** and **x** to be (a,b,c) and (x,y,z), respectively, then we can express the equation of $\ \ $ in the form



$$\mathbf{a} \bullet \mathbf{x} = 0.$$

This defines a plane Π with the vector $\mathbf{a}$ as a normal to it; without loss of generality, we shall assume that a, b and c have been chosen so that $\mathbf{a}$ has length 1.

Let r be the reflection of S^2 in the plane Π; we shall find a matrix for this mapping r of S^2 to itself.

We shall interchangeably call this *reflection in* Π and *reflection in the great circle* in which Π intersects S^2.

The image of a point $\mathbf{x}$ of S^2 is the point $r(\mathbf{x})$. Now the line joining the points $\mathbf{x}$ and $r(\mathbf{x})$ is a line parallel to the normal vector $\mathbf{a}$, so we must have that

$$r(\mathbf{x}) = \mathbf{x} + t\mathbf{a}, \qquad \text{for some value of the parameter } t.$$

For $r(\mathbf{x}) - \mathbf{x} = t\mathbf{a}$, for some t.

We can find this value of t by observing that since $\mathbf{x}$ lies on S^2 so does its image $r(\mathbf{x})$, and so

$$(\mathbf{x} + t\mathbf{a}) \bullet (\mathbf{x} + t\mathbf{a}) = 1.$$

This implies that

$$\mathbf{x} \bullet \mathbf{x} + 2t\,\mathbf{x} \bullet \mathbf{a} + t^2\mathbf{a} \bullet \mathbf{a} = 1,$$

so that

$$2t\,\mathbf{x} \bullet \mathbf{a} + t^2 = 0.$$

For $\mathbf{x} \bullet \mathbf{x} = 1$ and $\mathbf{a} \bullet \mathbf{a} = 1$.

Now, if $\mathbf{x} \bullet \mathbf{a} = 0$, then the point $\mathbf{x}$ lies in the plane Π in which we are reflecting, and then as you would expect $t = 0$ and $r(\mathbf{x}) = \mathbf{x}$.

For then clearly $r(\mathbf{x}) = \mathbf{x}$.

If $\mathbf{x} \bullet \mathbf{a} \neq 0$, then we may exclude the possibility that $t = 0$. It follows from the equation $2t\mathbf{x} \bullet \mathbf{a} + t^2 = 0$ that $t = -2\mathbf{x} \bullet \mathbf{a}$, and so

$$r(\mathbf{x}) = \mathbf{x} - 2(\mathbf{x} \bullet \mathbf{a})\mathbf{a}.$$

To represent this mapping via a matrix, we express this equation in terms of coordinates and group the terms carefully:

$$\begin{aligned} r(x, y, z) &= (x, y, z) - 2(ax + by + cz)(a, b, c) \\ &= \Big(\left(1 - 2a^2\right)x - 2aby - 2acz,\ -2abx + \left(1 - 2b^2\right)y \\ &\qquad - 2bcz,\ -2acx - 2bcy + \left(1 - 2c^2\right)z \Big), \end{aligned}$$

so that it can be expressed in matrix form as

$$\begin{pmatrix} x \\ y \\ z \end{pmatrix} \mapsto \begin{pmatrix} 1 - 2a^2 & -2ab & -2ac \\ -2ab & 1 - 2b^2 & -2bc \\ -2ac & -2bc & 1 - 2c^2 \end{pmatrix} \begin{pmatrix} x \\ y \\ z \end{pmatrix}.$$

Theorem 3 Reflection of S^2 in the plane Π with equation $ax + by + cz = 0$, where $a^2 + b^2 + c^2 = 1$, is given by the mapping $\mathbf{x} \mapsto \mathbf{A}\mathbf{x}$ where

$$\mathbf{A} = \begin{pmatrix} 1 - 2a^2 & -2ab & -2ac \\ -2ab & 1 - 2b^2 & -2bc \\ -2ac & -2bc & 1 - 2c^2 \end{pmatrix}.$$

Notice that in the particular case when the plane is the equatorial plane, with equation $z = 0$ (so that $a = b = 0$ and $c = 1$), Theorem 3 gives the matrix for the mapping $\mathbf{x}$ $\mathbf{Ax}$ to be

$$\mathbf{A} = \begin{matrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{matrix}$$

that you met above.

> **Problem 8** Determine the matrix $\mathbf{A}$ such that the mapping $\mathbf{x}$ $\mathbf{Ax}$ represents reflection of S^2 in the plane with equation $3x + 4y \quad 5z = 0$.

Remark

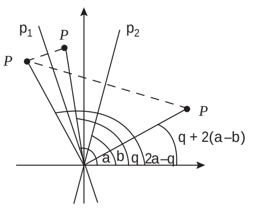
There is another way to find the matrix representing a reflection in a great circle. Let the point P be one of the polar points of the plane through O that meets S^2 in the given great circle. Let R be a rotation taking P to the North Pole N, and let r be reflection in the equatorial plane of S^2. Then the composition mapping $R\ ^{1}rR$ represents reflection of S^2 in .

We omit the details of this calculation.

We now establish a result relating products of reflections of S^2 to rotations of S^2. It is the exact analogue of a result in Euclidean geometry. The result holds also for general reflections and rotations of R^3, so we prove it in that more general setting.

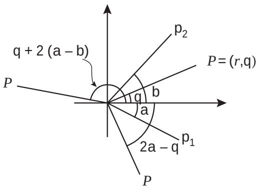
Subsection 5.2.1, margin note alongside Problem 4

> **Theorem 4** The product of any two reflections of R^3 in planes through O that meet in a common line is a rotation about that common line.



Proof By choosing coordinate axes suitably, we may arrange that the common line is the z-axis. The planes are therefore vertical, and it follows that each reflection leaves the z-coordinate of each point unaltered. It is therefore sufficient to look at the effect of each reflection and composite on planes perpendicular to the z-axis; we shall discuss the (x, y)-plane, but a similar argument applies to all planes parallel to this one.

Let the first plane $_1$ make an angle with the positive x-axis and the second plane $_2$ make an angle with the positive x-axis. Let a point P in the (x, y)-plane have plane polar coordinates $(r, \ )$. Then the image of P under reflection in $_1$ is the point P with polar coordinates $(r, 2 \quad)$. The image of P under the reflection in $_2$ is the point P with polar coordinates $(r, 2 \quad (2 \quad)) = (r, \ + 2(\quad))$. This is the image of P under rotation about the common line of $_1$ and $_2$, through twice the angle between the planes.



We deduce from this theorem that the composite of reflections in two great circles on S^2 is a rotation of S^2 about the line common to the planes defining the great circles, and through twice the angle between them. We can also deduce that every rotation is a product of two reflections; these reflections are in planes that have the axis of rotation as their common line, and are separated by half the angle of the rotation (but they are otherwise arbitrary).

Example 3 Prove that the image of a circle C on S^2 under an isometry t of S^2 to itself is a circle.

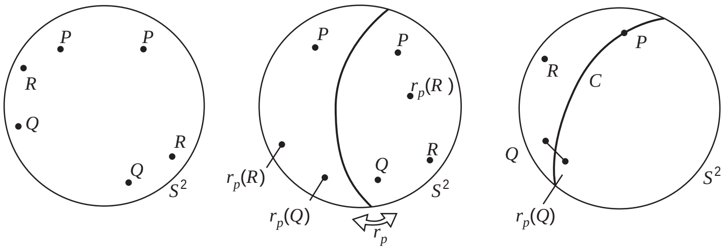
Solution Let the circle C be cut out by a plane , and let be the line through the origin perpendicular to . Let meet S^2 at the points P and P. Then all points of C are the same distance from P.

Since t is an isometry, the points of $t(C)$ are all the same distance from $t(P)$. It follows that they lie on a circle, which must be the circle cut out on S^2 by the plane $t(\ )$. □

We now establish the following important result.

Theorem 5 The Product Theorem
Every isometry of S^2 is a product of at most three reflections in great circles.

Proof The key idea in this proof is the observation that *an isometry of S^2 is known completely when its effect on three points (which do not lie on a common great circle) is known*. We shall prove this observation in the course of proving the theorem.



Let P, Q and R be three points not lying on the same great circle, and let P, Q and R be their images under an isometry t of S^2 to itself. Let r_P be a reflection of S^2 in a great circle that sends P to P. Consider the angle in $\mathbb{R}^3$ with arms $P\ r_P(Q)$ and $P\ Q$, and let C be the great circle that bisects this angle and the segment joining $r_P(Q)$ and Q. Reflection in C fixes P and sends $r_p(Q)$ to Q. Suppose that this reflection sends $r_P(R)$ to R.

See left figure above.
See centre figure above.
See right figure above.

The distance of R from P is the same as the distance RP (call it d_P), and the distance of R from Q is the same as the distance QR (call it d_Q), since both reflections are isometries. So the point R lies on the intersection of the circle with centre P and radius d_P and the circle with centre Q and radius d_Q; so too does the point R.

Then it may be that R and R coincide, in which case we have found a product of two reflections sending R to R. Or it may be that R and R do not coincide but a reflection in the great circle through P and Q maps R to R, and so three reflections have been used.

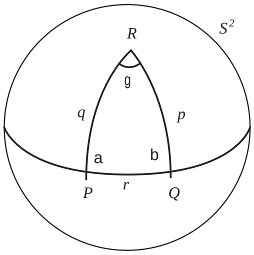
We now claim that any isometry fixing three points on S^2 fixes every point of S^2. Let P, Q and R be the points, let M be any other point on S^2, and let t be the isometry fixing the points P, Q and R. Then $t(M)$ lies on the circle with centre P and radius PM and on the circle with centre Q and radius QM. Of the two points satisfying this condition, only one also lies on the circle with centre R and radius RM, and that is the point M itself; so the image of M under t is M, and therefore t fixes every point of S^2. It follows that if two isometries t_1 and t_2 agree on three points, then they agree on every point, since the composite t_2^{1} t_1 satisfies the conditions of our last remark.

We deduce that the isometry mapping the points P, Q and R to the points P, Q and R must be the product of the two or three reflections that we described above. This completes the proof.

It does not follow that these reflections are uniquely determined recall the case of the rotation discussed above.

Finally in this subsection we show that the Isosceles Triangle Theorem in spherical geometry can be established using a reflection in a great circle.

Theorem 6 Isosceles Triangle Theorem
Let a triangle PQR on S^2 have sides PQ of length r, QR of length p, and RP of length q, and let $p = q$. Also, let the angles at the vertices P, Q and R be , and , respectively. Then = .



Proof Consider the reflection in the great circle that is the internal bisector of the angle PRQ.

It maps the great circle through R and P to the great circle through R and Q; and, since it is an isometry and $p = q$, it therefore maps P to Q, and Q to P. It maps the great circle through P and Q to itself, and so it interchanges the angles and , which shows that = .

7.2.3 Direct Isometries

The Product Theorem allows us to deduce that every isometry is either a reflection, a rotation or the composite of a rotation and a reflection. For if it is a composite of two reflections, then it is a rotation; and if it is a composite of three reflections, then the composite of the first two is a rotation.

Theorem 5

It is clear that every rotation of S^2 is an direct isometry of S^2.

We shall now see that every direct isometry of S^2 is a product of rotations. For each reflection reverses the orientation of angles, and so the product of two reflections preserves the orientation of angles, while the product of three reflections reverses it again. So a direct isometry must be the product of an *even* number of reflections and therefore be a rotation.

For the product of any pair of reflections is a rotation.

It is instructive to give a direct proof of this result that does not use the Product Theorem, because reflections are not easy to handle geometrically or algebraically.

First, any direct isometry of S^2 that fixes the North Pole N must map each circle of latitude to itself, and so must be a rotation of that circle. Let D and E be points on different circles of latitude; they remain the same distance apart, so the rotation of their two circles of latitude must be through the same angle. It follows that every circle of latitude on S^2 is rotated equally, and so the isometry fixing N must be a rotation about ON.

Next, let M be a direct isometry that sends a point P to P and a point Q to Q, and let R be a rotation that sends P to P. Then $M \quad R^{\ 1}$ is an isometry that fixes P. We may assume that $P = N$ (if need be by additionally composing with a rotation that sends P to N). Then the isometry $M \quad R^{\ 1} = R(Z, \ )$, by the remarks in the previous paragraph; so the direct isometry $M = R(Z, \ ) \quad R$ is a product of two rotations. We deduce that *every* direct isometry is a product of rotations.

We shall now see that every direct isometry of S^2 is a single rotation.

Since every 3 × 3 matrix with real entries (such as a product of rotations must be) must have a real eigenspace, then any such 3 × 3 matrix describing an isometry of S^2 to itself must leave the points where its eigenspace meets S^2 fixed. Since it is also a direct symmetry, it must therefore be a rotation about those points. It follows that every direct isometry of S^2 to itself is simply a rotation.

See Appendix 2.

We can deduce from this also the fact that the composite of two rotations of S^2 is also a rotation of S^2, since the composite is itself a direct isometry.

We summarize these facts as follows.

Theorem 7

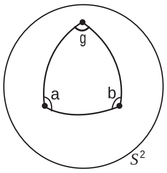
(a) Every isometry of S^2 is a reflection, a rotation, or the composite of a reflection and a rotation.
(b) Every direct isometry of S^2 is a rotation, and vice versa.

Problem 9 Prove that the composite of an even number of reflections of S^2 in great circles is a rotation of S^2.

7.3 Spherical Trigonometry

7.3.1 Spherical Triangles

Recall that a triangle on S^2, or a *spherical triangle*, consists of the arcs of three great circles joining three points on S^2. We first establish that spherical triangles exist with any given angles; more precisely, we establish the following result.



Theorem 1 Given any three angles , and with $+ \quad + \quad >$, there exists a spherical triangle with those angles.

In fact we also require that $+ \quad + \quad < 5$ in view of Theorem 3 below but we shall not go into this here.

Proof We use the idea of stereographic projection, under which circles on S^2 correspond to generalized circles (that is, lines or circles) in the extended plane.

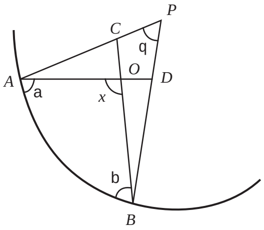
Theorem 7 of Subsection 5.2.4 (in which stereographic projection was introduced).

By a rotation of S^2, if necessary, we may assume that one of the vertices of a triangle on the unit sphere is at the South Pole, S.

Under stereographic projection a triangle on S^2 with one vertex at the South Pole S corresponds to a circular-arc triangle in the plane (that is, a triangle in $\mathbb{C}$ whose sides are arcs of generalized circles) with one vertex at O, the centre of the unit circle $\mathbb{C}$, and two straight sides. It follows that to prove the theorem it is enough to construct a triangle of this form in $\mathbb{C}$ that has the specified angles. This we now do; in our construction we assume that and lie between 0 and $\frac{}{2}$, for simplicity.

Recall that stereographic projection is angle-preserving (Theorem 8 of Subsection 5.2.4).

Consider the circular-arc triangle ABP in $\mathbb{C}$ that has angles $\frac{}{2}$ at A, $\frac{}{2}$ at B, and at P, where PA and PB are straight lines (so that P is the centre of the circle through A and B). Let D be the point on PB such that the angle BAD equals , let C be the point on PA such that the angle ABC equals , let AD and BC meet at O, and let the angle AOB equal x (as shown). Our first task is to evaluate x.



Both the angles AOC and BOD are equal to x. By considering the triangles AOC and BOD in turn, we deduce that

$$PCO = (\quad x) + \frac{}{2} \quad = \frac{3}{2} \quad x \quad ,$$

and

$$PDO = (\quad x) + \frac{}{2} \quad = \frac{3}{2} \quad x \quad .$$

Then the sum of the angles of the quadrilateral $PCOD$ is

$$2 \quad = \quad + \frac{3}{2} \quad x \quad + x + \frac{3}{2} \quad x \quad ,$$

so that

$$x = \quad + \quad .$$

It follows that $x =$ if and only if

$$= \quad + \quad + \quad .$$

Hence if we repeat the construction with the value $+ \quad +$ for , the circular-arc triangle ABO has the desired angles , and . It follows from the earlier discussion that by stereographic projection we can then construct the required spherical triangle on S^2 with these angles.

This is possible, since by hypothesis $+ \quad + \quad > \quad .$

A modification of the above argument gives the following important result, which we state without proof.

Theorem 2 The sum of the angles of any spherical triangle is greater than π.

In view of Theorems 1 and 2, it is useful to assign a name to the difference between the sum of the angles of a spherical triangle and π: this measures how far the triangle departs from being Euclidean.

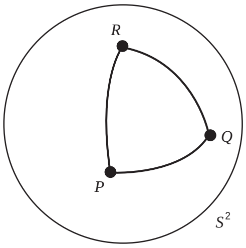
Definition The **angular excess** of a spherical triangle is the difference between the sum of the angles of the triangle and π.

Problem 1 Construct spherical triangles with angular excess of

(a) 0.01 radians, (b) 3.14 radians.

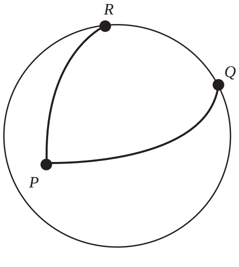
Subsection 7.1.1

Recall that earlier when we defined a distance PQ between two given points P and Q on S^2, we noted that there were two 'line segments' PQ. Now, for definiteness, we call the shorter of these two the **strict line segment** PQ. (If both are of length π, we choose either in some explicit way.)

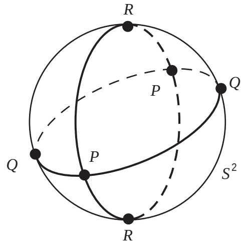


Similarly, when we defined a triangle △PQR with three given vertices P, Q and R on S^2, we noted that there were several such triangles. For definiteness, we now call the triangle whose sides are strict line segments the **strict triangle** △PQR. Then it is possible to rotate the sphere in such a way that the whole of the strict triangle can be seen at one time. (You should convince yourself that this is the case.) The **inside** of the strict triangle △PQR is then defined to be the region of S^2 bounded by the three strict line segments. The **outside** is the complement of the inside.

We now investigate the regions into which the corresponding great circles defining the strict triangle △PQR divide S^2. Notice first that the equatorial plane defining each of the relevant great circles cuts S^2 into two regions. A second great circle (and equatorial plane) divides each of these regions into two, giving four regions. Finally a third great circle (and equatorial plane) divides each of these regions into two, giving eight regions: so there are eight spherical triangles with given vertices P, Q and R on S^2.



Now let us look at the strict triangle △PQR more closely. For definiteness, we will assume that the vertices P, Q and R are chosen in clockwise order as viewed by an observer at the centre of the sphere. Rotate the sphere to move R to the North Pole, and Q to some point in the (y, z)-plane. By our choice of the orientation of △PQR and the fact that the line segments PR and PQ are strict line segments, it follows that this rotation leaves P on 'the front' of the sphere, where we can see it.

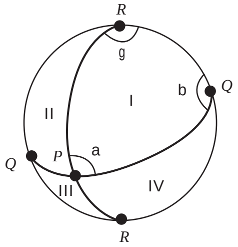


The great circle through R and Q is the 'rim' of S^2 that we can see. So the great circle RP meets it again at R', say, the diametrically opposite point to R; and the great circle QP meets it again at Q', say, the diametrically opposite point to Q. Similarly the great circles PR and PQ meet again at P', say, the diametrically opposite point to P.

So, associated with the strict triangle PQR in this particular position on S^2 there are three great circles, each meeting in two diametrically opposite points; a total of six points in all. The great circles define eight triangles:

the strict triangle PQR and the triangles $PQ\ R$, $PQ\ R$ and $PR\ Q$ (all visible on the front of S^2), and
four triangles $P\ QR$, $P\ Q\ R$, $P\ Q\ R$ and $P\ R\ Q$ round the back .

In fact, each of the eight triangles has a diametrically opposite triangle to which it is congruent (under the map (x, y, z) $(\ x,\ y,\ z)$). For example, the triangle PQR is diametrically opposite to the triangle $P\ Q\ R$.



In the figure in the margin we have marked the four visible triangles PQR, $PQ\ R$, $PQ\ R$ and $PR\ Q$ with Roman numerals I, II, III and IV, respectively. Similarly, we denote their diametrically opposite triangles $P\ Q\ R$, $P\ QR$, $P\ QR$ and $P\ RQ$ with Roman numerals I , II , III and IV , respectively.

In order to label equal angles conveniently, let us denote by the angle QPR in the strict triangle PQR, by the angle PQR, and by the angle QRP. A useful observation is that two great circles meet at the same angles at each of their points of intersection; so, for example, the angles QPR and $Q\ P\ R$ are equal.

Example 1 Show that the triangles PQR and $P\ Q\ R$ have their angles equal in pairs.

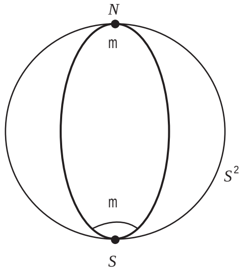
Solution The angle QPR at P in PQR is formed by two great circles that meet again at P , forming the angle $Q\ P\ R$ at P in $P\ Q\ R$, so they must be equal.

A similar argument shows that the angles at vertices Q and Q , and the angles at vertices R and R , are also equal. □

Problem 2 Determine the angles in each of triangles II, III, and IV, in terms of , and .

Area of a Triangle

We next find the area of a spherical triangle in terms of its angles. In this discussion, we introduce the term **lune** to denote a two-sided polygon defined by two great circles, choosing arbitrarily which of the four such regions on the sphere we mean.

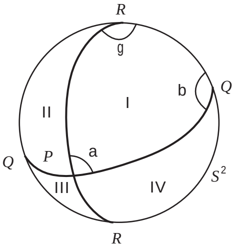


A lune with vertices at N and S, and angle μ.

The area of a lune is clearly proportional to the corresponding angle between the two great circles, the *angle of the lune.* Now when the lune has angle $\frac{\ }{2}$, its area is (for the lune is then one-quarter of S^2, which has area 4); so by proportion the area of a lune of angle μ, say, is 2μ.

The front of S^2 as shown in the margin consists of two lunes with vertices R and R , each formed of two strict triangles, I + IV and II + III (using the above notation for triangles). The lune I + IV has area 2 , since it has angle . With a slight abuse of notation we express this fact about areas in the form

$$\text{I} + \text{IV} = 2 \; .$$



A similar argument involving the lune with vertices Q and Q yields the equation

$$\text{I} + \text{II} = 2 \; ,$$

and then with the lune with vertices P and P yields the equation

$$\text{I} + \text{III} = 2 \; .$$

Since triangles III and III are congruent, we may rewrite this last equation as

$$\text{I} + \text{III} = 2 \; .$$

Adding the three equations, we obtain

$$3 \bullet \text{I} + \text{II} + \text{III} + \text{IV} = 2(\; + \; + \;).$$

Also, the area of the front of S^2 is

$$\text{I} + \text{II} + \text{III} + \text{IV} = 2 \; .$$

It follows that

$$2 \bullet \text{I} + 2 \; = 2(\; + \; + \;)$$

or

$$\text{I} = (\; + \; + \;) \qquad .$$

This completes the proof of the following theorem for triangles, in the special case that they are strict triangles.

The general case is proved by dividing an arbitrary triangle into strict triangles, and applying the special case to each; we omit the details.

Theorem 3 The area of a spherical triangle is equal to its angular excess.

Problem 3 Construct a spherical triangle of area $\frac{3}{4}$.

7.3.2 Dual Triangles

The somewhat oddly nature of the definition of a strict triangle pays off handsomely in a feature of spherical geometry that was often exploited in the 18th century by Euler and Lagrange, two of the pioneer figures in spherical geometry.

We required that the sides of a strict triangle be less than or equal to in length; for simplicity in what follows, we shall ignore the case of equality.

Let A, B and C be the vertices of a strict triangle, with angles , and at the vertices, respectively, and opposite sides of length a, b and c, respectively. Each side and angle of the triangle ABC has magnitude between 0 and .

We now construct a new spherical triangle $A B C$, called the **dual** of the original triangle ABC, with vertices A, B and C, as follows. Its angles at A, B and C are a, b and c, respectively; and its sides are $A B$ of length , $B C$ of length , and $C A$ of length .

One way of constructing such a triangle is as follows. Extend the segments AB and AC to segments AD and AD, each of length $\frac{}{2}$, and draw the great circle through D and D (this is the equator for A). Similarly, extend the segments BC and BA to segments BE and BE, each of length $\frac{}{2}$, and draw the great circle through E and E (this is the equator for B); and extend the segments CA and CB to segments CF and CF, each of length $\frac{}{2}$, and draw the great circle through F and F (this is the equator for C). Then either of the strict triangles defined by the great circles DD, EE and FF is a spherical triangle with the desired properties.

For example, choose the one that overlaps ABC, and denote its vertex on EE and FF by A, its vertex on FF and DD by B, and its vertex on DD and EE by C. We now check that the triangle $A B C$ is indeed dual to the original triangle ABC.

The lengths of CF and CB are both $\frac{}{2}$, since $A FF B$ is the equator for C. But B is on the equator $B DD C$ for A, so $B A = \frac{}{2}$. Thus A and C are on the equator for B, so that the great circle $FACD$ defined by A and C must be the equator for B. This means that D lies on the equator for B, so $B D = \frac{}{2}$. Similarly $DC = \frac{}{2}$.

Now consider the equator $B DD C$ for A, and denote by O the centre of the sphere. The angle DOD is equal to $BAC =$ (since both DOD and BAC are just the angle between the planes OAB and OAC); thus DD lies on a (great) circle of radius 1, and so the length of DD is also (since DD is equal to DOD). It follows that the length of $B C$ is

$$B C = B D + DC \quad DD = \frac{}{2} + \frac{}{2} \quad = \quad .$$

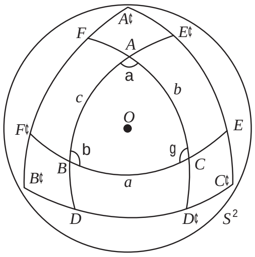
Similarly the length of $C A$ is , and the length of $A B$ is .

Next, by construction $CF = \frac{}{2}$ and $BE = \frac{}{2}$. It follows that the length of $F E$ is

$$F E = F C + BE \quad BC = \frac{}{2} + \frac{}{2} \quad a = \quad a.$$

Hence the angle $F OE$ equals a (since $F BCE$ is a circle of radius 1 with centre O and hence $F OE$ equals the length of $F E$), so that the angle $F A E$ also equals a (since both are just the angle between the planes $OA F$ and $OA E$). It follows that the angle $B A C$ equals a, as required. Similarly, $A B C =$ b and $B C A =$ c.

We have therefore established the following theorem.



$A B C$ is dual to ABC.

Theorem 4 Dual Triangles Theorem

With every strict spherical triangle there is associated another triangle , called its *dual*, whose angles are the complements of the sides of and whose sides are the complements of the angles of .

Here by the complement of a quantity x we mean the quantity x.

Here is an example of how the theorem proves useful. Let ABC be a strict triangle with $ABC = ACB$. Then, if $A\ B\ C$ is its dual (which exists by Theorem 4), we have $A\ C = A\ B$; it then follows from the Isosceles Triangle Theorem that $A\ B\ C = A\ C\ B$. It then follows by duality that $AC = AB$. This is the converse of the Isosceles Triangle Theorem, in the case of strict triangles.

Section 7.2.2, Theorem 6

We ask you to prove the general case of the converse in Section 7.6.

Problem 4 Let A, B and N be the points (1, 0, 0), (0, 1, 0) and (0, 0, 1) on S^2. Prove that the triangle ABN is congruent to any of its duals.

7.3.3 Distance between Two Points

In real life we are often interested in the (spherical) distance between points on the surface E of the Earth, whose radius is about 4000 miles. The comparable problem for S^2 is to find a formula for the distance between two points of S^2. Then a scaling map

$$\begin{aligned} t : S^2 &\qquad E \\ \mathbf{x} &\qquad 4000\mathbf{x} \end{aligned}$$

provides an answer to the original question concerning E.

In metric units, the radius of the Earth is about 6378 km.

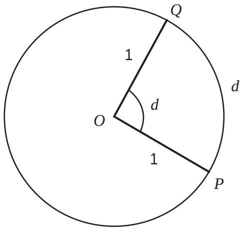
Here we take the unit of measurement for the radius S^2 to be 1 mile.

Let P and Q be points on S^2 with Cartesian coordinates (p_1, p_2, p_3) and (q_1, q_2, q_3), respectively, whose distance apart on S^2 is d. It follows that, if O denotes the centre of S^2, the angle POQ also equals d.

Then the dot product of the vectors OP and OQ is

$$OP \bullet OQ = p_1q_1 + p_2q_2 + p_3q_3 = 1 \bullet 1 \bullet \cos d,$$

so that $\cos d = p_1q_1 + p_2q_2 + p_3q_3$.



great circle

Theorem 5 The distance d on S^2 between the points (p_1, p_2, p_3) and (q_1, q_2, q_3) is given by

$$\cos\ d = p_1q_1 + p_2q_2 + p_3q_3.$$

In the expression $\cos d$, d must be taken in radians, as usual.

In applications to E, we must remember that if a point has latitude and longitude then it has colatitude $= \frac{\ }{2}$ and Cartesian coordinates (cos sin , sin sin , cos).

The latitudes and longitudes of various cities are approximately as follows.

City	Latitude	Longitude
New York	41	74
Rio de Janeiro	23	43
Sydney	34	151
Tokyo	36	140

Remember that (geographers) longitude West of the Greenwich meridian is *negative*.

Example 2 Estimate the distance between New York and Sydney, taking the radius of the Earth as 4000 miles.

Solution The colatitudes of New York and Sydney are $90 \quad 41 = 49$ and $90 + 34 = 124$, so that the coordinates of the corresponding points P and Q on S^2 are

$$\begin{aligned}&(\cos(\quad 74)\sin(49), \sin(\quad 74)\sin(49), \cos(49))\\ &\quad (0.2756 \bullet 0.7547, \quad 0.9613 \bullet 0.7547, 0.6561)\\ &\quad (0.208, \quad 0.725, 0.656),\end{aligned}$$

and

$$\begin{aligned}&(\cos(151)\sin(124), \sin(151)\sin(124), \cos(124))\\ &\quad (\quad 0.8746 \bullet 0.8290, 0.4848 \bullet 0.8290, \quad 0.5592)\\ &\quad (\quad 0.725, 0.402, \quad 0.559).\end{aligned}$$

Hence the distance between New York and Sydney is approximately $4000d$ miles, where

$$\begin{aligned}\cos d &\quad 0.208 \bullet 0.725 \quad 0.725 \bullet 0.402 \quad 0.656 \bullet 0.559\\ &\quad 0.151 \quad 0.291 \quad 0.367 = \quad 0.809.\end{aligned}$$

Thus $d \quad \cos^{\ 1}(\quad 0.809) \quad 2.513$ radians, and the required distance $4000d$ $\quad 4000 \bullet 2.51 \quad 10\,050$ miles. □

Problem 5 Estimate the distance between Tokyo and Rio de Janeiro, taking the radius of the Earth as 4000 miles.

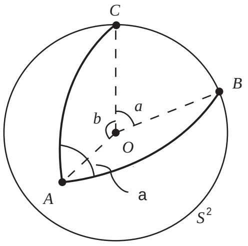
Right-Angled Triangles

It only makes sense to discuss Pythagoras Theorem in those geometries with a *distance.* We have already seen Pythagoras Theorem in hyperbolic geometry, so what is the analogue in spherical geometry?

Theorem 8 of Subsection 6.4.3

Theorem 6 Pythagoras' Theorem
Let ABC be a triangle on S^2 in which the angle at C is a right angle. If a, b and c are the lengths of BC, CA and AB, then

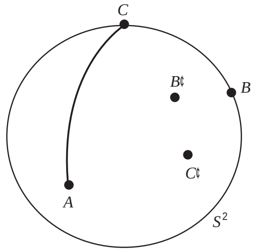
$$\cos c = \cos a \times \cos b.$$



Proof We may rotate S^2 so that C is the North Pole $N \ (0, 0, 1)$ of S^2, A lies on the Greenwich meridian and has coordinates $(\sin b, 0, \cos b)$, and B has coordinates $(0, \sin a, \cos a)$.

We then apply the rotation $R(Y, \quad b)$ to S^2. This maps A to C, C to some point C , and B to some point B .

Since the sphere has radius 1, at A, $\ = b$ and $\ = 0$; and at B, $\ = \frac{}{2}$ and $\ = a$.



Let denote the angle CAB. Then the rotation $R(Y,\ \ b)$ maps the angle CAB to the angle $C\ CB$, so that the angle $C\ CB\ =\ $; it follows that the angle $ACB\ =\ $ since $ACB\ +\ \ B\ CC\ =\ $. Hence the longitude of B is . Also, the colatitude of B is

$$\text{length of CB} = \text{length of AB} = c.$$

So the coordinates of B are

$$\begin{aligned}&(\cos(\quad)\sin c, \sin(\quad)\sin c, \cos c)\\ &= (\ \ \cos\ \ \sin c,\ \sin\ \ \sin c, \cos c).\end{aligned} \qquad (1)$$

But we also have as coordinates of B

$$R(Y,\ \ b)(B) = \begin{matrix}\cos b & 0 & \sin b\\ 0 & 1 & 0\\ \sin b & 0 & \cos b\end{matrix} \qquad \begin{matrix}0\\ \sin a\\ \cos a\end{matrix}$$

$$= \begin{matrix}\sin b\cos a\\ \sin a\\ \cos b\cos a\end{matrix} \quad \bullet \qquad (2)$$

Here we use the formulas for coordinates under isometries given in Subsection 7.2.1.

Equating the third coordinates in (1) and (2), we get the formula

$$\cos c = \cos a \times \cos b,$$

as required.

For example, if $a = 1, b = 2$ and $ACB = \frac{}{2}$, then

$$\cos c = \cos 1 \times \cos 2 \quad 0.5403 \bullet (\ \ 0.4161) \quad 0.2248,$$

so that c 1.798.

Problem 6 PQR is a triangle on S^2 in which the angle at R is a right angle and the lengths of PQ and PR are 1.7 and 1.9, respectively. Estimate the length of QR.

Remark

For all values of x, $\cos x = 1 \quad \frac{x^2}{2!} +$ higher powers of x; so, when x is small, $\cos x \quad 1 \quad \frac{1}{2}x^2$. It follows that, if we are dealing with small triangles on S^2, then the conclusion of Theorem 6 may be interpreted in the form

$$1 \quad \tfrac{1}{2}c^2 \qquad 1 \quad \tfrac{1}{2}a^2 \bullet 1 \quad \tfrac{1}{2}b^2 \qquad 1 \quad \tfrac{1}{2}a^2 \quad \tfrac{1}{2}b^2,$$

Here we drop the term in a^2b^2, since it is smaller than the remaining terms.

so that $c^2 \quad a^2 + b^2$. Thus Theorem 6 is a close approximation to the Euclidean version of Pythagoras Theorem in $\mathbb{R}^2$.

The area formula for S^2 suggests that the angles of a spherical triangle determine its size as well as its shape. In fact, any three pieces of the six possible

Theorem 3

pieces of information about a triangle (its three angles and the lengths of its three sides) determine the remaining three.

We prove this fact here for right angled triangles; a proof for general triangles can then be constructed by dividing a general triangle into two right angled triangles using an altitude.

Returning to the formula in the proof of Theorem 6 for the coordinates of B and equating the first and second coordinates, we obtain

$$\cos\ \sin c = \sin b \cos a \quad \text{and} \quad \sin\ \sin c = \sin a.$$

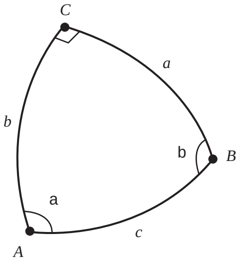
Dividing the second of these by the first, we get $\tan\ = \tan a / \sin b$.

Re-arranging the above formulas to make them easier to remember, we have the following result.

Theorem 7 Let ABC be a triangle on S^2 in which the angle at C is a right angle. If a, b and c are the lengths of BC, CA and AB, and denotes the angle CAB, then

$$\cos c = \cos a \times \cos b,$$

$$\sin\ = \frac{\sin a}{\sin c}, \quad \text{and} \quad \tan\ = \frac{\tan a}{\sin b}.$$



In the proof of Theorem 6 and before Theorem 7

A similar discussion to that above gives that

$$\cos\ \sin c = \sin a \cos b \quad \text{and} \quad \sin\ \sin c = \sin b,$$

so that

$$\sin\ = \frac{\sin b}{\sin c} \quad \text{and} \quad \tan\ = \frac{\tan b}{\sin a}.$$

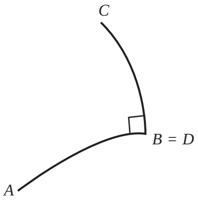
From these formulas and those in Theorem 7 above, it follows that in a right-angled triangle two further pieces of information about the triangle enable us to determine all its angles and sides.

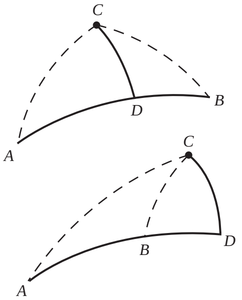
> **Problem 7** PQR is a triangle on S^2 in which the angle at R is a right angle and the lengths of PQ and PR are 1.7 and 1.9, respectively. Estimate the angle QPR.

7.3.4 Spherical Trigonometry

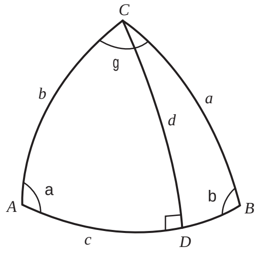
In this subsection we deduce various formulas of spherical trigonometry for strict triangles by dropping perpendiculars from a vertex of a spherical triangle to the opposite side, giving two right-angled ones for which we already have formulas. First, we verify that we can always drop a perpendicular from a point to a line. It follows that a spherical triangle has 3 altitudes.

Given a strict segment AB and a point C on S^2 that form a triangle ABC, there is always a great circle through C perpendicular to AB. This great circle meets the great circle of which AB is part in two points, which we call D and D. Since D and D are antipodal points, they are a distance apart, so one of three things must happen.





1. One of D and D coincides with A or B. The corresponding strict line segment is the **perpendicular** from C to AB. This case will not lead us to any new results, so we do not consider it further.
2. One of D and D, say D, lies between A and B. Then we call CD the **perpendicular** from C to AB; it lies inside ABC.
3. One of D and D, say D, is such that the distance AD is less than and B lies between A and D. Then we again call CD the **perpendicular** from C to AB; in this case it lies outside ABC.



Now consider a strict spherical triangle ABC, in which the sides AB, BC and CA have lengths c, a and b, respectively, and the angles at A, B and C are , and , respectively. Drop the perpendicular CD from C to AB, and let d denote the length of CD.

If we apply the second formula in Theorem 7 to triangle ADC we get

$$\sin \quad = \frac{\sin d}{\sin b},$$

so that $\sin d = \sin \quad \times \sin b$. Applying a similar argument to triangle BDC we get $\sin d = \sin \quad \times \sin a$.

Thus, $\sin \quad \times \sin b = \sin \quad \times \sin a$, which is more memorable in the form

$$\frac{\sin}{\sin a} = \frac{\sin}{\sin b}.$$

Then, by a similar argument involving the perpendicular from A to BC, we obtain the following result.

Theorem 8 Sine Rule for a Strict Spherical Triangle
Let ABC be a strict triangle on S^2, in which the sides AB, BC and CA have lengths c, a and b, respectively, and the angles at A, B and C are , and respectively. Then

$$\frac{\sin}{\sin a} = \frac{\sin}{\sin b} = \frac{\sin}{\sin c}.$$

We can use an argument similar to that in the proof of Pythagoras Theorem to find further results.

Theorem 6

Let ABC be a strict triangle on S^2. We may rotate S^2 so that C is the North Pole $N(0, 0, 1)$, A lies on the Greenwich meridian and has coordinates $(\sin b, 0, \cos b)$, and B has coordinates $(\cos \quad \sin a, \sin \quad \sin a, \cos a)$.

We then apply the rotation $R(Y, \quad b)$ to S^2. This maps A to C, C to some point C, and B to some point B. As we saw earlier, the coordinates of B are $(\quad \cos \quad \sin c, \sin \quad \sin c, \cos c)$.

In the proof of Theorem 6

But we also have as coordinates of B

$$R(Y,\quad b)(B) = \begin{pmatrix} \cos b & 0 & \sin b \\ 0 & 1 & 0 \\ \sin b & 0 & \cos b \end{pmatrix} \begin{pmatrix} \cos \quad \sin a \\ \sin \quad \sin a \\ \cos a \end{pmatrix}$$

$$= \begin{pmatrix} \cos b \cos \quad \sin a \quad \sin b \cos a \\ \sin \quad \sin a \\ \sin b \cos \quad \sin a + \cos b \cos a \end{pmatrix}.$$

Equating the third coordinates in the two expressions for B we get

$$\cos c = \sin b \cos \quad \sin a + \cos b \cos a.$$

Theorem 9 Cosine Rule for Sides of a Strict Spherical Triangle
Let ABC be a strict triangle on S^2, in which the sides AB, BC and CA have lengths c, a and b, respectively, and the angles at A, B and C are , and , respectively. Then

$$\cos c = \cos a \cos b + \sin a \sin b \cos \quad .$$

Notice that this formula reduces to Pythagoras Theorem when is a right-angle.

Example 3 Let ABC be a strict isosceles triangle on S^2, in which the sides AB, BC and CA have lengths c, a and a, respectively, and the angles at A, B and C are , and , respectively. Prove that

(a) $\cos c = \cos^2 a + \sin^2 a \cos \quad$; (b) $\cos \quad = \dfrac{\tan \frac{1}{2}c}{\tan a}$.

Solution Putting $b = a$ in the conclusion of Theorem 9, we obtain the formula (a).

Next, by applying Theorem 9 to find $\cos a$, we get

$$\cos a = \cos a \cos c + \sin a \sin c \cos \quad .$$

We may then rearrange this formula to get

$$\cos \quad = \frac{\cos a (1 \quad \cos c)}{\sin a \sin c}$$

$$= \frac{\cos a \bullet 2 \sin^2 \frac{1}{2}c}{\sin a \bullet 2 \sin \frac{1}{2}c \cos \frac{1}{2}c} = \frac{\tan \frac{1}{2}c}{\tan a},$$

as required. □

Here we use the identities

$$\cos 2x = 1 \quad 2 \sin^2 x$$

and

$$\sin 2x = 2 \sin x \cos x$$

for $x \quad$ R.

Problem 8 Let ABC be a strict equilateral triangle on S^2, in which the sides have length a and the angles are equal to . Prove that

$$\cos \quad = \frac{\cos a}{1 + \cos a}.$$

We can now use any dual triangle $A\ B\ C$ of ABC to prove a new trigonometric result. The dual triangle has sides of length , and , and has angles of magnitude a, b and c. By applying Theorem 9 to the dual triangle and using the formulas $\sin(\ \ x) = \sin x$ and $\cos(\ \ x) = \ \cos x$, we get

You met dual triangles in Subsection 7.3.2.

$$\cos\ \ = \cos\ \ \cos\ \ \ \ \sin\ \ \sin\ \ \cos c;$$

and we can reformulate this formula as follows.

Theorem 10 Cosine Rule for Angles of a Strict Spherical Triangle
Let ABC be a strict triangle on S^2, in which the sides AB, BC and CA have lengths c, a and b, respectively, and the angles at A, B and C are , and , respectively. Then

$$\cos\ \ = \sin\ \ \sin\ \ \cos c\ \ \ \ \cos\ \ \cos\ \ .$$

7.4 Spherical Geometry and the Extended Complex Plane

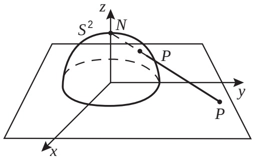
Earlier we studied the Riemann sphere and stereographic projection of the sphere onto the extended complex plane $\mathbb{C} = \mathbb{C}\ \ \{\ \ \}$.

Subsection 5.2.4

Here we denote the Riemann sphere by S^2 rather than $\mathbb{S}$.

7.4.1 Stereographic Projection

In this section we regard stereographic projection as a mapping of the sphere S^2 onto an extended plane $\mathbb{R}^2\ \ \{\ \ \}$, under which the point (X, Y, Z) maps onto the point $(X, Y, Z) = \ \frac{X}{1\ \ Z}, \frac{Y}{1\ \ Z}$; the inverse mapping is given by



$$^{1}(x, y) = \ \frac{2x}{x^2 + y^2 + 1}, \frac{2y}{x^2 + y^2 + 1}, \frac{x^2 + y^2\ \ \ 1}{x^2 + y^2 + 1}\ \ .$$

Example 1 Let C denote a great circle on S^2 that is the intersection of S^2 with the plane $aX + bY + cZ = 0$, where $a^2 + b^2 + c^2 = 1, c = 0$.

Since $c = 0$, C does not pass through the North Pole N of S^2.

(a) Determine the point N that is the image of N under reflection in C.
(b) Determine the images of N and C in $\mathbb{R}^2$ under stereographic projection .
(c) Verify that $(N\ )$ is the centre of the circle (C).

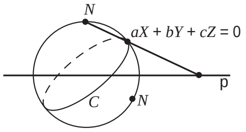
Solution

(a) The point N has coordinates

We follow the approach of Subsection 7.2.2.

$$\begin{aligned}&(0,0,1)\ \ \ 2\{(0,0,1) \bullet (a,b,c)\}(a,b,c)\\ &= (0,0,1)\ \ \ 2c(a,b,c) = \ \ \ 2ac,\ \ \ 2bc, 1\ \ \ 2c^2\ \ .\end{aligned}$$

(b) From the formula for , the image of N under is



$$(\ \ 2ac,\ \ 2bc, 1\ \ \ 2c^2) = \frac{2ac}{1\ \ \ (1\ \ \ 2c^2)}, \frac{2bc}{1\ \ \ (1\ \ \ 2c^2)}$$

$$= \quad \frac{a}{c}, \ \ \frac{b}{c} \quad .$$

Here we use the fact $c = 0$.

From the formula for ^{1} the image (C) of C has equation

$$a\frac{2x}{x^2+y^2+1} + b\frac{2y}{x^2+y^2+1} + c\frac{x^2+y^2\ \ \ 1}{x^2+y^2+1} = 0;$$

we may rewrite this in the form

$$2ax + 2by + c\ \ \ x^2 + y^2\ \ \ \ 1\ \ \ = 0,$$

or

$$x^2 + y^2 + 2\frac{a}{c}x + 2\frac{b}{c}y\ \ \ \ 1 = 0.$$

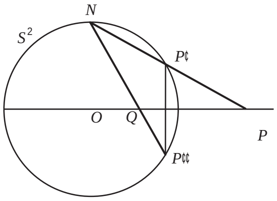
Again we use the fact $c = 0$.

(c) Since the equation of the circle (C) may be written in the form

$$x + \frac{a}{c}\ \ ^2 + \ \ \ y + \frac{b}{c}\ \ \ ^2 = 1 + \frac{a^2+b^2}{c^2} = \frac{1}{c^2},$$

the centre of (C) is the point $\frac{a}{c}, \ \ \frac{b}{c}$, that is, the point $(N\ )$. □

Problem 1 Let $P = (x, y)$ be a point in $\mathbb{R}^2$ other than the origin. Let P be the point on S^2 that corresponds to P under stereographic projection, P the reflection of P in the (X, Y)-plane, and Q the point in $\mathbb{R}^2$ that corresponds to P under stereographic projection.



(a) Determine the coordinates of P , P and Q.

(b) Prove that P and Q are inverse points with respect to the unit circle $x^2 + y^2 = 1$ in $\mathbb{R}^2$.

There is a simple and useful expression for the image under stereographic projection of a point on S^2 with given colatitude and longitude.

Example 2 The point P on S^2 with colatitude and longitude has coordinates (cos sin , sin sin , cos). Prove that the image P of P under stereographic projection has coordinates $\frac{\cos}{\tan\ \frac{1}{2}}, \frac{\sin}{\tan\ \frac{1}{2}}$.

Recall that the latitude of P is $= \ \overline{2}$.

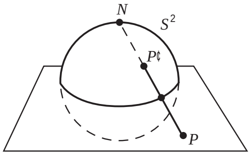
Solution From the formula for , the image P of P under is the point

$$\frac{\cos\quad\sin}{1\quad\cos}, \frac{\sin\quad\sin}{1\quad\cos}$$

$$= \frac{\cos\quad \bullet 2\sin\ \frac{1}{2}\quad \cos\ \frac{1}{2}}{2\sin^2\ \frac{1}{2}}, \frac{\sin\quad \bullet 2\sin\ \frac{1}{2}\quad \cos\ \frac{1}{2}}{2\sin^2\ \frac{1}{2}}$$

$$= \frac{\cos}{\tan\ \frac{1}{2}}, \frac{\sin}{\tan\ \frac{1}{2}}\quad ,$$

as required. □



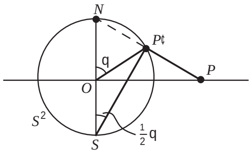
Next, we obtain a neat formula relating the distance on S^2 between the South Pole S and a point P on S^2 to the distance of the corresponding point $P = \quad (P\ )$ from O in $\mathbb{R}^2$.

Let P be a point $(x, 0)$ in $\mathbb{R}^2, x > 0$. The corresponding point $P\ = \quad ^1(P)$ on S^2 has coordinates $\frac{2x}{1+x^2}, 0, \frac{x^2\ 1}{x^2+1}$; it follows from the definition of spherical polar coordinates on S^2 as $(\cos\ \sin\ , \sin\ \sin\ , \cos\ )$, where is colatitude, that the colatitude of P satisfies the equation

$$\tan\quad = \frac{2x}{x^2\quad 1}. \tag{1}$$

Then if the spherical distance of P from S is d, the colatitude of P also satisfies the equation $\quad + d = \quad$, so that

$$\tan\quad = \quad \tan d. \tag{2}$$



Then, if we denote by T the quantity $\tan\ \frac{1}{2}d$, it follows from equations (1) and (2) that $\frac{2x}{x^2\ 1} = \quad \frac{2T}{1\ T^2}$. We can write this equation in the form $(T\quad x)(1 + xT) = 0$; and, since both x and T are positive it follows that $T = x$. In other words $\tan\ ^1 x = \tan\ ^1 T = \frac{1}{2}d$, so that $d = 2\tan\ ^1 x$.

Since a rotation of S^2 and $\mathbb{R}^2$ about the Z-axis does not change any of the distances in the above argument, we deduce the following result.

Theorem 1 Let a point P on S^2 map under stereographic projection to a point P in $\mathbb{R}^2$ with coordinates $(r\cos\ , r\sin\ )$. Then the spherical distance of P from the South Pole S is $2\tan\ ^1(r)$.

Here Q does not represent colatitude.

Problem 2 Let P and Q be the points $(2, 2)$ and $(3, 3)$ in $\mathbb{R}^2$, and P and Q the corresponding points on S^2 under the mapping $\quad ^1$. Use Theorem 1 to determine the spherical distance $P\ Q$.

7.4.2 Conjugate Transformations

We have seen a correspondence between points of the sphere S^2 and points of the extended plane. We now investigate the correspondence between spherical transformations and Möbius transformations.

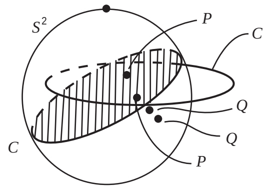
Subsection 7.4.1

Earlier we saw that a spherical transformation is the composition of at most three reflections in great circles, and that the composition of any two reflections is a rotation. Here we shall see that reflection in a great circle corresponds to inversion in the image of that circle under stereographic projection, and that a rotation of S^2 corresponds to a particular kind of Möbius transformation. Thus we have two equivalent descriptions of spherical transformations, one on the sphere using 3 × 3 matrices, and one in the extended plane using Möbius transformations.

Theorems 5 and 4 of Subsection 7.2.2

Firstly, we establish the following pleasant result.

Theorem 2 Let P and Q be points on S^2 that are mirror images under reflection in a great circle C, and let the images of P, Q and C under stereographic projection be P, Q and C, respectively. Then P and Q are inverse points with respect to C.



Proof The great circle lies in a plane, say, through the origin. consists of those points in $\mathbb{R}^3$ that are equidistant from the points P and Q. So any sphere through P and Q has its centre somewhere in , and so any circle on S^2 through P and Q also has its centre in . Thus any circle C on S^2 through P and Q meets the great circle C at right angles.

Under stereographic projection , the circles C and C map to generalized circles; since stereographic projection is angle-preserving, these images meet at right angles.

Now let C be any generalized circle through P and Q. The image of C under ^{1} is a circle on S^2 through P and Q; so $^1(C)$ is some circle C on S^2 that meets C at right angles. Then, since stereographic projection is angle-preserving, it follows that C meets C at right angles.

But C is any circle through P and Q, so any circle through P and Q meets C at right angles. It follows that P and Q are inverse points with respect to C, as required.

Here we are using Theorem 4 of Subsection 5.5.2.

Notice that, if C_1 and C_2 are a great circle and a little circle on S^2, and C_1 and C_2 are their images in the extended plane under , then there exists a

Möbius transformation that maps C_1 onto C_2, but there cannot be a rotation of S^2 that maps C_1 onto C_2. Hence there are Möbius transformations of the extended plane that do not correspond to rotations of the sphere.

Now, inversion in a generalized circle in the extended plane is necessarily a Möbius transformation composed with a complex conjugation. It follows from Theorem 2 that any spherical transformation corresponds to a Möbius transformation, composed (if need be) with a complex conjugation.

By Theorem 10, Subsection 5.3.7

So each rotation R of S^2 corresponds to some Möbius transformation of the extended plane by means of stereographic projection . If P is a point in the extended plane, it follows that $^{1}(P)$ is a point on S^2; R $^{1}(P)$ is the image of that point after the rotation, and R $^{1}(P)$ is the projection of that image onto the extended plane.

For both are orientation-preserving mappings.

So, R ^{1} is a mapping of the extended plane to itself. We therefore make the following definition.

Definition Let R denote a rotation of S^2, and stereographic projection. Then the transformation R ^{1} of the extended plane is called the **conjugate transformation** of the rotation R.

It follows from the above discussion that the image of the group of rotations of S^2 under is a group of Möbius transformations.

Lemma The conjugate transformation of a rotation of S^2 is a Möbius transformation of the extended plane.

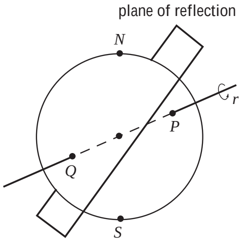
This was proved in the earlier discussion.

Indeed it can be proved that the mapping R R ^{1} maps the group of rotations of S^2 isomorphically onto a group of Möbius transformations of the extended plane, but that it is not the whole group of Möbius transformations. We now characterize the Möbius transformations that are conjugate to rotations of S^2.

We omit a proof of this fact.

We saw this in the discussion above.

Theorem 3 A Möbius transformation M that is conjugate to a rotation of S^2 is of the form $M(z) = \frac{az+b}{\bar{b}z+\bar{a}}$, where a, b C.



Proof There is one family of rotations of S^2 that we can easily relate to Möbius transformations, namely rotations around the Z-axis. Their conjugate transformations are simply rotations about the origin through the same angle. Our strategy will be to use reflections of S^2 to reduce a given rotation of S^2 to one about the Z-axis.

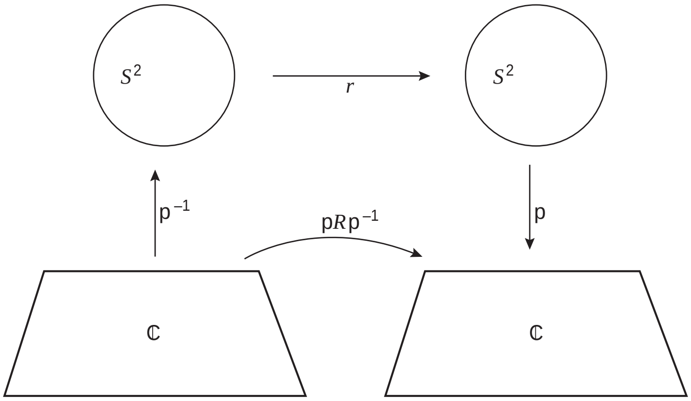
Let R denote a rotation of S^2 about the (diametrically opposite) points P and Q of S^2, through an angle , and let r denote the reflection in a suitable great circle of S^2 that maps P to the North Pole N; so that $r(P) = N$. Then since r is a reflection, it is its own inverse, so that $r(N) = P$. Similarly $r(Q) = S$, the South Pole, and $r(S) = Q$.

So we shall often use r and r ^{1} interchangeably below.

The spherical transformation $r^{-1}Rr$ is a direct isometry of S^2, and so is a rotation of S^2. Since

$$\begin{aligned} r^{-1}Rr\;(N) &= r^{-1}R\;(r(N))\\ &= r^{-1}R\;(P)\\ &= r^{-1}R(P) = r^{-1}(P) = N, \end{aligned}$$

the point N is a fixed point of the rotation; similarly S is also a fixed point. So $r^{-1}Rr$ is a rotation of S^2 about the Z-axis.



It follows that the transformation $(r^{-1}Rr)^{-1}$ is a rotation of the (x, y)-plane about the origin. Denoting this by M, it follows that $M(z) = e^{i}z$, for some real number .

Now

$$\begin{aligned} M &= r^{-1}Rr^{-1}\\ &= r^{-1\;-1}R^{-1}r^{-1}\\ &= r^{-1}R^{-1}r^{-1}; \end{aligned}$$

For $^{-1}$ is the identity map of S^2 to itself.

so that, since we know M, in order to know R^{-1} it is now sufficient to find r^{-1}.

Since N and P map to each other under the reflection r in a suitable great circle of S^2, the mapping r^{-1} must be inversion in a circle in the plane.

By Theorem 2 and $r^{-1} = r$.

Now the great circle of S^2 is the intersection of the sphere $X^2 + Y^2 + Z^2 = 1$ with some plane $aX + bY + cZ = 0$; we may assume that $a^2 + b^2 + c^2 = 1$. Since the plane cannot be vertical, $c = 0$.

This assumption will simplify our calculations.

By applying the formula for $^{-1}$ to the equation of the plane, we see that the image of the great circle is a circle C in the (x, y)-plane with equation

$$2ax + 2by + c\;x^2 + y^2 - 1 = 0,$$

or

$$x^2 + y^2 + 2\frac{a}{c}x + 2\frac{b}{c}y \quad 1 = 0.$$

The circle C has centre $\quad \frac{a}{c}, \quad \frac{b}{c}$, and the square of its radius is

For, $a^2 + b^2 + c^2 = 1$

$$1 + \quad \frac{a}{c} \quad ^2 + \quad \frac{b}{c} \quad ^2 = \frac{1}{c^2}\bullet$$

Next we express things in terms of complex numbers. Let $\quad = \frac{a}{c} \quad i\frac{b}{c}$, so that $\text{ﬂ} = |\quad|^2 = \frac{a^2+b^2}{c^2}$. Now inversion in C is a mapping of the form

is the centre of the circle in the plane.

$$\begin{aligned} z \quad & \frac{(1/c)^2}{\overline{\overline{z}}} + \\ &= \frac{\text{ﬂ}z \quad |\quad|^2 + (1/c)^2}{\text{ﬂ}z \quad \text{ﬂ}} \\ &= \frac{\text{ﬂ}z + 1}{\text{ﬂ}z \quad \text{ﬂ}}, \end{aligned}$$

You met this formula in Theorem 3, Subsection 5.2.1.

so that

For, $\quad |\quad|^2 + (1/c)^2 = 1$

$$r \quad ^1(z) = \frac{\text{ﬂ}z + 1}{\text{ﬂ}z \quad \text{ﬂ}}\bullet$$

Then

$$M(\quad r \quad ^1)(z) = e^{i} \quad \bullet \frac{\text{ﬂ}z + 1}{\text{ﬂ}z \quad \text{ﬂ}},$$

so that

$$\begin{aligned} R \quad ^1(z) &= \frac{e^{\quad i} \quad \bullet \frac{\text{ﬂ}z+1}{z} \quad + 1}{e^{\quad i} \quad \bullet \frac{\text{ﬂ}z+1}{z} \quad \text{ﬂ}} \\ &= \frac{e^{\quad i}\ (\text{ﬂ}z + 1) + (z \quad\quad)}{e^{\quad i}\ (\text{ﬂ}z + 1) \quad \text{ﬂ}(z \quad\quad)} \\ &= \frac{z \ |\quad|^2 e^{\quad i} \quad + 1 \quad + (\quad e^{\quad i} \quad\quad)}{z(\text{ﬂ}e^{\quad i} \quad \text{ﬂ}) + (e^{\quad i} \quad + |\quad|^2)} \\ &= \frac{z \ |\quad|^2 e^{\quad i\quad /2} + e^{i\quad /2} \quad + \quad e^{\quad i\quad /2} \quad\quad e^{i\quad /2}}{z \quad \text{ﬂ}e^{\quad i\quad /2} \quad \text{ﬂ}e^{i\quad /2} \quad + \quad e^{\quad i\quad /2} + |\quad|^2 e^{i\quad /2}}; \end{aligned}$$

thus $\quad R \quad ^1(z) = \frac{az+b}{\bar{b}z+\bar{a}}$, where $a = |\quad|^2 e^{\quad i\quad /2} + e^{i\quad /2}$ and $b = \quad e^{\quad i\quad /2} \quad e^{i\quad /2}$, as required.

Remark

Notice that the Möbius transformations $M(z) = \frac{az+b}{\bar{b}z+\bar{a}}$ conjugate to a rotation of S^2 are rather like the Möbius transformations representing direct hyperbolic transformations $M(z) = \frac{az+b}{\bar{b}z+\bar{a}}$, with $|b| < |a|$.

You met these Möbius transformations in Theorem 2, Subsection 6.2.1.

Problem 3 The two fixed points of a rotation of S^2 are distinct from N and S. Show that they map under stereographic projection to points in $\mathbb{C}$ of the form s and $-1/\bar{s}$.

Example 3 Prove that a Möbius transformation M that is conjugate to a rotation $R(Y, \theta)$ of S^2 is of the form $M(z) = \frac{az-b}{bz+a}$ where a, b are real.

Solution A rotation $R(Y, \theta)$ of S^2 fixes the points $(0,1,0)$ and $(0,-1,0)$, which map under stereographic projection to the points i and $-i$, respectively.

By Theorem 3, a conjugate Möbius transformation must be of the form

$$M(z) = \frac{cz+d}{-\bar{d}z+\bar{c}};$$

We use c and d to avoid using the letters a and b for several different things.

this fixes i and $-i$ if

$$i = \frac{ci+d}{-\bar{d}i+\bar{c}} \quad \text{and} \quad -i = \frac{-ci+d}{\bar{d}i+\bar{c}},$$

which we can rewrite in the form

$$\bar{d} + \bar{c}i = ci + d \quad \text{and} \quad \bar{d} - \bar{c}i = -ci + d.$$

Adding these equations gives $2\bar{d} = 2d$, so that d is real, and subtracting the equations gives $2\bar{c}i = 2ci$, so that c is real.

It follows that M has the desired form $M(z) = \frac{az-b}{bz+a}$, with a in place of c and $-b$ in place of d. □

Problem 4 Prove that a Möbius transformation M that is conjugate to a rotation $R(X, \theta)$ of S^2 is of the form $M(z) = \frac{az+ib}{ibz+a}$, where a, b are real.

We end with some interesting observations concerning Möbius transformations. A *fixed point* of a Möbius transformation $M(z) = \frac{az+b}{cz+d}$, $ad - bc \neq 0$, is a point z for which $M(z) = z$, that is, $\frac{az+b}{cz+d} = z$ or $cz^2 + (d-a)z - b = 0$. Since a quadratic equation can have at most two roots, it follows that a Möbius transformation can have at most two fixed points.

Problem 5 Determine the fixed points in $\mathbb{C}$ and in $\hat{\mathbb{C}}$ of the following Möbius transformations:

$$z \mapsto z+1; \quad z \mapsto -\frac{4}{z+4}; \quad z \mapsto -\frac{4}{z+5}.$$

Example 4 Prove that a Möbius transformation M with distinct fixed points a and b in $\mathbb{C}$ maps the family $\mathcal{A}$ of Apollonian circles defined by the point circles a and b to itself.

Solution Let B be the family of generalized circles through a and b.

Since M has fixed points a and b, it maps the family B onto itself. Also, since a Möbius transformation preserves angles, M thus maps the family of generalized circles that is orthogonal to those in B to itself. This family is the family A of Apollonian circles defined by the point circles a and b. □

A Möbius transformation maps generalized circles onto generalized circles.

By Theorem 3, Subsection 5.5.1

Example 5 Prove that a Möbius transformation M with distinct fixed points a and b in C *either* maps each circle in the family A of Apollonian circles defined by the point circles a and b to itself *or* it maps no circle in A to itself.

Solution By a suitable Möbius transformation f, we can map the point a to 0 and b to . Then f maps the family A of Apollonian circles defined by the point circles a and b to the family B of concentric circles with centre 0.

Then $f \quad M \quad f^{\ 1}$ is a Möbius transformation, and it maps 0 to 0 and to . It follows that $f \quad M \quad f^{\ 1}$ is of the form $z \qquad Kz$, for some non-zero complex number K.

If $|K| = 1$, then $f \quad M \quad f^{\ 1}$ maps each concentric circle in B to itself; but if $|K| = 1$ then $f \quad M \quad f^{\ 1}$ maps no circle in B to itself.

If we then apply the mapping $f^{\ 1}$ to return to the original situation, the required result follows at once. □

It is easy to verify that a Möbius transformation of C that has 0 and as its fixed points is necessarily of the form $z \qquad Kz$.

7.4.3 Coaxal Circles

Stereographic projection enables us to interpret the theory of coaxal circles, including all its special cases, very elegantly on the sphere S^2.

You met coaxal circles in Subsection 5.5.2.

Earlier you saw that, if C is the circle cut out on S^2 by the plane with equation $aX + bY + cZ + d = 0$, then stereographic projection maps C to:

In the proof of Theorem 7 of Subsection 5.2.4

(a) the circle with equation

$$x^2 + y^2 + 2\frac{a}{c+d}x + 2\frac{b}{c+d}y \quad \frac{c \quad d}{c+d} = 0, \quad \text{if } c = \quad d;$$

(b) the straight line with equation

$$ax + by \quad \frac{c \quad d}{2} = 0, \quad \text{if } c = \quad d.$$

If $c = \quad d$, the circle C passes through N.

Problem 6 Prove that a circle in R^2 with equation

$$x^2 + y^2 + 2 \quad x + 2 \quad y + \quad = 0$$

corresponds under stereographic projection to the circle cut out on S^2 by the plane with equation

$$2 \quad X + 2 \quad Y + (1 \qquad)Z + (1 + \quad) = 0.$$

Definition The circle in $\mathbb{R}^2$ with equation

$$x^2 + y^2 + 2 \quad x + 2 \quad y + \quad = 0$$

and the plane with equation

$$2 \quad X + 2 \quad Y + (1 \qquad)Z + (1 + \quad) = 0$$

are said to be **associated**.

That is, they correspond to each other under stereographic mapping.

We now use the idea of associated planes and circles to revisit the theory of coaxal circles.

Let C_1 and C_2 be distinct circles in $\mathbb{R}^2$ with equations

We allow C_1 and C_2 to be point circles.

$$x^2 + y^2 + 2 \quad {}_1 x + 2 \quad {}_1 y + \quad {}_1 = 0$$

and

$$x^2 + y^2 + 2 \quad {}_2 x + 2 \quad {}_2 y + \quad {}_2 = 0,$$

respectively; then their corresponding associated planes ${}_1$ and ${}_2$ have equations

$$2 \quad {}_1 X + 2 \quad {}_1 Y + (1 \qquad {}_1)Z + (1 + \quad {}_1) = 0$$

and

$$2 \quad {}_2 X + 2 \quad {}_2 Y + (1 \qquad {}_2)Z + (1 + \quad {}_2) = 0.$$

Now, either ${}_1$ and ${}_2$ are parallel or they are not parallel; they cannot be the same plane, since the associated circles are distinct.

First, suppose that ${}_1$ and ${}_2$ are not parallel, so that they have a common line, say.

For arbitrary p and q, $p \quad = \quad q$, let C_{pq} be the generalized circle with equation

$$\frac{p}{p+q} \quad x^2 + y^2 + 2 \quad {}_1 x + 2 \quad {}_1 y + \quad {}_1$$
$$+ \frac{q}{p+q} \quad x^2 + y^2 + 2 \quad {}_2 x + 2 \quad {}_2 y + \quad {}_2 \quad = 0,$$

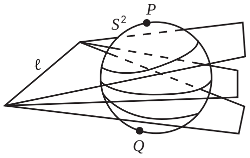
and let ${}_{pq}$ be its associated plane, with equation

$$\frac{p}{p+q}(2 \quad {}_1 X + 2 \quad {}_1 Y + (1 \qquad {}_1)\, Z + (1 + \quad {}_1))$$
$$+ \frac{q}{p+q}(2 \quad {}_2 X + 2 \quad {}_2 Y + (1 \qquad {}_2)\, Z + (1 + \quad {}_2)) = 0.$$

The associated plane ${}_{pq}$ passes through the line ; so, as p and q vary, ${}_{pq}$ gives a family of planes through . There are three cases to consider.

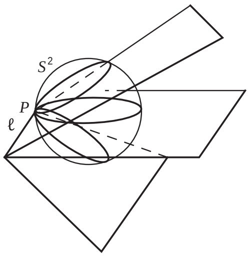
Case 1: The line does not meet S^2.

Here the family of planes cuts out a family of circles in S^2 consisting of two point circles P and Q and a set of disjoint circles in between these.



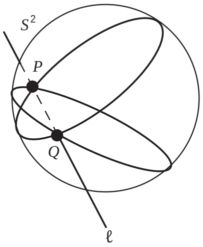
Under stereographic projection from N, the associated circles in the plane form an Apollonian family: a family of coaxal circles with two point circles.

Case 2: The line touches S^2 (at the point P, say).
Here, every plane of the family meets S^2. The plane tangent to the sphere at the point P meets it in a single point, P. All the other planes cut S^2 in a circle. All these circles have a common tangent at P, which is the line .



Under stereographic projection from N, the associated circles in the plane form a family of coaxal circles having a common tangent. If N and P are distinct, the image circles are true circles except for one straight line; if N coincides with P, the images are parallel lines.

Case 3: The line cuts S^2 in two points, say P and Q.
Here, every plane of the family meets S^2. Each plane cuts the sphere in a circle passing through the points P and Q.



Under stereographic projection from N, the associated circles in the plane form a family of coaxal circles with two common points. If N, P and Q are distinct, the image circles are true circles except for one straight line; if N coincides with either P or Q, say P, the images are straight lines passing through the image of Q.

On the other hand, if the associated planes $_1$ and $_2$ are parallel then the family of planes $_{pq}$ consists of the planes parallel to $_1$ and $_2$, and the circles they cut out on the sphere consist of two point circles and a set of disjoint circles in between these.

This is similar to the situation in Case 1 above.

7.5 Planar Maps

We use maps of the Earth on a daily basis: for example. street maps of towns, road maps of countries, geological maps of continents, and for land, sea and air travel. Most of our maps are on flat sheets of paper, rather than globes; and we have to reduce the actual dimensions by a convenient *scale factor*, such as 1:12,000,000 for a continent, 1:100,000 for a map of a large city, or 1:25,000 for a detailed neighbourhood map.

Here, scale factor = length on map divided by length on Earth s surface.

We will assume in this section that the Earth is a sphere. In fact, the shape of the Earth is closer to that of an *oblate spheroid*, a sphere flattened near each pole and with a bulge around the equator. This bulge results from the rotation of the Earth, and causes its equatorial diameter to be over 26 miles (43 km) greater than its pole-to-pole diameter

Now an ideal planar map would represent shapes on the Earth s surface in such a way that relative distances, relative areas, shape, and angles are preserved under the operation of mapping. Unfortunately, no ideal map is possible!

For example, let ABC be a triangle on S^2, and let P, Q, R be the points on the planar map that correspond to A, B, C, respectively. Then the sides of ABC are line segments on S^2, that is, parts of great circles; and the sum of its angles exceeds . The sides of PQR are line segments in the plane, and the sum of its angles is . So we cannot simultaneously have geodesics on S^2

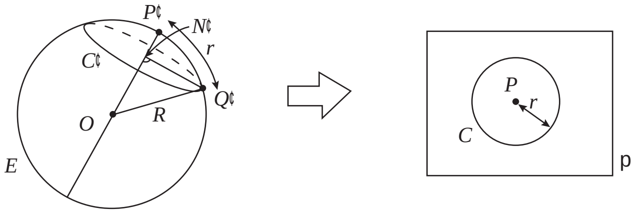
Subsection 7.3.1, Theorem 2

mapping onto geodesics in the plane AND preserve angles. This shows that an ideal planar map cannot exist.

Recall that ‘geodesics’ are curves of shortest length between two points.

Furthermore, Euler showed in 1775 that it is not possible to map a portion of the Earth's surface onto a planar map in such a way that relative distances (that is, distances up to a scaling factor) are preserved.

Leonhard Euler (1707–1783) was a prolific Swiss analyst, who worked for Frederick the Great (Prussia) and Catherine the Great (Russia) even after becoming blind.



To see this, let E denote the surface of the Earth, a sphere with centre O and radius R; and let $P' \in E$ be the centre of a circle C' on E of radius r (we will suppose that $r < \frac{1}{2}\pi R$, so that C' lies in a hemisphere on E with P' as pole). Suppose that some ideal mapping represents the hemisphere onto a flat sheet, Π say, and let P, C on Π represent P', C' on E.

Here r is a distance measured along the surface.

Since the mapping scales all distances by the same scale factor, c say, all points on E at a distance r from P' map to points at a distance cr from P; hence C' is represented on Π by a circle C of radius cr, so that the length of C is $2\pi cr$.

Next, let Q' be any point on C', and N' the foot of the perpendicular from Q' to OP'. Then $\angle P'OQ' = \frac{r}{R}$, so that $Q'N' = R\sin(\angle P'OQ') = R\sin\left(\frac{r}{R}\right)$. But the circle C' is a circle in $\mathbb{R}^3$ with radius $Q'N'$, so that its length is $2\pi R\sin\left(\frac{r}{R}\right)$. Hence its representation C on Π must have length $c \times 2\pi R\sin\left(\frac{r}{R}\right)$.

We deduce from the last two paragraphs that

$$2\pi cr = 2\pi cR\sin\left(\frac{r}{R}\right),$$

so that

$$\frac{r}{R} = \sin\left(\frac{r}{R}\right).$$

This equality is impossible, since $\frac{\sin x}{x} < 1$ for all x with $0 < x < \frac{\pi}{2}$.

This is a standard result in Calculus.

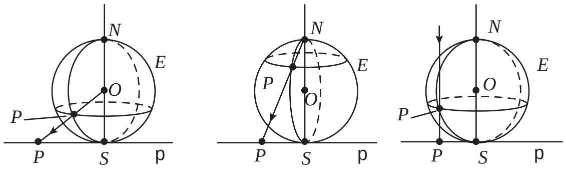
So we have proved that it is not possible to represent a portion of the Earth's surface on a planar map in such a way that relative distances are preserved. It follows from this, too, that no (precisely accurate) planar map of a portion of E can have a fixed scale factor for the whole map.

In fact, there are three principal types of *map projections* for representing the spherical Earth, E, on a flat sheet of paper, Π. In their work, cartographers often use the term *meridians* to denote lines of latitude, and *parallels* to denote lines of longitude: we will follow this convention here.

In addition there are various purely mathematical approaches, for special purposes.

Azimuthal Projections

Azimuthal projections of E onto are ones where we project E onto a sheet that is tangent to E at some point, often the South Pole S. We can think of the projection mapping in the following way: a light source placed at some point (the *centre* of the projection) on the perpendicular to at the point of contact projects each point P on E onto a corresponding point P on . Wherever we place the source, meridians map to radial lines from the point of contact S, parallels to concentric circles with centre S, and directions from the point of contact are preserved.



If the source is placed at the centre of E, the projection is called the *gnomic projection*, and we obtain a map of the lower hemisphere of E. Since any plane through O meets E in a great circle and in a line, each line in comes from a great circle on E. Hence geodesics on E are mapped onto straight lines on .

By making the tangent point N, we could obtain a map of the upper hemisphere.

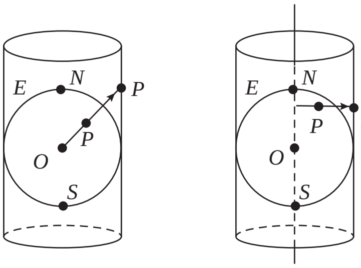
If the light source is placed at the North Pole N of E, we obtain a map of the whole of E $\{N\}$ on . This projection is called the *stereographic projection* of E onto , and is the stereographic projection that you met earlier. It preserves angles, and so is called a *conformal* projection.

Subsection 5.2.4

If the light source is placed at infinity along the direction SON, and we consider only the upper hemisphere or the lower hemisphere of E, then we obtain a map of one hemisphere of E onto that is actually circular. This projection is called the *orthogonal* or *orthographic projection*. It preserves distances along parallels.

Cylindrical projections

Cylindrical projections of E onto are ones where we project E onto a sheet that is rolled in the form of a cylinder round E, touching it at its Equator; then we slit the sheet and flatten it.



In one cylindrical projection, a light source placed at the centre O of E, the *centre* of the projection, projects each point P on E onto a corresponding point P on . Parallels map to horizontal circles that become horizontal lines when we unwrap the sheet, and meridians to vertical lines. The equator is mapped to itself, and areas near the North and South Poles become greatly enlarged.

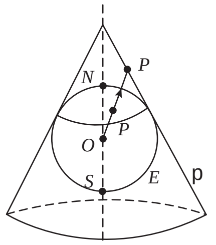
Another cylindrical projection projects each point P on E horizontally onto the nearest point P on . Again, parallels map to horizontal circles that become horizontal lines when we unwrap the sheet, and meridians to vertical lines. This projection preserves the relative sizes of areas, so it is called an *equal area projection*.

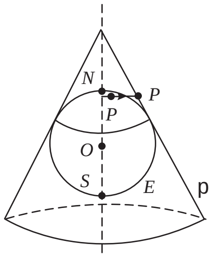
The well-known *Mercator projection* is a cylindrical map where the parallels are horizontal and the meridians vertical, but the spacing of the parallels is chose cunningly so that *paths of constant compass bearing* (that is, paths making the same angle with every meridian they cross) are shown as straight lines. This projection is invaluable in navigation, since sailors and aircrew using it do not need to constantly change the compass bearing of the course they follow.

Gerardus Mercator (Latinized form of Gerard Kremer) (1512 1594) was a Flemish map maker who devised this projection in 1569, and introduced the term atlas .

Conical projections

Conical projections of E onto are ones where we project E onto a sheet that is rolled in the form of a cone round E, touching it at some parallel; then we slit the sheet along a meridian and flatten it, taking on the shape of a sector of a circle.





We may, for example, project each point P on E to the corresponding point P on radially out from the centre of E, or horizontally out from the axis of the cone to the nearest point on . Parallels map to arcs of circles whose centres are at the vertex V of the flattened cone, and meridians to straight lines radially out from V. Conic projections are particularly useful for mapping large areas in the mid-latitudes that are wide from east to west (such as Canada).

There are many variations of these fundamental types, all designed for special purposes; but a full discussion is beyond the scope of this book. Map-making is a fascinating subject!

You should look at a good Atlas now to see the various types of projections that it uses.

7.6 Exercises

Section 7.1

1. (a) Determine the equation of the great circle on S^2 that passes through the points $\frac{1}{6}, \quad \frac{1}{6}, \frac{2}{6}$ and $\frac{1}{6}, \frac{2}{6}, \frac{1}{6}$.
   (b) Determine the equation of the little circle on S^2 that passes through the points $\frac{1}{6}, \frac{1}{6}, \frac{2}{6}$, $(0, 0, 1)$ and $\frac{1}{6}, \frac{2}{6}, \frac{1}{6}$.
2. Determine the spherical polar representation of the point $\frac{3}{2\ 2}, \quad \frac{3}{2\ 2}, \quad \frac{1}{2}$ on S^2. Hence state the latitude, colatitude, and longitude of this point.
3. Determine the coordinates on S^2 of San Francisco (38 N, 123 W) and Brisbane (27 S, 153 E).

Section 7.2

1. Determine the images of the point $\frac{3}{5\ 2}, \frac{4}{5\ 2}, \quad \frac{1}{2}$ under the mappings $R(X, \frac{}{3})$, $R(Y, \frac{3}{4})$ and $R(Z, \frac{5}{4})$.
2. Determine the matrix **A** of a rotation $\mathbf{x} \quad \mathbf{Ax}$ of S^2 that maps $\frac{3}{5\ 2}, \frac{4}{5\ 2}, \quad \frac{1}{2}$ to $\frac{4}{5\ 2}, \quad \frac{3}{5\ 2}, \frac{1}{2}$. Verify your answer by direct calculation.
3. (a) Determine the matrix **A** such that the mapping $r : \mathbf{x} \quad \mathbf{Ax}$ represents reflection of S^2 in the plane with equation $x \quad 2y + z = 0$.
   (b) Hence determine the image under r of the point $P \quad \frac{1}{14}, \quad \frac{2}{14}, \frac{3}{14}$.
   (c) Prove that the midpoint of P and $r(P)$ lies in the plane .
4. Let a triangle PQR on S^2 have sides PQ of length r, QR of length p, and RP of length q, and angles , and at the vertices P, Q and R, respectively; let = . Prove that $p = q$.
5. Express the rotation $R(X, \frac{}{4})$ of S^2 as the composition of two reflections of S^2 in great circles.

This is the converse of Theorem 6 of Subsection 7.2.2.

Section 7.3

1. Construct the following figures on S^2:
   (a) a spherical triangle of area $(2 \quad 0.1)$;
   (b) a lune of area $/3$.
2. An equilateral strict spherical triangle has area $\frac{}{12}$. Determine:
   (a) the magnitudes of its angles;
   (b) the lengths of its sides;
   (c) the area of a dual triangle.
3. Estimate the distance between Beijing (40 N, 117 E) and Lima (12 S, 77 W), taking the radius of the Earth as 4000 miles.
4. Let ABC be a triangle on S^2 in which the angle at C is a right angle. If a, b and c denote the lengths of BC, CA and AB, and and denote the angles CAB and CBA, prove that:

(a) $\cos c = \cot \quad \times \cot \quad ;$
(b) $\cos \quad = \tan a \times \cot c = \cos b \times \sin \quad ;$
(c) $\sin a = \tan b \times \cot \quad = \sin \quad \times \sin c$.

5. Let the spherical triangle ABC have sides AB, BC and CA of lengths 1, 0.6 and 1.3, respectively. Estimate the length of the perpendicular from B to CA.
6. Let the figure $ABCD$ on S^2 be a strict spherical square that is, have four sides of the same length r and four angles of the same magnitude . Determine r in terms of .
7. Prove that the distance d on S^2 between the points with spherical polar coordinates $(\cos{}_1 \sin{}_1, \sin{}_1 \sin{}_1, \cos{}_1)$ and $(\cos{}_2 \sin{}_2, \sin{}_2 \sin{}_2, \cos{}_2)$ is given by.

$$\cos d = \sin{}_1 \sin{}_2 \cos({}_1 \quad {}_2) + \cos{}_1 \cos{}_2.$$

A strict spherical square is one whose whole can be seen at one time after a suitable rotation of S^2.

Sometimes this formula can save you a bit of arithmetic.

Section 7.4

1. Let P and Q be the points $\frac{1}{2}, \frac{1}{2}$ and $\frac{1}{4}, \frac{1}{4}$ in R^2, and P and Q be the corresponding points on S^2 under the mapping ^{1}. Use Theorem 1 of Subsection 7.4.1 to determine the spherical distance $P\ Q$.
2. Determine the Möbius transformation that is conjugate to the rotation $R\ \ _{Y, \frac{}{4}}$ of S^2.
3. (a) Prove that a Möbius transformation that maps 0 to and to 0 is of the form $z \quad \frac{K}{z}$, for some non-zero complex number K.
   (b) Prove that a Möbius transformation M that maps a to b and b to a (where $a = b$) maps the family A of Apollonian circles defined by the point circles a and b to itself, and maps exactly one circle in A to itself.

Summary of Chapter 7

Introduction

The (Elliptic) Parallel Postulate Given any line and a point P not on , all lines through P meet . (That is, there are no lines through P that are parallel to .)

Section 7.1: Spherical Space

1. The **unit sphere** in R^3 is $S^2 = \ (x, y, z) : x^2 + y^2 + z^2 = 1\ $. Each point (x, y, z) on S^2 has an **antipodal point** $(\ x, \ y, \ z)$. The **North Pole** of S^2 is $N(0, 0, 1)$, and the **South Pole** is $S(0, 0, \ 1)$. The **equator** is the intersection of S^2 with the horizontal plane through the origin.
2. A **great circle** is the circle cut out on S^2 by a plane through the centre of S^2.

A **circle of longitude** is a great circle through N. The **Greenwich Meridian** is the part of the circle of longitude through $A(1,0,0)$ which has positive x-coordinates.

A **circle of latitude** is the curve of intersection of S^2 with a plane parallel to the equator. A **little circle** is the curve of intersection of S^2 with a plane that is not a great circle.

3. A **line** on S^2 joining two points P and Q, or a **line** PQ, is either arc with endpoints P and Q of a great circle through P and Q.
4. The **length** of a line on S^2 is the Euclidean length of the corresponding circular arc; the **distance** (or **spherical distance**) between two points P and Q on S^2 is the length of the shorter of the two lines PQ, and is often denoted simply as PQ.

   For any three points P, Q and R on S^2 that do not lie on a single great circle, the lines PQ, QR and RP form a **triangle** PQR.
5. Great circles are **geodesics** on S^2; that is, curves of shortest distance between points.
6. The distance between any two points P and Q on S^2 is equal to the angle that they subtend at the centre of S^2. There is always a great circle joining any two points on S^2.

   Spherical distance possesses all the natural properties that a distance function should possess.
7. Any two lines on S^2 meet in two points.
8. Corresponding to each point P on S^2 the **great circle associated with *P*** is the great circle of points 2 distant from P. Conversely, for each great circle there are two points of S^2 which play the role of its poles .
9. For any two points P and Q on S^2, there is a rotation of S^2 that maps P to Q.
10. Each point P on S^2 has **spherical polar coordinates** $(\cos \ \sin \ , \sin \ \sin \ , \cos \ )$, where $0 \quad < 2$ and 0 .

    The **colatitude** of P is the angle ; the **latitude** of P is $= \frac{}{2}$. The **longitude** of P is the angle .

    The distance of P from the North Pole is its colatitude .
11. A **circle** on S^2 is the set of points on S^2 that are equidistant from a given point of S^2; it is either a little circle or a great circle.

Section 7.2: Sperical transformations

1. An **isometry** of S^2 is a mapping of S^2 to itself that preserves distances between points. The isometries of S^2 form a group, the **group of spherical isometries**, denoted by the symbol $S(2)$.

   A direct isometry of S^2 preserves the orientation of angles on S^2; an **indirect isometry** of S^2 reverses them. Reflection of S^2 in a plane through the centre of S^2 is an **indirect isometry** of S^2.
2. The three elementary rotations of S^2 are its rotations about the coordinate axes.

The transformation

$$\begin{matrix} R(Z,\ ): & S^2 & S^2 \\ & \mathbf{x} & \mathbf{Ax} \end{matrix}$$

where $\mathbf{x} = \begin{matrix} x \\ y \\ z \end{matrix}$ and $\mathbf{A} = \begin{matrix} \cos & \sin & 0 \\ \sin & \cos & 0 \\ 0 & 0 & 1 \end{matrix}$ is a rotation of S^2 about the positive z-axis through an angle .

The transformation

$$\begin{matrix} R(X,\ ): & S^2 & S^2 \\ & \mathbf{x} & \mathbf{Ax} \end{matrix}$$

where $\mathbf{x} = \begin{matrix} x \\ y \\ z \end{matrix}$ and $\mathbf{A} = \begin{matrix} 1 & 0 & 0 \\ 0 & \cos & \sin \\ 0 & \sin & \cos \end{matrix}$ is a rotation of S^2 about the positive x-axis through an angle .

The transformation

$$\begin{matrix} R(Y,\ ): & S^2 & S^2 \\ & \mathbf{x} & \mathbf{Ax} \end{matrix}$$

where $\mathbf{x} = \begin{matrix} x \\ y \\ z \end{matrix}$ and $\mathbf{A} = \begin{matrix} \cos & 0 & \sin \\ 0 & 1 & 0 \\ \sin & 0 & \cos \end{matrix}$ is a rotation of S^2 about the positive y-axis through an angle .

3. The **inverse of an elementary rotation** through a given angle is an elementary rotation through the same angle but in the opposite direction. Its matrix is the transpose of the matrix of the original elementary rotation.
4. A rotation of S^2 that maps $A(1,0,0)$ to $P(\cos\ \ \sin\ ,\sin\ \ \sin\ ,\cos\ )$ is given by the composition $R(Z,\ )\,R\ \ Y,\ $, where $=\frac{\ }{2}$.
5. The **equatorial plane** of S^2 is the plane $z = 0$ that contains the equator of S^2. **Reflection in the equatorial plane** of S^2 is the mapping $\mathbf{x}\quad \mathbf{Ax}$ that sends the point $\mathbf{x} = (x,y,z)$ to the point $(x,y,\ z)$; it has matrix $\mathbf{A} = \begin{matrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{matrix}$.
6. Reflection of S^2 in the plane with equation $ax + by + cz = 0$, where $a^2 + b^2 + c^2 = 1$, is given by the mapping $\mathbf{x}\quad \mathbf{Ax}$ where $\mathbf{A} = \begin{matrix} 1\ \ 2a^2 & 2ab & 2ac \\ 2ab & 1\ \ 2b^2 & 2bc \\ 2ac & 2bc & 1\ \ 2c^2 \end{matrix}$.
7. The product of any two reflections of $\mathbb{R}^3$ in planes through O that meet in a common line is a rotation about that common line.
8. Every rotation is a product of two reflections; these reflections are in planes that have the axis of rotation as their common line, and are separated by half the angle of the rotation.
9. The image of a circle on S^2 under an isometry of S^2 to itself is a circle.
10. **The Product Theorem** Every isometry of S^2 is a product of at most three reflections in great circles.

    An isometry of S^2 is known completely when its effect on three points (which do not lie on a common great circle) is known.

11. **Isosceles Triangle Theorem** Let a triangle PQR on S^2 have sides PQ of length r, QR of length p, and RP of length q, and let $p = q$. Also, let the angles at the vertices P, Q and R be , and , respectively. Then = .
12. Every isometry of S^2 is a reflection, a rotation, or the composite of a reflection and a rotation.

    Every direct isometry of S^2 is a rotation, and vice versa.

Section 7.3: Spherical Trigonometry

1. Given any three angles , and with (5 >) + + > , there exists a spherical triangle with those angles.
2. The sum of the angles of any spherical triangle is greater than . The **angular excess** of a spherical triangle is the difference between the sum of the angles of the triangle and .
3. The **strict line segment** PQ is the shorter of the two line segments PQ. (If both are of length , we choose either in some explicit way.)

    The **strict triangle** PQR is that triangle PQR whose sides are strict line segments, and its inside is the region of S^2 that they bound; we can rotate S^2 so that the whole of the strict triangle can be seen at one time.
4. A **lune** is a 2-sided polygon bounded by two great circles
5. The area of a spherical triangle is equal to its angular excess.
6. **Dual Triangles Theorem** With every strict spherical triangle there is associated another triangle , called its *dual*, whose angles are the complements of the sides of and whose sides are the complements of the angles of . (The complement of a quantity x is the quantity x.)
7. The distance d on S^2 between the points (p_1, p_2, p_3) and (q_1, q_2, q_3) is given by $\cos d = p_1q_1 + p_2q_2 + p_3q_3$. The distance between corresponding points on the surface of the Earth is then given (in miles) by the scaling map **x** 4000**x**.
8. **Pythagoras' Theorem** Let ABC be a triangle on S^2 in which the angle at C is a right angle. If a, b and c are the lengths of BC, CA and AB, then $\cos c = \cos a \times \cos b$.

    Also $\sin \ = \sin a \ \ \sin c$ and $\tan \ = \tan a \ \ \sin b$.
9. We can always drop a perpendicular from a point on S^2 to a line on S^2.
10. Let ABC be a **strict triangle** on S^2, in which the sides AB, BC and CA have lengths c, a and b, respectively, and the angles at A, B and C are , and , respectively. Then

    Sine Rule $\frac{\sin}{\sin a} = \frac{\sin}{\sin b} = \frac{\sin}{\sin c}$;

    Cosine Rule for Sides $\cos c = \cos a \cos b + \sin a \sin b \cos$;

    Cosine Rule for Angles $\cos \ = \sin \ \sin \ \cos c \ \ \cos \ \cos$.

Section 7.4: Spherical Geometry and the Extended Complex Plane

1. The image of the point P (cos sin %sin sin , cos)% under stereographic projection has coordinates cos tan $\frac{1}{2}$, sin tan $\frac{1}{2}$.

2. Let a point P on S^2 map under stereographic projection to a point P in $\mathbb{R}^2$ with coordinates $(r\cos\ , r\sin\ )$. Then the spherical distance of P from the South Pole S is $2\tan\ ^{1}(r)$.
3. Let P and Q be points on S^2 that are mirror images under reflection in a great circle C , and let the images of P , Q and C under stereographic projection be P, Q and C, respectively. Then P and Q are inverse points with respect to C.
4. Let R denote a rotation of S^2, and stereographic projection. Then the transformation $R\ ^{1}$ of the extended plane is the **conjugate transformation** of the rotation R.

   The conjugate transformation of a rotation of S^2 is a Möbius transformation of the extended plane.
5. A Möbius transformation M that is conjugate to a rotation of S^2 is of the form $M(z) = (az+b) \quad \bar{b}z + \bar{a}$, where $a, b \quad \mathbb{C}$.

   A Möbius transformation can have at most two fixed points.
6. The circle in $\mathbb{R}^2$ with equation $x^2 + y^2 + 2\ x + 2\ y + \ = 0$ and the plane with equation $2\ X + 2\ Y + (1\ )Z + (1 + \ ) = 0$ are said to be **associated**.

Section 7.5: Planar Maps

1. It is not possible to map a portion of the Earth s surface onto a planar map in such a way that relative distances are preserved. There is no ideal planar map.
2. **Azimuthal projections** of the Earth E onto a flat sheet of paper are ones where we project E onto placed tangent to E at some point, often the South Pole S.

   The **gnomic projection** uses the centre of E as the centre of projection, stereographic projection uses the North Pole of E as the centre of projection, and *orthogonal* or *orthographic projection* uses rays from infinity parallel to the polar axis.
3. **Cylindrical projections** of E onto are ones where we project E onto a sheet that is rolled in the form of a cylinder round E, touching it at its Equator; then we slit the sheet along a meridian and flatten it.
4. **Conical projections** of E onto are ones where we project E onto a sheet that is rolled in the form of a cone round E, touching it at some parallel; then we slit the sheet along a meridian and flatten it, taking on the shape of a sector of a circle.

8 The Kleinian View of Geometry

We now describe in detail what we have called the Kleinian view of geometry. As we said earlier, this is a powerful way in which the geometries we have presented can be unified and seen as different aspects of the same idea.

Chapter 0

8.1 Affine Geometry

Klein argued that in any geometry there are properties of figures that one discusses, but these properties vary from one geometry to another. In Euclidean geometry, segments have lengths, lines cross at angles one can measure; it makes sense to ask if a given triangle is equilateral, and so on. But none of these properties makes sense in affine geometry. There one may speak only of ratios of lengths along parallel lines, and all triangles are (affine) congruent. Klein interpreted this as follows: in each geometry we are studying the same space of points, the familiar plane $\mathbb{R}^2$. In Euclidean geometry we admit only the transformations that preserve length. These are transformations of the form

$$t(\mathbf{x}) = \mathbf{U}\mathbf{x} + \mathbf{a},$$

where $\mathbf{U}$ is an orthogonal 2×2 matrix and $\mathbf{a} \in \mathbb{R}^2$.

Because every transformation in Euclidean geometry preserves lengths, and therefore angles, it makes sense to speak of distance in this geometry.

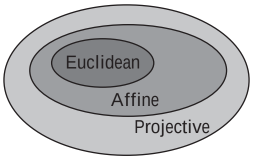
In affine geometry, however, we admit all transformations of the form

$$t(\mathbf{x}) = \mathbf{A}\mathbf{x} + \mathbf{b},$$

where $\mathbf{A}$ is an invertible 2×2 matrix and $\mathbf{b} \in \mathbb{R}^2$. Because every transformation in affine geometry preserves ratios of lengths along parallel lines, it makes sense to speak of such ratios in this geometry. But because there are affine transformations that do not preserve length, it does not make sense to speak of distance in this geometry.

Klein observed that rather more is true. In both geometries, the allowable transformations form a group. This was a novel observation at the time, for Group Theory as such was only just being discovered. Moreover, the group of Euclidean transformations is a subgroup of the group of affine transformations.

This observation enabled Klein to unify the two geometries. He said that both geometries concern the same space $\mathbb{R}^2$, that each geometry involves a group of transformations which act on this space, and that the Euclidean group is a subgroup of the affine group. In this sense Euclidean geometry is a *subgeometry* of affine geometry.

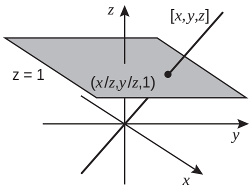


The hard work comes with the remaining geometries. How can affine geometry and projective geometry be unified? Projective geometry is not about the plane $\mathbb{R}^2$ but about projective space $\mathbb{RP}^2$. Its transformations are written as 3×3 homogeneous matrices, not as 2×2 matrices. To accomplish the unification, we must first establish that the space $\mathbb{R}^2$ can be regarded as a subset of $\mathbb{RP}^2$.

Here, *homogeneous* means that the matrix can be multiplied by any non-zero real number without affecting the transformation.

To do this, we consider the subset of Points in $\mathbb{RP}^2$ that pierce the standard embedding plane $z = 1$. We shall temporarily denote this subset by $\mathbb{RP}^2_0$, so that

$$\mathbb{RP}^2_0 = \{[x, y, z] : z = 0\}.$$



Now each point (x, y) in $\mathbb{R}^2$ can be identified with the Point $[x, y, 1]$ in $\mathbb{RP}^2_0$; and, conversely, each Point $[x, y, z] = [x/z, y/z, 1]$ in $\mathbb{RP}^2_0$ can be identified with the point $(x/z, y/z)$ in $\mathbb{R}^2$. This provides us with a one–one correspondence between $\mathbb{R}^2$ and $\mathbb{RP}^2_0$ which enables us to regard $\mathbb{R}^2$ as a subset of $\mathbb{RP}^2$.

Next (following Klein) we prove a result which shows that the affine group can be considered as a subgroup of the projective group.

Theorem 1 The group of affine transformations can be identified with the subgroup of projective transformations that map $\mathbb{RP}^2_0$ onto itself.

Proof A projective transformation which maps $\mathbb{RP}^2_0$ onto itself is also one that maps the ideal Line $z = 0$ onto itself. It is therefore sufficient to characterize the projective transformations which map ideal Points to ideal Points.

It is clear that the set of projective transformations which map the Line $z = 0$ onto itself is a group. For, if t is a transformation which maps ideal Points to ideal Points, then so is its inverse t^{-1}; and, if t and s are projective transformations which map ideal Points to ideal Points, then so is $t \circ s$. We denote this group by $P_0(2)$.

Recall that the group of all projective transformations is denoted by $P(2)$.

Let $\mathbf{A} = \begin{pmatrix} a & b & c \\ d & e & f \\ g & h & k \end{pmatrix}$ be a matrix associated with a projective transformation t. Then t maps ideal Points to ideal Points if and only if

$$\begin{pmatrix} a & b & c \\ d & e & f \\ g & h & k \end{pmatrix} \begin{pmatrix} x \\ y \\ 0 \end{pmatrix} = \begin{pmatrix} ? \\ ? \\ 0 \end{pmatrix},$$

where we do not care what numbers the ? s stand for, so long as they are not both zero. It follows that t maps ideal Points to ideal Points if and only if

$$gx + hy + 0 = 0.$$

This must hold for all $x = 0$ and all $y = 0$, so $g = h = 0$. Since $\mathbf{A}$ is invertible, it follows that $\det \mathbf{A} = k(ae \quad db) = 0$, so $k = 0$ and $(ae \quad db) = 0$. Moreover, since the matrices associated with a projective transformation are determined only up to a non-zero real multiple, we can divide $\mathbf{A}$ by k. If we then rewrite a/k as a, b/k as b, and so on, we see that the transformations in $P_0(2)$ are precisely those projective transformations which have an associated matrix of the form

$$\begin{matrix} a & b & c \\ d & e & f \\ 0 & 0 & 1 \end{matrix}\ , \quad \text{where } ae \quad db = 0.$$

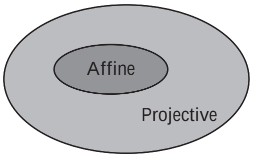
Let us now consider the effect that such a transformation has on Points in $\mathbb{RP}^2_0$. If $^{\#}\ x\ , y\ , 1\ ^{\$}$ is the image of $[x, y, 1]$ under the transformation, then

$$\begin{matrix} x \\ y \\ 1 \end{matrix} = \begin{matrix} a & b & c \\ d & e & f \\ 0 & 0 & 1 \end{matrix} \quad \begin{matrix} x \\ y \\ 1 \end{matrix} = \begin{matrix} ax + by + c \\ dx + ey + f \\ 1 \end{matrix} .$$

This equation provides us with a relationship between x, y and $x\ , y$ which we can rewrite in the form

$$\begin{matrix} x \\ y \end{matrix} = \begin{matrix} a & b \\ d & e \end{matrix} \quad \begin{matrix} x \\ y \end{matrix} + \begin{matrix} c \\ f \end{matrix} .$$

Since $ae \quad db = 0$ it follows that we can map the point (x, y) associated with the Point $[x, y, 1]$ to the point $(x\ , y\ )$ associated with the Point $[x\ , y\ , 1]$ by an affine transformation. We conclude that the group $P_0(2)$ may be identified with the affine group $A(2)$.



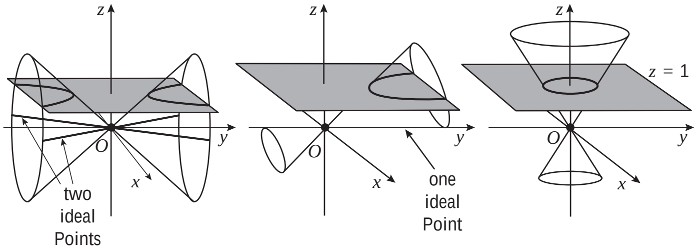
It follows that the space $\mathbb{R}^2$ of affine geometry can be considered as a subset of projective space $\mathbb{RP}^2$, and that the group $A(2)$ of affine geometry can be considered as a subgroup of the projective group $P(2)$. In other words, affine geometry is a *subgeometry* of projective geometry.

It is important to realize that in the process of extracting affine space from projective space we lose all the ideal Points on the ideal Line, and that this omission can have a significant effect on figures. For example, in projective geometry any two Lines meet at a Point. But if the Point of intersection is an ideal Point, then the corresponding affine figure consists of two lines that do not meet. This gives rise to the affine concept of parallel lines, which is meaningless in projective geometry. The fact that parallelism is an affine property can be checked easily by recalling that an affine transformation corresponds to a projective transformation which maps ideal Points to ideal Points. Under such a transformation, Lines which intersect at an ideal Point map to Lines which intersect at an ideal Point. This is an alternative proof of the following theorem that we first proved in Chapter 2.

Theorem 2 An affine transformation maps parallel straight lines to parallel straight lines.

Subsection 2.3.3, Theorem 3

Parallelism is not the only new property to arise from the omission of ideal Points. In affine geometry, three distinct types of (non-degenerate) conic arise because there are three ways in which a projective conic can meet the ideal Line. In the first figure below, the projective conic and the Line cross at two Points; the corresponding picture in $\mathbb{R}^2$ is that of a hyperbola. In the second figure, the projective conic and the Line touch at one Point; the corresponding picture in $\mathbb{R}^2$ is that of a parabola. In the third figure, the projective conic and the Line do not meet at any Point; the corresponding picture in $\mathbb{R}^2$ is that of an ellipse.



So hyperbolas, parabolas and ellipses are plane conics which correspond to projective conics with two, one and no ideal Points missing, respectively. Since affine transformations correspond to projective transformations which map ideal Points to ideal Points, they cannot change the number of ideal Points on a projective conic, and hence cannot change the type of the plane conic. This is an alternative proof of the following theorem first proved in Chapter 2.

Subsection 2.5.1, Theorem 4

Theorem 3 Affine transformations map ellipses to ellipses, parabolas to parabolas, and hyperbolas to hyperbolas.

So far, we have discussed some affine properties that do not make sense in projective geometry. By contrast, any property in projective geometry must also be a property in affine geometry. Indeed, *any property that is preserved by the group of all projective transformations must also be preserved by the subgroup of all affine transformations*.

For example, tangency is a property of projective conics, so every projective transformation maps tangents to tangents. In particular, a projective transformation which corresponds to an affine transformation must map a tangent whose Point of contact is not an ideal Point to a tangent whose Point of contact is not an ideal Point. Interpreting this observation as an affine result, we obtain the following theorem which we first met in Chapter 2.

Theorem 4 Let t be an affine transformation, and let be a tangent to a conic C. Then $t(\ )$ is a tangent to the conic $t(C)$.

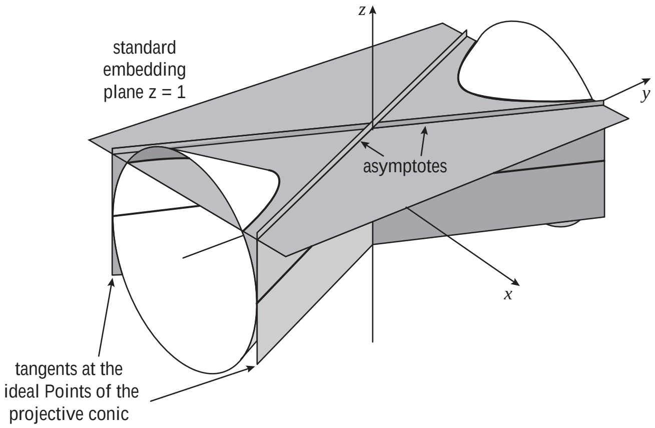
Subsection 2.5.1, Theorem 7

Notice that in this proof of the theorem we did not have to consider tangents whose Point of contact is an ideal Point. But to what does such a tangent correspond in R^2? The answer depends on how many ideal Points lie on the projective conic.

A projective conic which passes through one ideal Point corresponds to a parabola in R^2. Since such a projective conic meets the ideal Line at precisely one Point, the tangent at that Point must be the ideal Line $z = 0$. This tangent does not correspond to anything in R^2!

Recall that a Line is a *tangent* to a projective conic if it meets the conic at precisely one Point.

More interesting are those projective conics which pass through two ideal Points. Such a projective conic corresponds to a hyperbola in R^2. The tangents which touch the projective conic at its two ideal Points correspond to lines in R^2, and these lines are defined to be the asymptotes of the hyperbola.



z
standard embedding plane z = 1
y
asymptotes
x
tangents at the ideal Points of the projective conic

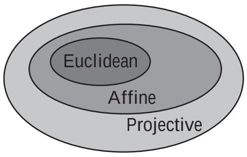
Since affine transformations correspond to those projective transformations which map ideal Points to ideal Points, it follows that tangents at ideal Points map to tangents at ideal Points, and hence that asymptotes map to asymptotes. This proves the following theorem which you met in Chapter 2.

Subsection 2.5.1, Theorem 6

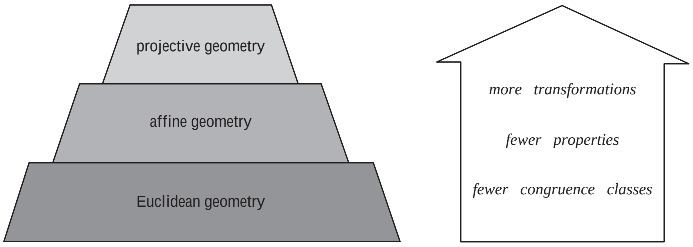
Theorem 5 Let t be an affine transformation, and let H be a hyperbola with asymptotes $\ _1$ and $\ _2$. Then $t(H)$ has asymptotes $t(\ _1)$ and $t(\ _2)$.

We now summarize what we have done so far.

Geometry	Space	Transformations	Invariants
Projective	$\mathbb{R}P^2 = \mathbb{R}^2$ + ideal Line	$t : [\mathbf{x}] \quad [\mathbf{Ax}]$, where $\mathbf{A}$ is a 3×3 invertible matrix	incidence, collinearity, cross-ratio
Affine	$\mathbb{R}^2$	$t : \mathbf{x} \quad \mathbf{Ax} + \mathbf{b}$, where $\mathbf{A}$ is a 2×2 invertible matrix	ratios along parallel lines
Euclidean	$\mathbb{R}^2$	$t : \mathbf{x} \quad \mathbf{Ux} + \mathbf{a}$, where $\mathbf{U}$ is a 2×2 orthogonal matrix	length, angle



We can think of the geometries in this table as forming a hierarchy of geometries with projective geometry at the top. Any property of a geometry in the hierarchy is also a property of the geometries further down the hierarchy. Also, theorems that are valid in one geometry in the hierarchy also hold in geometries further down.



As we move up the hierarchy, the group of transformations becomes larger and so the congruence classes of figures merge together as more and more figures become congruent to each other. In Euclidean geometry, two triangles are congruent if and only if they have the same side lengths, and two conics are congruent if and only if they are of the same type (hyperbola, parabola or ellipse) and have the same shape and size. In affine geometry, any two triangles are congruent, and conics are congruent if and only if they are of the same type. In projective geometry, any two triangles are congruent and any two projective conics are congruent.

8.2 Projective Reflections

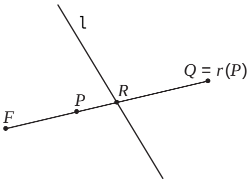
The cross-ratio enables us to introduce a type of projective transformation that generalizes reflection in Euclidean geometry.

Definitions Let F be a Point that does not lie on a Line . Then a **projective reflection** in with **centre** F and non-zero **parameter** k is a mapping

$$\begin{aligned} r : \mathbb{RP}^2 &\to \mathbb{RP}^2 \\ P &\mapsto Q \end{aligned}$$

where

(a) $Q = P$, if P lies on ℓ;
(b) the cross-ratio $(FRPQ) = k$, where R is the Point of intersection of FP and ℓ.



Remark

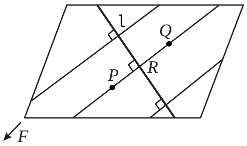
Provided that P does not lie on ℓ, then by varying the parameter k we can arrange that the Point Q is any Point on the Line FP other than the Points F, R and P.

We now indicate why this map is called a projective reflection.

Let ℓ' be the representation of a Line ℓ in an embedding plane π, and consider all the lines in π that are perpendicular to ℓ'. Since these lines are parallel, they must correspond to Lines in $\mathbb{RP}^2$ which meet at an ideal Point, F say. Let r denote the projective reflection in ℓ with centre F and parameter $k = -1$. Then, in the embedding plane π the effect of r is to map each (non-ideal) point P' to its Euclidean reflection in ℓ'.

r fixes the Points of ℓ so that its effect in π is to fix the points of ℓ'.

Next consider a Point P that does not lie on ℓ, and let $Q = r(P)$. Then PQ passes through F and meets ℓ at the Point R, where $(FRPQ) = -1$. For the embedding plane π, F is an ideal Point, so that

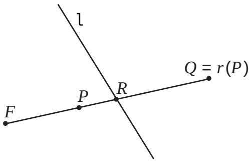


$$(FRPQ) = \frac{Q'R'}{P'R'} = -1$$

(where R', P' and Q' are the representations of R, P and Q in π). The point R' is therefore the midpoint of $P'Q'$. Moreover, since PQ passes through F, $P'Q'$ must be perpendicular to ℓ', so Q' is the Euclidean reflection of P' in ℓ', as suggested.

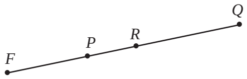
We now relate projective reflections to projective transformations.

Theorem 1 A projective reflection is a projective transformation.



Proof Consider the projective reflection r in the Line ℓ with centre F and parameter k, and let $Q = r(P)$ where P is a Point of $\mathbb{RP}^2$ that does not belong to $\ell \cup \{F\}$. Then $(FRPQ) = k$, where R is the Point of intersection of PQ and ℓ.

By the Fundamental Theorem of Projective Geometry there is a projective transformation t which maps F to $F' = [0, 0, 1]$ and which maps the Line ℓ to the Line with equation $z = 0$. (This can be achieved by mapping a pair of Points on to $[1, 0, 0]$ and $[0, 1, 0]$.) If $P = t(P)$, $Q = t(Q)$ and $R = t(R)$, then, since t preserves cross-ratio, it follows that $(F\,R\,P\,Q\,) = (FRPQ) = k$.



Now, if $P = [a, b, c]$, then the Line through P and F has equation $bx = ay$, and so it meets the Line $z = 0$ at $R = [a, b, 0]$. As Q also lies on the Line $bx = ay$, we can write $Q = [a, b, d]$, for some d; here $d = 0$, since Q does not lie on .

Since

$$(a, b, c) = 1 \bullet (a, b, 0) + c \bullet (0, 0, 1)$$

and

$$(a, b, d) = 1 \bullet (a, b, 0) + d \bullet (0, 0, 1),$$

if follows that $k = (F\,R\,P\,Q\,) = c/d$, so that $d = c/k$. Hence the mapping $s : \mathbb{RP}^2 \quad \mathbb{RP}^2$ which sends P to Q is the projective transformation defined by

$$s([a, b, c]) = [a, b, c/k].$$

Also, s fixes the Points of $\{F\,\}$. Thus the transformation r which maps P to Q must be equal to the composite $t^{\ 1} \quad s \quad t$ and so must be a projective transformation, as required.

Remarks

1. If the parameter $k = 1$, then s and hence $r = t \quad s \quad t^{\ 1}$ are the identity map.
2. If $k = 1$, then the only Points fixed by r are F and the Points of ; for, if
$$s([a, b, c]) = [a, b, c/k] = [a, b, c],$$
then either $c = 0$ (in which case $[a, b, c]$ lies on) or $a = b = 0$ (in which case $[a, b, c] = F\,$).
3. If $k = 0$, then s, and hence r, is not a projective transformation.

We showed earlier that every projective transformation can be expressed as a composite of perspectivity transformations. In fact, a similar result holds for projective reflections.

Theorem 4, Subsection 3.3.4

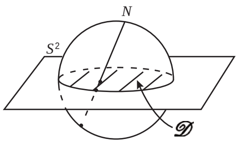
Theorem 2 Every projective transformation can be expressed as a composite of a finite number of projective reflections.

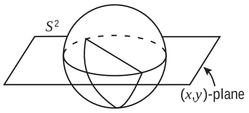
We omit a proof, since we shall not use this result.

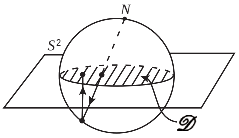
8.3 Hyperbolic Geometry and Projective Geometry

First we introduce a new way of representing lines in hyperbolic geometry that will be useful in explaining how hyperbolic geometry is related to projective geometry. In this representation lines appear straight, but angles are no longer represented accurately. The realization that this could be done was one of the crucial discoveries made by Klein around the time he was preparing his Erlangen Program.

To obtain the new representation we use two mappings, stereographic projection and orthogonal projection. Stereographic projection from the North Pole of S^2 maps the Southern hemisphere onto the interior of the unit disc $\mathbb{D}$, and the equator to the boundary of $\mathbb{D}$. Its inverse therefore maps $\mathbb{D}$ onto the Southern hemisphere. It is an angle-preserving map, so it sends an arc of a generalized circle in $\mathbb{D}$, which is perpendicular to the equator, to an arc of a circle on the sphere perpendicular to the equator such an image may be thought of as a circular arc hanging vertically downwards.



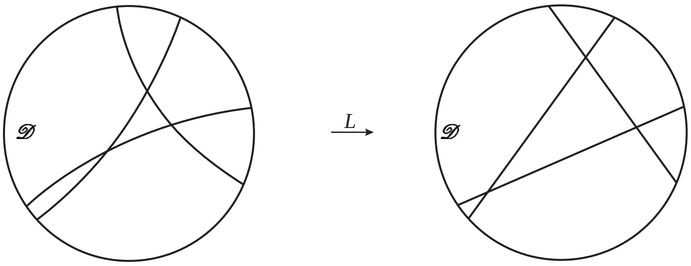




Orthogonal projection maps each point (x, y, z) in $\mathbb{R}^3$ along a line parallel to the z-axis to the point $(x, y, 0)$ in the (x, y)-plane. It maps the Southern hemisphere and the equator back onto $\mathbb{D}$. It maps a circular arc on the sphere perpendicular to the equator onto a segment of a straight line.

Definition The **linearization map** L of the unit disc $\mathbb{D}$ onto itself consists of the inverse of the stereographic projection map followed by the orthogonal projection map.

Then L fixes every point of the boundary of the unit disc $\mathbb{D}$, and maps arcs of generalized circles perpendicular to the boundary of $\mathbb{D}$ to segments of straight lines.



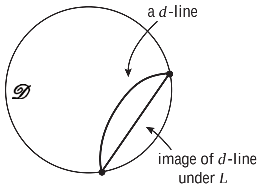
Three hyperbolic lines in the Poincaré model

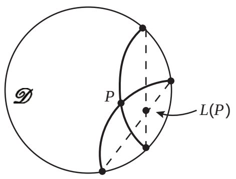
Their images under L

The linearization map transforms the Poincaré model of hyperbolic geometry into a new model of hyperbolic geometry in which d-lines are represented by straight line segments. We call this new model of hyperbolic geometry the *Beltrami Klein model*, after the Italian mathematician Eugenio Beltrami (1833 1900) who discovered it, and the German mathematician Felix Klein, who connected it to projective geometry.

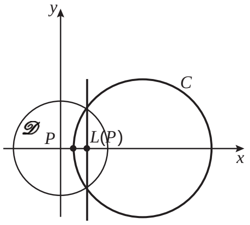
It is important to realize that although d-lines look straight in this model, angles are not represented accurately.

By considering the definition of L as the composite of the inverse of stereographic projection followed by orthogonal projection, it is clear that the image of the d-line joining two points on the boundary of $\mathbb{D}$ is the straight line segment joining the points. To find the image of a point P of $\mathbb{D}$ under L, consider





two d-lines through P and locate their end-points on the boundary of $\mathbb{D}$. Then $L(P)$ is the point where the corresponding chords intersect. Notice that, if it helps, we can always assume that one of the d-lines is a diameter of $\mathbb{D}$.



Example 1 Find the image under L of the point $P(r, 0)$ in $\mathbb{D}$.

Solution Notice first that it is sufficient to consider the image under L of the x-axis and the d-line through P at right angles to the x-axis.

The transformation L maps the x-axis to itself (as a line, not pointwise). The d-line through P perpendicular to the x-axis is part of the circle C with equation

$$x^2 + y^2 - 2ax + 1 = 0. \qquad (1)$$

The centre of C is on the x-axis, so there is no y-term in equation (l).

Since $P(r, 0)$ lies on C, it follows from equation (1) that $r^2 - 2ar + 1 = 0$, so that $a = \frac{r^2+1}{2r}$.

The circle C with equation (1) meets the boundary of $\mathbb{D}$ where

$$x^2 + y^2 - 2ax + 1 = 0 \quad \text{and} \quad x^2 + y^2 = 1.$$

The chord of $\mathbb{D}$ through the two points of intersection of C and the boundary of $\mathbb{D}$ is found by subtracting these two equations, and so it has equation

$$2 - 2ax = 0, \quad \text{or} \quad ax = 1.$$

It follows that the image $L(P)$ of P is the point $\left(\frac{1}{a}, 0\right) = \left(\frac{2r}{1+r^2}, 0\right)$. □

According to the Kleinian view of geometry, to define a geometry we must specify a space of points and a group of transformations acting on that space. Our new Beltrami–Klein model of hyperbolic geometry agrees with the (earlier) Poincaré model as far as the space of points is concerned: the space is the unit disc $\mathbb{D}$. The group of transformations is different, although isomorphic to the original group; the new group consists of all transformations of $\mathbb{D}$ to itself of the form LtL^{-1}, where t is a hyperbolic transformation. Clearly, if t is a hyperbolic transformation mapping $\mathbb{D}$ to itself and d-lines to d-lines, then LtL^{-1} is a transformation mapping $\mathbb{D}$ to itself and chords to chords.

To connect transformations of the form LtL^{-1} with projective geometry, we shall show that every such transformation LtL^{-1} is a projective transformation which maps $\mathbb{C}$ to itself and $\mathbb{D}$ to itself. It is sufficient to prove this in the case

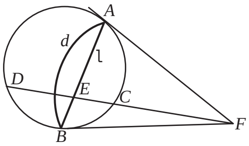
$\mathbb{C} = \{(x, y) : x^2 + y^2 = 1\}$

that t is a hyperbolic reflection; for, if $t = t_1 \circ t_2 \circ \dots \circ t_n$ is a decomposition of t into hyperbolic reflections then it follows that

$$LtL^{-1} = \left(L \circ t_1 \circ L^{-1}\right) \circ \left(L \circ t_2 \circ L^{-1}\right) \circ \dots \circ \left(L \circ t_n \circ L^{-1}\right)$$

is a decomposition of LtL^{-1} into projective transformations with the required properties; then it follows that LtL^{-1} is a projective transformation with the required properties.

Theorem 1 Let t be the hyperbolic reflection in the d-line d joining the boundary points A and B of $\mathcal{D}$, and let F be the pole of the (Euclidean) line ℓ through A and B. Then LtL^{-1} is the projective reflection r in ℓ with centre F and parameter -1.



Proof First we show that LtL^{-1} agrees with r on $\mathcal{C}$. To do this, observe that lines through F are perpendicular to d, so the hyperbolic reflection r maps a given point C of $\mathcal{C}$ to the other point D of $\mathcal{C}$ that lies on FC. Since L maps $\mathcal{C}$ to itself, it follows that $LtL^{-1}(C) = D$.

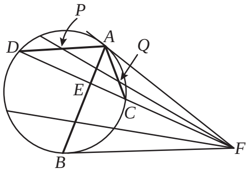
Now let E be the point of intersection of FC with ℓ. Then, since F is the polar of ℓ with respect to $\mathcal{C}$, it follows that the cross-ratio $(FECD) = -1$. Hence

$$r(C) = D = LtL^{-1}(C),$$

as required.

By the result of Exercise 7 on Subsection 4.3, in Subsection 4.6.

Next we show that LtL^{-1} agrees with r on $\mathcal{D}$. To do this, let P be an arbitrary point of $\mathcal{D}$. Then let AP meet $\mathcal{C}$ at D, and let AC meet FP at Q. We will verify that $r(P) = Q$.



We know that $r(A) = A$ and that $r(D) = C$, so that r must map AD to AC. We also know that r maps the line FP to itself, so that it must map P (the point of intersection of AD and FP) to the point of intersection of AC and FP), namely the point Q. Thus $r(P) = Q$.

Now we consider the transformation LtL^{-1}. It certainly maps chords of $\mathcal{D}$ to chords; so, to find $LtL^{-1}(P)$ we may take AD and FP as two Lines through P, and find their images. The images of AD and FP are AC and FP, so that the image of P is Q. That is, $LtL^{-1}(P) = Q$.

Thus LtL^{-1} and r agree on both $\mathcal{C}$ and $\mathcal{D}$.

We have thus shown that every hyperbolic transformation t corresponds to a projective transformation LtL^{-1} which fixes $\mathcal{C}$ and maps its interior $\mathcal{D}$ to itself. In a similar way we can verify that every projective transformation that fixes $\mathcal{C}$ and maps $\mathcal{D}$ to itself corresponds to a hyperbolic transformation.

Here we think of $\mathcal{C}$ as being embedded in a suitable embedding plane.

We omit the details of this.

This shows that hyperbolic geometry can be considered as the sub-geometry of projective geometry in which the space of points is the set of points inside the fixed projective conic $\mathcal{C}$, and its group of transformations corresponds to those projective transformations mapping $\mathcal{C}$ to itself and the inside $\mathcal{D}$ of $\mathcal{C}$ to itself.

We defined the *inside* of a projective conic in Subsection 4.1.2.

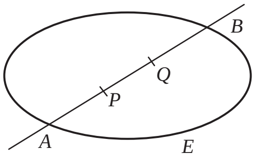
In fact, since all non-degenerate conics are projectively equivalent, we can replace C in the above discussion by any non-degenerate conic E. This may be achieved by replacing the linearization map L by the composite map $s \circ L \circ s^{-1}$, where s is a projective transformation that maps C onto E.

We omit the details.

Defining Hyperbolic Distance in the Projective Setting

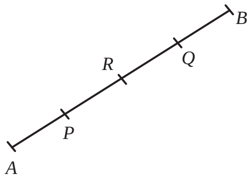
The fact that hyperbolic geometry may be considered a sub-geometry of projective geometry enables us to give a new method for defining distance in hyperbolic geometry. Projective transformations preserve cross-ratio, which involves four Points; distance involves only two points. So we shall have a ready-made sense of distance in the Beltrami–Klein model of projective geometry as soon as we can connect two interior Points of a projective conic (for simplicity, we shall take C as our projective conic) with a set of four collinear Points. This is easy — we join the two given Points P and Q by a Line that meets the projective conic in the Points A and B.

Historically, it was this discovery that excited Klein.



We know that the cross-ratio $(ABPQ)$ is unaltered by any projective transformation, and so in particular by the projective transformations that map the interior of the projective conic E to itself.

We now investigate whether we can sensibly define the hyperbolic distance d from P to Q by the formula $d(P,Q) = (ABPQ)$. The first thing we should want is that distance along a line is additive: that is, if R also lies on the d-line through P and Q, and R lies between P and Q, then is it true that



$$d(P,Q) = d(P,R) + d(R,Q)?$$

It follows from the definition of cross-ratio that

$$d(P,Q) = (ABPQ) = \frac{AP}{PB} \div \frac{AQ}{QB},$$

$$d(P,R) = (ABPR) = \frac{AP}{PB} \div \frac{AR}{RB},$$

and

$$d(R,Q) = (ABRQ) = \frac{AR}{RB} \div \frac{AQ}{QB}.$$

In this discussion we shall not bother to distinguish between Points and the corresponding points in a suitable embedding plane, for simplicity.

Hence, if we use the definition $d(P,Q) = (ABPQ)$, then $d(P,Q) \neq d(P,R) + d(R,Q)$ but instead $d(P,Q) = d(P,R) \bullet d(R,Q)$. This suggests that in the Beltrami–Klein model we should instead define distance between arbitrary points P and Q of D by the formula

$$d(P,Q) = k \log_e(ABPQ), \quad \text{for some number } k,$$

Recall that $\log_e(xy) = \log_e x + \log_e y$, for any positive numbers x and y.

since then distance d is additive. (In fact, the arbitrariness in the choice of the constant k is analogous to the freedom we have to choose the radius of the sphere in spherical geometry. However, we choose the sign of k so that distances are non-negative.)

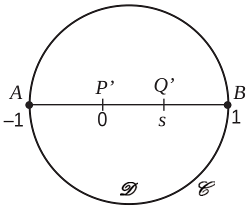
To define a distance function d for the Poincaré model, let the conic E be the unit circle C and define the distance d between two points P and Q in D to be the distance d' between the corresponding points $P' = L(P)$ and $Q' = L(Q)$ in the Beltrami–Klein model. That is, we define

Notice that we use d' here, temporarily, to avoid confusion.

$$d(P,Q) = d'(P',Q').$$

To verify that this definition agrees with that given when we introduced hyperbolic geometry earlier, let P be the origin and let Q be an arbitrary point $(r,0)$ on the positive x-axis. Then, by Example 1, $P' = L(P)$ is also at the origin and $Q' = L(Q) = (s,0)$, where $s = \frac{2r}{1+r^2}$. Since the x-axis meets $\mathcal{C}$ at the points $A(-1,0)$ and $B(1,0)$, it follows that

Subsection 6.3.1



$$\begin{aligned} d(P,Q) &= d'(P',Q') \\ &= k\log_e(ABP'Q') \\ &= k\log_e\left(\frac{1}{-1} \div \frac{1+s}{-(1-s)}\right) \\ &= k\log_e\left(\frac{1-\frac{2r}{1+r^2}}{1+\frac{2r}{1+r^2}}\right) \\ &= k\log_e\left(\frac{1-2r+r^2}{1+2r+r^2}\right) \\ &= -k\log_e\left(\left(\frac{1+r}{1-r}\right)^2\right) \\ &= -2k\log_e\left(\frac{1+r}{1-r}\right). \end{aligned}$$

Here we use that

$$\log_e\left(\frac{1}{x}\right) = -\log_e(x)$$

and

$$\log_e\left(x^2\right) = 2\log_e(x).$$

By choosing $k = -\frac{1}{4}$ and representing P and Q by the complex numbers 0 and $z = r + 0i$, respectively, we obtain

$$d(0,z) = \frac{1}{2}\log_e\left(\frac{1+|z|}{1-|z|}\right).$$

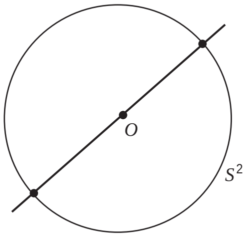
This is the logarithm formula for hyperbolic distance in $\mathbb{D}$ that you met earlier.

Subsection 6.3.1

8.4 Elliptic Geometry: the Spherical Model

To bring (the spherical model of) elliptic geometry into the Kleinian fold, we need to connect its space S^2 to the space $\mathbb{RP}^2$ of projective points and its group to the group of projective transformations.

With each point of S^2 we can associate a line through the origin, the line that joins the given point to the origin; this map assigns the same line to a pair of antipodal points. Conversely, given a projective point we can associate it with the pair of diametrically opposite points that it cuts out on S^2. In this way, we see that there is a 2–1 map of S^2 to $\mathbb{RP}^2$ that sends each pair of antipodal points on S^2 to the line through the origin (the projective point) that they define.



Since a spherical transformation sends antipodal points to antipodal points, it maps projective points to projective points. Also, every spherical transformation maps great circles to great circles, and so maps projective lines to projective lines. So it is clear that spherical transformations are projective transformations, and the group of spherical transformations is a subgroup of the projective group.

Projective Geometry and Spherical Geometry

Spherical geometry is a subgeometry of projective geometry which preserves the Euclidean angle between two lines through the origin in $\mathbb{R}^3$; the exact description of the subgroup is quite subtle, however, because the map from points of S^2 to Points in $\mathbb{RP}^2$ is 2–1.

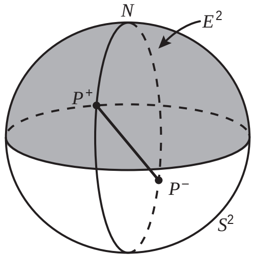
The description lies beyond the scope of this book.

One method of representing a projective point by a single point on S^2 is to keep exactly half of S^2, in some sensible way. For example, let E^2 be the subset of S^2 defined by

Here we give an informal description of the representation.

$$\begin{aligned} E^2 = {} & \text{northern hemisphere}, \{(x,y,z) : z > 0\} \\ & \cup\ \text{half the equator}, \{(x,y,z) : z = 0, x > 0\} \cup \{B(0,1,0)\}. \end{aligned}$$

Then every line through the origin meets E^2 in exactly one point, and every projective line meets E^2 in half a great circle.



The 2–1 map from S^2 to $\mathbb{RP}^2$ therefore gives a 1–1 map from S^2 to E^2: every point of $\mathbb{RP}^2$ corresponds to a unique point of E^2, and every point of E^2 defines a unique Point of $\mathbb{RP}^2$. So E^2 provides 'a complete picture' of projective space $\mathbb{RP}^2$.

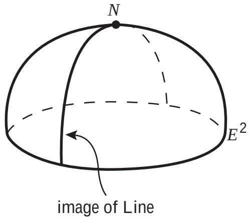
To see what's odd about E^2, consider the Points corresponding to the points $(\sin\theta, 0, \cos\theta)$ on S^2 as they trace out the Line $y = 0$ in $\mathbb{RP}^2$. Each such Point gives rise to two points on S^2:

$$P^+ = (\sin\theta, 0, \cos\theta) \quad \text{and} \quad P^- = (-\sin\theta, 0, -\cos\theta).$$

As θ goes from 0 to $\pi/2$, the point P^+ lies in E^2. But when $\theta > \pi/2$, the point P^- lies in E^2, rather than the point P^+, and this continues as θ goes from $\pi/2$ to $3\pi/2$ (including $\theta = 3\pi/2$). Then as θ goes from $3\pi/2$ to 2π, it is again the point P^+ that lies in E^2.

Here we discuss the points of S^2 that correspond to the complete Line $y = 0$.

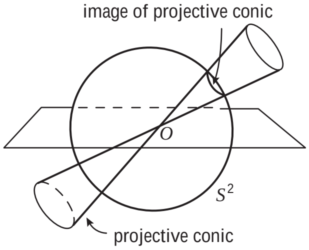
So in E^2 the image of the Line is one-half of a great circle, described twice. There is an awkward switch in E^2 from the Euclidean point corresponding to the projective point being P^+ to being P^-. We cope with this by imagining the pairs of antipodal points to be 'joined up'; that is, we agree to regard antipodal points in the equator of S^2 as 'being the same point'.

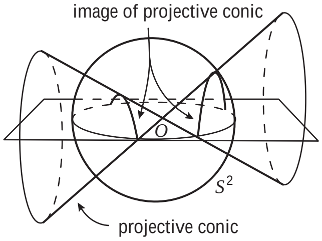


Conics appear equally odd. For example, let E denote a projective conic made up of Euclidean lines through the origin of $\mathbb{R}^3$ that form a right circular (Euclidean) cone in $\mathbb{R}^3$. This cone meets S^2 in two *little circles*.

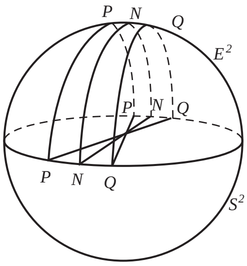
Suppose first that the points P^+ all lie in E^2, so that the cone does not meet the equatorial plane in S^2. Then the points in E^2 that correspond to E form a little circle on S^2.

Suppose next that the cone cuts the equatorial plane of S^2. Then we must switch from P^+ to P^- as the Point describes the Line, and the points in E^2 that correspond to E form two curves (parts of little circles) on S^2.





To see what s really odd about this, thicken up the Line until it is a strip bounded by two little circles in S^2. The boundaries of the strip can be taken to be two projective conics, one on either side of the Line. Since the image of the Line meets the equator in S^2, we know that the images of the (associated) projective conics also meet the equator of S^2.



Now trace the image of the Line on S^2. As you trace the Line from N to N , the curve PP (which is part of a projective conic $PP\ P$) is to your right, and the curve QQ (which is part of a projective conic $QQ\ Q$) is to your left.

When you reach the equator, the equatorial points N and N are identified, and you can complete your journey round S^2 to return to N. But the point P is identified with Q , so that the moving point that started from P returns to Q; similarly, the point Q is identified with P , so that the moving point that started from Q returns to P.

The curve $P\ \ PP$ that was on your right is now on your left, and the curve $Q\ \ QQ$ that was on your left is now on your right. The image of the strip is a strip in which the ends have been joined after receiving a half-twist. The image is a *Möbius band*, which illustrates a significant mathematical point: 2-dimensional real projective space $\mathbb{RP}^2$ is not *orientable* that is, it cannot be given an everywhere-consistent sense of left and right.

Möbius bands are beloved of conjurers!

That is, of *orientation*.

Inversive Geometry and Spherical Geometry

In inversive geometry, we study transformations which map generalized circles to generalized circles and preserve the magnitude of angles. Every transformation in inversive geometry is composed of a sequence of inversions.

In spherical geometry, we study transformations which map great circles to great circles and preserve the magnitude of angles. Every transformation in spherical geometry is composed of a sequence of reflections in great circles, which are therefore inversions. It follows that spherical geometry is a subgeometry of inversive geometry, in exact analogy with the way that Euclidean geometry is a subgeometry of affine geometry.

We omit the full details.

8.5 Euclidean Geometry

Spherical geometry appears easier to understand than hyperbolic geometry because we can produce spheres S^2 as a model of the geometry, but there seems to be no surface in Euclidean 3-dimensional space which is a good model of hyperbolic geometry. One may exhibit pieces of hyperbolic geometry, but it was shown by David Hilbert around 1900 that *no* surface embedded in 3-dimensional space is a complete model of hyperbolic 2-dimensional space.

David Hilbert (1862 1943), a professor at Göttingen University, was a mathematical universalist, influential in the foundations of mathematics; he is best known for his 1900 23 Problems collection that profoundly influenced the course of 20th-century mathematics.

But it can be argued that space might be hyperbolic (indeed, some would say that, according to Einstein s theory of General Relativity, it is *more nearly* hyperbolic than Euclidean). This raises the question: Is Euclidean geometry a subgeometry of hyperbolic geometry? We sketch a discussion of the answer to this interesting question.

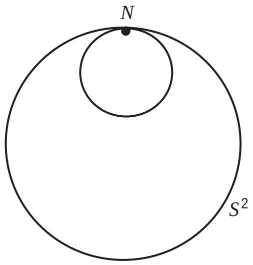
Remarkably, the answer to the question is YES: Euclidean geometry *is* a subgeometry of hyperbolic geometry

It lies beyond our scope to deal with the matter fully.

To see that this is so, we need first to go up a dimension . Hyperbolic 3-dimensional space can be modelled on the interior of the *unit ball*: a hyperbolic point is a point (x, y, z) such that $x^2 + y^2 + z^2 < 1$, and a d-line is an arc of a generalized circle perpendicular to S^2. All the other definitions in hyperbolic geometry generalize in the obvious way, including that of inversion and hyperbolic reflection. In particular, the transformations of hyperbolic geometry correspond to composites of inversions in spheres perpendicular to S^2.

$S^2 = (x, y, z)$: $x^2 + y^2 + z^2 = 1$.

In the unit ball *horospheres* are spheres that touch S^2 at a single point. For simplicity, we now fix our attention on the horosphere H_N that touches S^2 at N, and restrict our attention to the subgroup G_N, say, of hyperbolic transformations that map H_N to itself. Then we have the following remarkable result.



Theorem 1 The geometry on H_N is Euclidean geometry, and the group G_N acts on H_N as Euclidean isometries.

Proof Invert the whole figure in a sphere with centre N. The point N is mapped to infinity ; S^2 maps to a plane : $z = a$, say, and H_N maps to a plane parallel to , the plane : $z = b$, say. An element of G_N is an inversion in a generalized sphere through N and perpendicular to H_N; following composition with the first inversion, the element of G_N becomes an inversion in an unbounded generalized sphere perpendicular to the plane . These generalized spheres must in fact be planes perpendicular to the plane .

Now, inversion in a plane is Euclidean reflection in that plane. So the subgroup mapping the image of H_N to itself is the group generated by all Euclidean reflections, which is the group of Euclidean isometries. It follows that the geometry on the plane is Euclidean geometry. The desired result then follows by applying the inverse of the original inversion.

If indeed we had grown up believing that we lived in a hyperbolic 3-dimensional space, we should therefore be very familiar with spheres and horospheres!

Summary of Chapter 8

Section 8.1: Affine Geometry

1. The group of affine transformations can be identified with the subgroup of projective transformations that map $\mathbb{RP}^2_0$ onto itself.
2. Euclidean geometry is a subgeometry of affine geometry, which is itself a subgeometry of projective geometry; the three form a hierarchy. The higher up the geometry in the hierarchy, it has more transformations, fewer properties and fewer congruence classes.

Section 8.2: Projective Reflections

1. Let F be a Point that does not lie on a Line ℓ. Then a **projective reflection** r in ℓ with centre F and non-zero parameter k is a mapping of $\mathbb{RP}^2$ to itself, with P mapping to Q, where (i) $Q = P$ if P lies on ℓ and (ii) the cross-ratio $(FRPQ) = k$, where R is the Point of intersection of FP and ℓ.
2. A projective reflection is a projective transformation. Every projective transformation can be expressed as a composite of a finite number of projective reflections.

Section 8.3: Hyperbolic Geometry and Projective Geometry

1. **Orthogonal projection** maps $(x, y, z) \in \mathbb{R}^3$ to $(x, y, 0) \in \mathbb{R}^3$ or equivalently, to $(x, y) \in \mathbb{R}^2$.
2. The **linearization map** L of the unit disc $\mathbb{D}$ onto itself consists of the inverse of the stereographic projection map followed by the orthogonal projection map.
3. In the **Beltrami–Klein model** of hyperbolic geometry the space is $\mathbb{D}$ and the d-lines are straight-line segments.
4. Let t be the hyperbolic reflection in the d-line d joining the boundary points A and B of $\mathbb{D}$, and let F be the pole of the (Euclidean) line ℓ through A and B. Then LtL^{-1} is the projective reflection r in ℓ with centre F and parameter -1.
5. Every projective transformation that fixes $\mathcal{C}$ and maps $\mathbb{D}$ to itself corresponds to a hyperbolic transformation.

   Hyperbolic geometry can be considered as a subgeometry of projective geometry, where the points are points inside a fixed projective conic $\mathcal{C}$ and the group of transformations corresponds to those projective transformations mapping $\mathcal{C}$ onto itself and the inside of $\mathcal{C}$ to itself.
6. In the Beltrami–Klein model, we can define the **distance** between two points P and Q of $\mathbb{D}$ (where PQ meets $\mathcal{C}$ at A and B) by $d(P, Q) = k \log_e (ABPQ)$, where k is chosen so that distances are non-negative. This is equivalent to the definition of distance in the Poincaré model.

Section 8.4: Elliptic Geometry: the Spherical Model

1. There is a 2 1 map of S^2 to $\mathbb{RP}^2$ that sends each pair of antipodal points on S^2 to the line through the origin that they define. There is a 1-1 map of $E^2 = \{(x, y, z) : z > 0\} \quad \{(x, y, z) : z = 0, x > 0\} \quad \{(0, 1, 0)\}$ to $\mathbb{RP}^2$.
2. Spherical transformations are projective transformations; the group of spherical transformations is a subgroup of the projective group.
3. Spherical geometry is a subgeometry of inversive geometry.

Section 8.4: Euclidean Geometry

1. Euclidean geometry is a subgeometry of hyperbolic geometry
2. A point in 3-dimensional hyperbolic space is a point (x, y, z) with $x^2 + y^2 + z^2 < 1$, and a d-line is an arc of a generalized circle perpendicular to S^2.
3. A **horosphere** is a sphere in $\mathbb{R}^3$ that touches S^2 at a single point.

   Let H_N be the horosphere that touches S^2 at N, and G_N the subgroup of hyperbolic transformations that map H_N to itself. Then the geometry on H_N is Euclidean geometry, and the group G_N acts on H_N as Euclidean isometries.

It may be mentioned that a formula similar to (3.9) can also be obtained from (3.5) in replacing there $f(x_3)$ by $f'(\xi')(x_3 - \zeta)$, y_1 by $(x_1 - \zeta)f'(\xi_1)$, y_2 by $(x_2 - \zeta)f'(\xi_2)$, and $(y_2 - y_1)/(x_2 - x_1)$ by $f'(\xi_3)$. Then we get

$$\zeta - x_3 = \left[-\frac{f''(\xi)f'(\xi_1)f'(\xi_2)}{2f'(\xi')f'(\xi_3)^2}\right](\zeta - x_1)(\zeta - x_2).$$

Here the bracketed coefficient is less easy to handle than the corresponding coefficient in (3.9), since in the case $\xi' = \xi_3 = \xi$ the expression $f''(\xi)/f'(\xi)^3$ can be better estimated. On the other hand, the last formula also gives the inequality (3.10).

GEOMETRIC INTERPRETATION (FOURIER'S CONDITIONS)

6. We consider now the case where $y = f(x)$ has a graph as indicated below. Taking x_0 and x_1 as our initial approximations, we

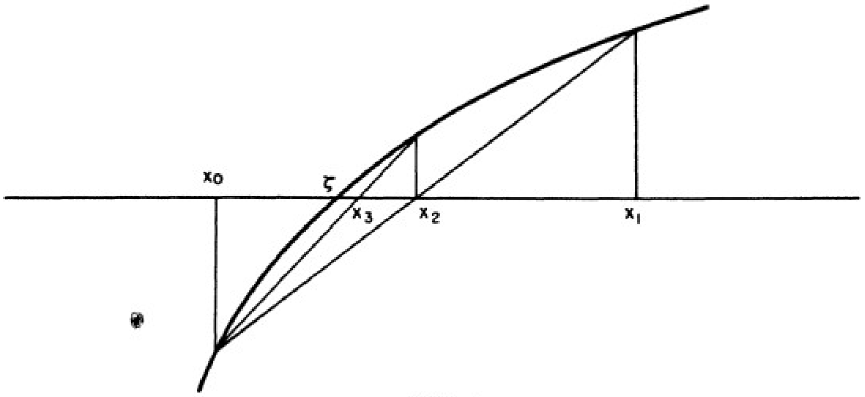

Fig. 1

obtain x_2. Taking now x_2 and x_0 as approximations, we obtain x_3. Continuing this process, we obtain a sequence of points $x_1, x_2, x_3, \ldots$, where generally

$$x_{\nu+1} = \frac{x_0 f(x_\nu) - x_\nu f(x_0)}{f(x_\nu) - f(x_0)} \qquad (\nu = 1, 2, \ldots). \tag{3.12}$$

Does x_ν $(\nu = 1, 2, \ldots)$ converge?

7. If the geometric situation is as we have drawn in Fig. 1, then x_ν converges indeed. For $x_1, x_2, x_3, \ldots$ lie on the concave side of the arc and cannot go beyond ζ; i.e., we have a monotonic decreasing sequence which is bounded from below by ζ and hence must converge to a limit ζ_0.

Is ζ_0 the root ζ of $f(x) = 0$? Subtracting ζ_0 from both sides of (3.12) and taking the limit as $\nu \to \infty$, we obtain

$$0 = \frac{x_0 f(\zeta_0) - \zeta_0 f(x_0) - \zeta_0 [f(\zeta_0) - f(x_0)]}{f(\zeta_0) - f(x_0)} = f(\zeta_0) \frac{x_0 - \zeta_0}{f(\zeta_0) - f(x_0)} \cdot$$

Now $x_0 \neq \zeta_0$; hence, $f(\zeta_0) = 0$ and ζ_0 is a zero of $f(x)$ in J_x and therefore equal to ζ.

To use the argument outlined above, the curve must have no points of inflection in the considered domain; for instance, it is sufficent to assume that $f''(x) \neq 0$ throughout J_x. As to x_0, we must take it in such a way that $f(x_0)f''(x_0) > 0$.

If the conditions listed above (the so-called *Fourier conditions*) are not satisfied, e.g., if x_0 is a point for which $\operatorname{sgn} f(x_0) \neq \operatorname{sgn} f''(x_0)$, we may get a sequence which still converges to ζ but oscillates about ζ. Such a case will be considered in Chapter 5. See also Example 1 in Section 17.

ITERATION WITH SUCCESSIVE ADJACENT POINTS

8. The convergence of the method of false position is considerably improved in the long run if, instead of constantly using x_0 as one of the interpolation points, we use at each step the two last points of the sequence:

$$x_{\nu+1} = \frac{x_{\nu-1} f(x_\nu) - x_\nu f(x_{\nu-1})}{f(x_\nu) - f(x_{\nu-1})} \qquad (\nu = 1, 2, \ldots). \tag{3.13}$$

Applying (3.9) to (3.12), we replace x_1, x_2, x_3 by x_0, x_ν, $x_{\nu+1}$ and obtain

$$\zeta - x_{\nu+1} = \left[-\frac{f''(\xi)}{2f'(\xi)^3} f'(\xi_1) f'(\xi_2)(\zeta - x_0) \right] (\zeta - x_\nu), \tag{3.14}$$

$$\xi \prec (\zeta, x_0, x_\nu), \quad \xi_1 \prec (x_0, \zeta), \quad \xi_2 \prec (x_\nu, \zeta).$$

If the modulus of the bracketed expression is always $\leqq \rho$, $\rho < 1$, and does not tend to zero, we have what is called *linear convergence.* From (3.14) it follows then in the case of the formula (3.12)

$$|\zeta - x_\nu| \leqq \rho^{\nu-1} |\zeta - x_1|, \qquad \rho < 1. \tag{3.15}$$

Dandelin Bounds for Newton-Raphson Iteration

1. We assume as in Chapter 9 replacing there y_0 by z_0 that in the interval J_0: $x_0 \leqq x \leqq z_0$, the Fourier conditions and in particular the conditions (9.0) are satisfied. Let x_0 and z_0 be the starting points, where the sequence x_ν $(\nu = 0, 1, \ldots)$ is defined by the Newton-Raphson formula (6.3) and the sequence z_ν is obtained by applying the *regula falsi* to $x_{\nu-1}$ and $z_{\nu-1}$; i.e.,

$$z_{\nu+1} = z_\nu - f(z_\nu)\,\frac{z_\nu - x_\nu}{f(z_\nu) - f(x_\nu)} \qquad (\nu = 0, 1, \ldots). \qquad (10.1)$$

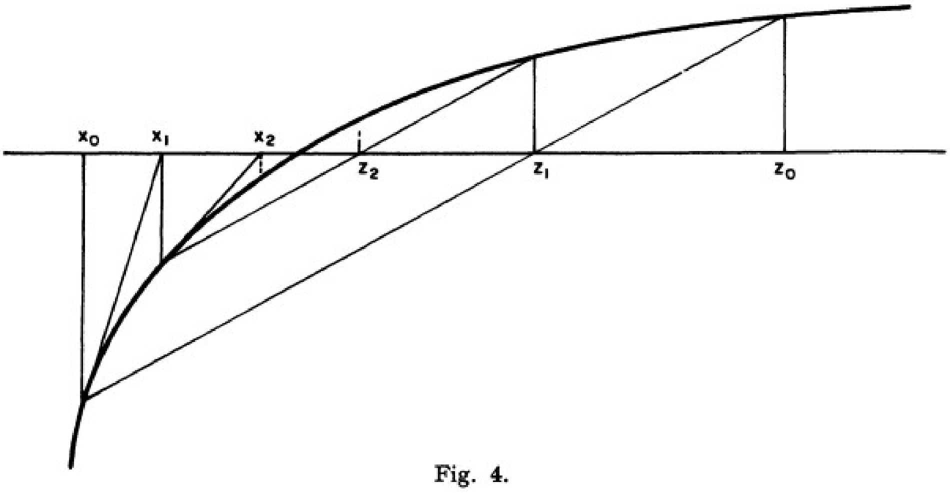

Fig. 4.

We see from Fig. 4 immediately that the z_ν decrease monotonically to a certain number η and it follows now from (10.1) that

$$\frac{f(z_\nu)}{[f(z_\nu) - f(x_\nu)]/(z_\nu - x_\nu)}$$

tends to zero. But here the denominator remains between two positive bounds $[\min f'(x), \max f'(x)]$, and therefore $f(\eta) = 0$, $\eta = \zeta$, $z_\nu \downarrow \zeta$. x_ν and z_ν are *Dandelin's bounds* for ζ.

We introduce μ_ν by

$$\mu_\nu = \frac{z_\nu - \zeta}{\zeta - x_\nu} \qquad (\nu = 0, 1, \ldots) \tag{10.2}$$

and put $J_1 = \langle x_0, y_0 \rangle$ for a fixed $y_0 > \zeta$. Then we will prove

Theorem 10.1. *If $f^{(3)}(x)$ is continuous in J_0, the sequence μ_ν tends to a limit $\Lambda(z_0)$ with $\nu \to \infty$, uniformly for $\zeta < z_0 \leqq y_0$, where $\Lambda(z_0)$ is a continuous function of z_0, and decreases monotonically to 0 as z_0 tends to ζ.*

2. Proof. We have identically

$$\frac{z_{\nu+1} - \zeta}{z_\nu - \zeta} = 1 - \frac{f(z_\nu) - f(\zeta)}{z_\nu - \zeta} \frac{z_\nu - x_\nu}{f(z_\nu) - f(x_\nu)} \tag{10.3}$$

and can write

$$\frac{z_{\nu+1} - \zeta}{z_\nu - \zeta} = \frac{N}{D},$$

$$N = \frac{f(x_\nu) - f(z_\nu)}{x_\nu - z_\nu} - \frac{f(\zeta) - f(z_\nu)}{\zeta - z_\nu}, \qquad D = \frac{f(z_\nu) - f(x_\nu)}{z_\nu - x_\nu}. \tag{10.4}$$

The formula (9.7) is an identity true for all $\zeta \neq y_\nu$; hence, we can write

$$\frac{f(a) - f(b)}{a - b} = \int_0^1 f'[b + t(a - b)]\, dt = \int_0^1 f'[a + t(b - a)]\, dt \qquad (a \neq b). \tag{10.5}$$

Applying (10.5) to D and N in (10.4), we have

$$D = \int_0^1 f'[x_\nu + t(z_\nu - x_\nu)]\, dt, \tag{10.6}$$

$$N = \int_0^1 \{f'[z_\nu + t(x_\nu - z_\nu)] - f'[z_\nu + t(\zeta - z_\nu)]\}\, dt. \tag{10.7}$$

Now apply (10.5) to the integrand of (10.7); we obtain

$$N = -(\zeta - x_\nu)\int_0^1\!\!\int_0^1 f''[z_\nu + t(x_\nu - z_\nu) + ut(\zeta - x_\nu)]t\,dt\,du. \tag{10.8}$$

3. Now put

$$\frac{z_{\nu+1} - \zeta}{(z_\nu - \zeta)(\zeta - x_\nu)} = \frac{N/(\zeta - x_\nu)}{D} = \frac{N^*}{D}, \qquad N^* = \frac{N}{\zeta - x_\nu} \tag{10.9}$$

and consider

$$S = \int_0^1\!\!\int_0^1 f''(x_\nu + uth)t\,du\,dt, \tag{10.10}$$

where $h = \zeta - x_\nu$. We introduce, instead of u, a new variable of integration, y, by $y = x_\nu + uth$, and have

$$hS = \int_0^1 \int_{x_\nu}^{x_\nu + th} f''(y)\,dy\,dt = \int_0^1 [f'(x_\nu + th) - f'(x_\nu)]\,dt,$$

$$h^2S = \int_0^1 f'(x_\nu + th)h\,dt - hf'(x_\nu).$$

Since the integrand is $d[f(x_\nu + th)]/dt$, and $x_\nu + h = \zeta$, we have

$$h^2S = f(\zeta) - f(x_\nu) - hf'(x_\nu) = -[f(x_\nu) + hf'(x_\nu)],$$

$$-\frac{h^2S}{f'(x_\nu)} = \frac{f(x_\nu)}{f'(x_\nu)} + h,$$

$$-\frac{h^2S}{f'(x_\nu)} = x_\nu - x_{\nu+1} + \zeta - x_\nu = \zeta - x_{\nu+1},$$

$$\frac{-S}{f'(x\ )} = \frac{\zeta - x_{\nu+1}}{(\zeta - x_\nu)^2}. \tag{10.11}$$

Dividing (10.9) by (10.11), we have from (10.2)

$$\frac{(z_{\nu+1}-\zeta)/(\zeta-x_{\nu+1})}{(z_\nu-\zeta)/(\zeta-x_\nu)} = -\frac{N^*}{S}\frac{f'(x_\nu)}{D} = \frac{\mu_{\nu+1}}{\mu_\nu}. \qquad (10.12)$$

4. We will have to show that μ_ν tends to a limit. First we state two well-known theorems on infinite products which we will need but shall not prove here.

Theorem A. *If* $\Sigma_{\nu=0}^{\infty}|c_\nu - 1|$ *converges and no* c_ν *is* $= 0$, *then* $\Pi_{\nu=0}^{\infty} c_\nu$ *converges to a limit* $\neq 0$.

Theorem B. *If the factors* c_ν *are continuous functions of a point and if* $\Sigma_{\nu=0}^{\infty}|c_\nu - 1|$ *converges uniformly for all points in a domain, then* $\Pi_{\nu=0}^{\infty} c_\nu$ *converges to a continuous function in this domain.*

We write now

$$\mu_n = \mu_0 \prod_{\nu=0}^{n-1} \frac{\mu_{\nu+1}}{\mu_\nu} = \mu_0 \frac{\prod_{\nu=0}^{n-1} Q_\nu}{\prod_{\nu=0}^{n-1} q_\nu}, \qquad (10.13)$$

where by (10.12)

$$Q_\nu = -\frac{N^*}{S}, \qquad q_\nu = \frac{D}{f'(x_\nu)} \qquad (\nu = 0, 1, \ldots). \qquad (10.14)$$

5. Consider first

$$Q_\nu - 1 = \frac{-N^* - S}{S}. \qquad (10.15)$$

From (10.8), (10.9), and (10.10) follows

$$-N^* - S$$
$$= \int_0^1\int_0^1 \{f''[z_\nu + t(x_\nu - z_\nu) + ut(\zeta - x_\nu)] - f''[x_\nu + ut(\zeta - x_\nu)]\}\, t\, dt\, du.$$

Applying (10.5) to the integrand, we have

$$-N^* - S$$
$$= (z_\nu - x_\nu)\int_0^1\int_0^1\int_0^1 t(1-t) f^{(3)}[x_\nu + ut(\zeta - x_\nu) + w(1-t)(z_\nu - x_\nu)]\, dw\, dt\, du.$$

Since $t(1-t)$ is nonnegative in $\langle 0, 1\rangle$, we apply the generalized mean value theorem of the integral calculus and obtain

$$-N^*-S=(z_\nu-x_\nu)f^{(3)}(\xi)\int_0^1\int_0^1\int_0^1(1-t)t\,dt\,dw\,du,\qquad \xi\prec(x_\nu, z_\nu).$$

Integrating, we have

$$-N^*-S=\frac{f^{(3)}(\xi)}{6}(z_\nu-x_\nu),\qquad \xi\prec(x_\nu, z_\nu).\tag{10.16}$$

From (10.10) the generalized mean value theorem leads to

$$S=f''(\eta)\int_0^1\int_0^1 t\,dt\,du,\qquad S=\frac{f''(\eta)}{2},\qquad \eta\prec(x_\nu, z_\nu).\tag{10.17}$$

From (10.15), (10.16), and (10.17) follows

$$Q_\nu-1=\frac{z_\nu-x_\nu}{3}\frac{f^{(3)}(\xi)}{f''(\eta)},\qquad \xi,\eta\prec(x_\nu, z_\nu).\tag{10.18}$$

6. On the other hand, by (10.14) and (10.6),

$$q_\nu-1=\frac{D-f'(x_\nu)}{f'(x_\nu)},\tag{10.19}$$

$$D-f'(x_\nu)=\int_0^1\{f'[x_\nu+t(z_\nu-x_\nu)]-f'(x_\nu)\}\,dt.\tag{10.20}$$

Applying (10.5) to (10.20), we obtain by the generalized mean value theorem

$$D-f'(x_\nu)=(z_\nu-x_\nu)\int_0^1\int_0^1 f''[x_\nu+ut(z_\nu-x_\nu)]t\,dt\,du$$

$$=(z_\nu-x_\nu)f''(\xi_1)\int_0^1\int_0^1 t\,dt\,du,\qquad \xi_1\prec(x_\nu, z_\nu).$$

$$D-f'(x_\nu)=\frac{z_\nu-x_\nu}{2}f''(\xi_1),\qquad \xi_1\prec(x_\nu, z_\nu),$$

and from (10.19)

$$q_\nu - 1 = \frac{z_\nu - x_\nu}{2} \frac{f''(\xi_1)}{f'(x_\nu)}, \qquad \xi_1 \prec (x_\nu, z_\nu). \tag{10.21}$$

7. We introduce M_k and m_k by

$$\max_{\langle x_0, y_0 \rangle} |f^{(k)}(x)| = M_k, \qquad \min_{\langle x_0, y_0 \rangle} |f^{(k)}(x)| = m_k \qquad (k = 1, 2, 3). \tag{10.22}$$

From (10.18) and (10.21) we have then

$$|Q_\nu - 1| \leqq |z_\nu - x_\nu| K, \qquad |q_\nu - 1| \leqq |z_\nu - x_\nu| K, \tag{10.23}$$

where

$$K = \max\left(\frac{1}{3}\frac{M_3}{m_2}, \frac{1}{2}\frac{M_2}{m_1}\right). \tag{10.24}$$

8. But, on the other hand, from (6.9) and (9.17), we have

$$\frac{\zeta - x_{\nu+1}}{(\zeta - x_\nu)^2} \to \kappa, \qquad \frac{\zeta - x_{\nu+1}}{\zeta - x_\nu} \sim \kappa(\zeta - x_\nu) \to 0.$$

Hence $\Sigma_{\nu=0}^{\infty} |\zeta - x_\nu|$ is convergent.

Similarly, from (3.11) and (9.17) we have

$$\frac{\zeta - z_{\nu+1}}{(\zeta - z_\nu)(\zeta - x_\nu)} \to \kappa, \qquad \frac{\zeta - z_{\nu+1}}{\zeta - z_\nu} \sim \kappa(\zeta - x_\nu) \to 0,$$

and $\Sigma_{\nu=0}^{\infty} |\zeta - z_\nu|$ is convergent. From

$$z_\nu - x_\nu = z_\nu - \zeta + \zeta - x_\nu, \qquad |z_\nu - x_\nu| \leqq |\zeta - x_\nu| + |\zeta - z_\nu|$$

the convergence of $\Sigma_{\nu=0}^{\infty} |z_\nu - x_\nu|$ now follows.

9. We now show that $\Sigma_{\nu=0}^{\infty} |z_\nu - x_\nu|$ is *uniformly convergent* as a function of z_0 if, for a fixed y_0, $\zeta < z_0 \leqq y_0$. Notice that the points x_ν do not depend on z_ν. We will keep x_0 fixed and discuss what happens as $z_0 \downarrow \zeta$. Now all z_ν are strictly increasing functions of z_0. The initial value of z_0 is $y_0 = z_0'$; denote corresponding values of z_ν by z_ν'. Then

$$z_\nu \leqq z_\nu' \qquad (\nu = 0, 1, \ldots),$$

and hence

$$|z_\nu - x_\nu| \leqq |z_\nu' - x_\nu|.$$

Therefore by (10.23)

$$|Q_\nu - 1| \leqq K\,|z_\nu' - x_\nu|, \qquad |q_\nu - 1| \leqq K|z_\nu' - x_\nu|.$$

This holds for $\zeta < z_0 \leqq y_0$. Hence $\Sigma_{\nu=0}^{\infty}|Q_\nu - 1|$, $\Sigma_{\nu=0}^{\infty}|q_\nu - 1|$ converge *uniformly* if z_0 varies between ζ and y_0. We see by Theorem B that both products $\Pi_{\nu=0}^{\infty}Q_\nu$ and $\Pi_{\nu=0}^{\infty}q_\nu$ converge uniformly for these z_0, and from (10.13) it follows now that $\lim_{\nu\to\infty}\mu_\nu$ exists uniformly for all z_0 between ζ and y_0. Now the z_ν are rational and continuous functions of z_0. By (10.2) the μ_ν are also continuous functions of z_0 and we see that $\Lambda(z_0)$ is a continuous function of z_0 for $\zeta < z_0 \leqq y_0$.

10. If $z_0 = \zeta$, then each $z_\nu = \zeta$ $(\nu = 0, 1, \ldots)$ and it follows that for $z_0 \downarrow \zeta$ each $\mu_\nu(z_0)$ tends to 0. As each $\mu_\nu(z_0)$ is a monotonically increasing function of z_0, so is $\Lambda(z_0)$ in the interval $\zeta < z_0 \leqq y_0$. Therefore, as $\Lambda(z_0) \geqq 0$, it tends to limit Λ_0 as $z_0 \downarrow \zeta$. On the other hand, for any positive ε there exists a $\mu_k(z_0)$ such that we have

$$|\Lambda(z_0) - \mu_k(z_0)| \leqq \varepsilon \qquad (\zeta < z_0 \leqq y_0).$$

We have therefore

$$\Lambda(z_0) \leqq \varepsilon + \mu_k(z_0)$$

and, as $z_0 \downarrow \zeta$, $\Lambda_0 \leqq \varepsilon$. We see that $\Lambda_0 = 0$, i.e., $\Lambda(z_0) \downarrow 0$ $(z_0 \downarrow \zeta)$. It follows that the error from the z_ν side can be made an arbitrarily small part of the error from the x_ν side if we start with a sufficiently close point z_0.

Gauge theories can be formulated in the *background field approach*, as introduced by B. de Witt and others (cf. [20]). In this approach, the quantum field theory depends on a background field, but not on any one in particular, and the theory enjoys background gauge invariance.

Is it enough to have quantum gravity formulated in such a way?[1]

It can be argued that the only vacuum expectation value consistent with diffeomorphisms invariance is

$$\langle 0|g_{\alpha\beta}|0\rangle = 0 \tag{2}$$

in which case the answer to the above question ought to be in the negative, because this is a singular background and curvature invariants do not make sense. It all boils down as to whether the ground state of the theory is diffeomorphism invariant or not. There is an example, namely three-dimensional gravity in which invariant quantization can be performed [70]. In this case at least, the ensuing theory is almost topological.

In all attempts of a canonical quantization of the gravitational field, one always ends up with an (constraint) equation corresponding physically to the fact that the total hamiltonian of a parametrization invariant theory should vanish. When expressed in the Schrödinger picture, this equation is often dubbed the *Wheeler-de Witt equation*. This equation is plagued by operator ordering and all other sorts of ambiguities. It is curious to notice that in ordinary quantum field theory there also exists a Schrödinger representation, which came recently to be controlled well enough as to be able to perform lattice computations [42].

Gauge theories can be expressed in terms of gauge invariant operators, such as Wilson loops . They obey a complicated set of equations, the loop equations, which close in the large N limit as has been shown by Makeenko and Migdal [43]. These equations can be properly regularized, e.g. in the lattice. Their explicit solution is one of the outstanding challenges in theoretical physics. Although many conjectures have been advanced in this direction, no definitive result is available.

3 The Canonical Approach

It is widely acknowledged that there is a certain tension between a $(3+1)$ decomposition implicit in any canonical approach, privileging a particular notion of time, and the beautiful geometrical structure of general relativity, with its invariance under general coordinate transformations.

Let us now nevertheless explore how far we can go on this road, following the still very much worth reading work of De Witt [20].

---

[1] This was, incidentally, the way G. Hooft and M. Veltman did the first complete one-loop calculation [65].

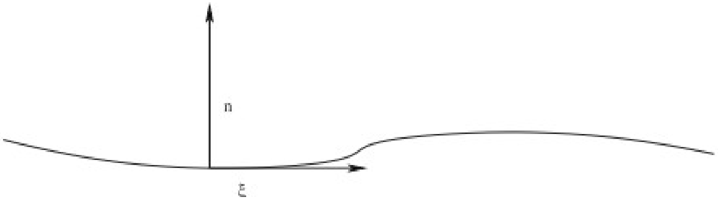

Fig. 1. Spacelike surface of codimension one

If (Fig. 1) we are given a spacelike surface (which will represent physically all spacetime events to which it will be assigned a fixed time), say

$$y^\alpha = f^\alpha(x^i)$$

The tangent vector to the surface are

$$\xi_i \equiv \partial_i f^\alpha \partial_\alpha$$

and the induced metric (that is, the pull-back to the surface of the spacetime metric) is

$$h_{ij} \equiv g_{\alpha\beta}\xi_i^\alpha \xi_j^\beta$$

The unit normal is then defined as;

$$\begin{aligned} &g_{\alpha\beta} n^\alpha \xi_i^\beta = 0 \\ &n^2 \equiv g_{\alpha\beta} n^\alpha n^\beta = 1 \end{aligned}$$

We are interested now in a set of such surfaces which covers all spacetime; that is, a foliation of (a portion of) the spacetime; namely a one-parameter family of spacelike disjoint hypersurfaces

$$\Sigma_t \equiv \{y^\alpha = f^\alpha(x^i, t)\}$$

In a classical analysis Arnowitt, Deser and Misner (ADM) [1] characterized the embedding via two functions: the *lapse* and the *shift* : we first define the vector (see Fig. 2)

$$N^\alpha \equiv \frac{\partial f^\alpha}{\partial t}$$

in terms of which the lapse, N, is just the projection in the direction of the normal, and the *shift*, N_i the (three) projections tangent to the hypersurface.

$$N^\alpha = N n^\alpha + N^i \xi_i^\alpha$$

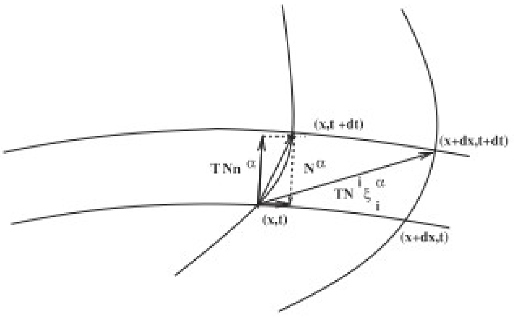

Fig. 2. ADM lapse and shift variables

All this amounts to a particular splitting of the full spacetime metric:

$$\begin{aligned} ds^2 &= g_{\alpha\beta} dx^\alpha dx^\beta = g_{\alpha\beta} df^\alpha df^\beta \\ &= g_{\alpha\beta}(N^\alpha dt + \xi_i^\alpha dx^i)(N^\beta dt + \xi_j^\beta dx^j) \\ &= N^2 dt^2 + h_{jk}(N^j dt + dx^j)(N^k dt + dx^k) \end{aligned}$$

or, what is the same,

$$g_{\mu\nu} = h^{ij}\xi_{i\mu}\xi_{j\nu} + n_\mu n_\nu$$

All surfaces which are equivalent from the intrinsic point of view, can be however embedded differently; the extrinsic curvature discriminates between them:

$$K_{ij} = -\xi_i^\alpha \nabla_\rho n_\alpha \xi_j^\rho$$

The Gauss-Codazzi equations relate intrinsic curvatures associated with the intrinsic geometry in the hypersurface with spacetime curvatures precisely through the extrinsic curvature:

$$R[h]_{lijk} = R[g]_{\alpha\beta\sigma\rho}\xi_l^\alpha \xi_i^\beta \xi_j^\sigma \xi_k^\rho - K_{ij}K_{lk} + K_{ik}K_{lj} \tag{3}$$

and

$$\nabla[h]_k K_{ij} - \nabla[h]_j K_{ik} = R_{\alpha\beta\sigma\rho} n^\alpha \xi_i^\beta \xi_j^\rho \xi_k^\sigma \tag{4}$$

whereas the curvature scalar is given by

$$R = R^{\alpha\beta}{}_{\alpha\beta} = 2R^{ni}{}_{ni} + R^{ij}{}_{ij} \tag{5}$$

In terms of this splitting, the Einstein-Hilbert action reads:

$$L_{EH} \equiv \sqrt{g} R[g] = N\sqrt{h}(R[h] + K_{ij}K^{ij} - K^2) - \partial_\alpha V^\alpha \tag{6}$$

with

$$V^\alpha = 2\sqrt{g}(n^\beta \nabla_\beta n^\alpha - n^\alpha \nabla_\beta n^\beta)$$

Primary constraints appear when defining canonical momenta:

$$p^\mu \equiv \frac{\partial L}{\partial \dot{N}_\mu} \sim 0$$

the momenta conjugate to the spatial part of the metric is:

$$\pi^{ij} \equiv \frac{\delta L}{\delta \dot{h}_{ij}} = -h^{1/2}(K^{ij} - K h^{ij})$$

The canonical commutation relations yield:

$$\{\pi^{ij}(\boldsymbol{x}), h_{kl}(\boldsymbol{x}')\} = -\delta(\boldsymbol{x}, \boldsymbol{x}')\frac{1}{2}(\delta^i_k \delta^j_l + \delta^j_k \delta^i_l)$$

The total Hamiltonian reads

$$H \equiv \int d^3x(\pi_\mu \dot{N}^\mu + \pi^{ij}\dot{h}_{ij} - L) = \int d^3x(N\mathcal{H} + N^i \mathcal{H}^i)$$

where

$$\mathcal{H}(h, \pi) = h^{-1/2}\left(\pi_{ij}\pi^{ij} - \frac{1}{2}\pi^2\right) - h^{1/2}R[h] \tag{7}$$

and

$$\mathcal{H}_i(h, \pi) = -2h_{ik}\partial_j \pi^{kj} - (2\partial_j h_{ki} - \partial_i h_{kj})\pi^{kj} = -2\nabla[h]_j \pi_i{}^j \tag{8}$$

The system of constraints is now consistent (that is, that the classical time evolution of the constraints is still a linear combination of constraints):

$$\dot{p}^\mu = \{p^\mu, H\} = (\mathcal{H}, \mathcal{H}_i) \sim 0$$

Second class constraints

$$N^\mu = f^\mu$$

can now be imposed. The whole hamiltonian analysis boils down to the two constraint equations

$$\mathcal{H} = 0$$
$$\mathcal{H}_i = 0$$

Much of the preceding analysis is actually quite generic for generally covariant systems. The full set of constraints obeys the Dirac-Schwinger algebra

$$\begin{aligned}
&\{\mathcal{H}(\boldsymbol{x}), \mathcal{H}(\boldsymbol{y})\} = [\mathcal{H}^i(\boldsymbol{x}) + \mathcal{H}^i(\boldsymbol{y})]\partial_i \delta(\boldsymbol{x}, \boldsymbol{y})\\
&\{\mathcal{H}_i(\boldsymbol{x}), \mathcal{H}(\boldsymbol{y})\} = \mathcal{H}(\boldsymbol{x})\partial_i \delta(\boldsymbol{x}, \boldsymbol{y})\\
&\{\mathcal{H}_i(\boldsymbol{x}), \mathcal{H}_j(\boldsymbol{y})\} = \mathcal{H}_i(\boldsymbol{y})\partial_j \delta(\boldsymbol{x}, \boldsymbol{y}) + \mathcal{H}_j(\boldsymbol{x})\partial_i \delta(\boldsymbol{x}, \boldsymbol{y})
\end{aligned} \tag{9}$$

which is nothing else than the Σ-projected algebra of the Diff(M) group.

Usually no reduction is made on the dynamical variables of the system, which amounts to keep h_{ij}, π^{ij} as (redundant) quantum variables. It is not clear how singular metrics can be avoided, because it is not easy to impose the condition that the metric is a positive definite operator.

Physical states in the Hilbert space are provisionally defined à la Dirac

$$\hat{\mathcal{H}}|\psi\rangle = 0$$
$$\hat{\mathcal{H}}_i|\psi\rangle = 0$$

It has been realized since long that this whole approach suffers from the *frozen time problem*, i.e., the Hamiltonian reads

$$H \equiv \int d^3x (N\mathcal{H} + N^i\mathcal{H}^i)$$

so that acting on physical states

$$\hat{H}|\psi\rangle = 0 \tag{10}$$

in such a way that Schrödinger's equation

$$i\frac{\partial}{\partial t}|\psi\rangle = \hat{H}|\psi\rangle \tag{11}$$

seemingly forbids any time dependence.

There are many unsolved problems in this approach, which has been kept at a formal level. The first one is an obvious operator ordering ambiguity owing to the nonlinearity. In the same vein, it is not clear whether it is possible to make the constraints hermitian. Besides, it is not clear that one recovers the full Diff invariance from the Dirac-Schwinger algebra. Actually, it is not known whether this is necessary; that is, what is the full symmetry of the quantum theory.

We can proceed further, still formally[2], using the Schrödinger representation defined in such a way that

$$(\hat{h}_{ij}\psi)[h] \equiv h_{ij}(x)\psi[h] \tag{12}$$

and

$$(\hat{\pi}^{ij}\psi)[h] \equiv -i\hbar\frac{\delta\psi}{\delta h_{ij}(x)}[h] \tag{13}$$

If we assume that diffeomorphisms act on wave functionals as:

$$\psi[f^*h] = \psi[h] \tag{14}$$

then the whole setup for the quantum dynamics of the gravitational field lies in Wheeler's *superspace* (nothing to do with supersymmetry) which is the set of three-dimensional metrics modulo three-dimensional diffs: $Riem(\Sigma)/Diff(\Sigma)$.

---

[2] It is bound to be formal as long as the problem of the infinities is not fully addressed. We know from the analysis of this representation for gauge theories in the lattice that those are the most difficult problems to solve.

The Hamiltonian constraint then implies the famous *Wheeler-De Witt equation.*

$$-\hbar^2 2\kappa^2 G_{ijkl}\frac{\delta^2\psi}{\delta h_{ik}\delta h_{jl}}[h] - \frac{\hbar}{2\kappa^2}R^{(3)}[h]\psi[h] = 0 \tag{15}$$

where the De Witt tensor is:

$$G_{ijkl} \equiv \frac{1}{\sqrt{h}}\left(h_{ij}h_{kl} - \frac{1}{2}h_{ik}h_{jl}\right) \tag{16}$$

Needless to say, this equation, suggestive as it is, is plagued with ambiguities. The manifold of positive definite metrics has been studied by De Witt. He showed that it has signature $(-1, +1^5)$, where the timelike coordinate is given by the breathing mode of the metric:

$$\zeta = \sqrt{\frac{32}{3}}h^{1/4} \tag{17}$$

and in terms of other five coordinates ζ^a orthogonal to the timelike coordinate, the full metric reads

$$ds^2 = -d\zeta^2 + \frac{3}{32}\zeta^2 g_{ab}d\zeta^a d\zeta^b \tag{18}$$

with

$$g_{ab} = tr\, h^{-1}\partial_a h h^{-1}\partial h \tag{19}$$

The five dimensional submanifold with metric g_{ab} is the coset space

$$SL(3,\mathbb{R})/SO(3) \tag{20}$$

It has been much speculated whether the timelike character of the dilatations lies at the root of the concept of time. The Wheeler-De Witt equation can be written in a form quite similar to the Klein-Gordon equation:

$$\left(-\frac{\partial^2}{\partial\zeta^2} + \frac{32}{3\zeta^2}g^{ab}\partial_a\partial_b + \frac{3}{32}\zeta^2 R^{(3)}\right)\Psi = 0 \tag{21}$$

The analogy goes further in the sense that also here there is a naturally defined scalar product which is not positive definite:

$$(\psi,\chi) \equiv \int_\Sigma \psi^* d\Sigma^{ij}G_{ijkl}\frac{\delta\chi}{i\delta h_{kl}} - \chi^* d\Sigma^{ij}G_{ijkl}\frac{\delta\psi}{i\delta h_{kl}} \tag{22}$$

8

Orthogonality

In Section 5.3 we introduced the dot product in $\mathbb{R}^n$ and extended the basic geometric notions of length and distance. A set $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ of nonzero vectors in $\mathbb{R}^n$ was called an **orthogonal set** if $\mathbf{f}_i \cdot \mathbf{f}_j = 0$ for all $i \neq j$, and it was proved that every orthogonal set is independent. In particular, it was observed that the expansion of a vector as a linear combination of orthogonal basis vectors is easy to obtain because formulas exist for the coefficients. Hence the orthogonal bases are the "nice" bases, and much of this chapter is devoted to extending results about bases to orthogonal bases. This leads to some very powerful methods and theorems. Our first task is to show that every subspace of $\mathbb{R}^n$ *has* an orthogonal basis.

SECTION 8.1 Orthogonal Complements and Projections

If $\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$ is linearly independent in a general vector space, and if $\mathbf{v}_{m+1}$ is not in $\text{span}\{\mathbf{v}_1, \dots, \mathbf{v}_m\}$, then $\{\mathbf{v}_1, \dots, \mathbf{v}_m, \mathbf{v}_{m+1}\}$ is independent (Lemma 1 Section 6.4). Here is the analog for *orthogonal* sets in $\mathbb{R}^n$.

Lemma 1

Orthogonal Lemma

Let $\{\mathbf{f}_1, \mathbf{f}_2, \dots, \mathbf{f}_m\}$ be an orthogonal set in $\mathbb{R}^n$. Given $\mathbf{x}$ in $\mathbb{R}^n$, write

$$\mathbf{f}_{m+1} = \mathbf{x} - \frac{\mathbf{x}\cdot\mathbf{f}_1}{\|\mathbf{f}_1\|^2}\mathbf{f}_1 - \frac{\mathbf{x}\cdot\mathbf{f}_2}{\|\mathbf{f}_2\|^2}\mathbf{f}_2 - \cdots - \frac{\mathbf{x}\cdot\mathbf{f}_m}{\|\mathbf{f}_m\|^2}\mathbf{f}_m$$

Then:

1. *$\mathbf{f}_{m+1} \cdot \mathbf{f}_k = 0$ for $k = 1, 2, \dots, m$.*
2. *If $\mathbf{x}$ is not in $\text{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$, then $\mathbf{f}_{m+1} \neq \mathbf{0}$ and $\{\mathbf{f}_1, \dots, \mathbf{f}_m, \mathbf{f}_{m+1}\}$ is an orthogonal set.*

PROOF

For convenience, write $t_i = (\mathbf{x}\cdot\mathbf{f}_i)/\|\mathbf{f}_i\|^2$ for each i. Given $1 \le k \le m$:

$$\begin{aligned}\mathbf{f}_{m+1}\cdot\mathbf{f}_k &= (\mathbf{x} - t_1\mathbf{f}_1 - \cdots - t_k\mathbf{f}_k - \cdots - t_m\mathbf{f}_m)\cdot\mathbf{f}_k \\ &= \mathbf{x}\cdot\mathbf{f}_k - t_1(\mathbf{f}_1\cdot\mathbf{f}_k) - \cdots - t_k(\mathbf{f}_k\cdot\mathbf{f}_k) - \cdots - t_m(\mathbf{f}_m\cdot\mathbf{f}_k) \\ &= \mathbf{x}\cdot\mathbf{f}_k - t_k\,\|\mathbf{f}_k\|^2 \\ &= 0\end{aligned}$$

This proves (1), and (2) follows because $\mathbf{f}_{m+1} \neq \mathbf{0}$ if $\mathbf{x}$ is not in $\text{span}\{\mathbf{f}_1, \dots, \mathbf{f}_m\}$.

Arrangements

Efi Fogel, Dan Halperin*, Lutz Kettner, Monique Teillaud, Ron Wein, and Nicola Wolpert

1.1 Introduction

Arrangements of geometric objects have been intensively studied in combinatorial and computational geometry for several decades. Given a finite collection S of geometric objects (such as lines, planes, or spheres) the *arrangement* $\mathcal{A}(S)$ is the *subdivision* of the space where these objects reside into cells as induced by the objects in S. Figure 1.1 illustrates a planar arrangement of circles, which consists of vertices, edges, and faces: a *vertex* is an intersection point of two (or more) circles, an *edge* is a maximal portion of a circle not containing any vertex, and a *face* is a maximal region of the plane not containing any vertex or edge. For convenience we also introduce two (artificial) vertices in each circle at the x-extreme points splitting the circle into two x-monotone arcs (thus each edge of the arrangement now has two distinct endpoints).

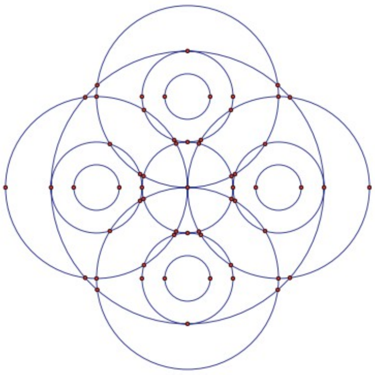

Fig. 1.1. An arrangement of 14 circles in the plane, with 53 faces (one of which is unbounded), 106 edges, and 59 vertices

Arrangements are defined and have been investigated for general families of geometric objects. One of the best studied type of arrangements is that of lines in the plane. This means that arrangements may have unbounded edges and faces. Furthermore, arrangements are defined in any dimension. There are, for example, naturally defined and useful arrangements of hypersurfaces in six-dimensional space, arising in the study of rigid motion of bodies in three-dimensional space.

---

* Chapter coordinator

Written evidence of the study of arrangements goes back to the nineteenth century (see [249]). We notice three periods in the *computational* study of arrangements. From the inception of computational geometry in the seventies till the mid eighties the focus was almost exclusively on the theoretical study of arrangements of unbounded linear objects, of hyperplanes. Many of the results obtained during this period are summarized in the book by Edelsbrunner [130]. The central role of arrangements in computational geometry has fortified in the following period, from the mid-eighties to the mid-nineties, where the theoretical focus has shifted toward arrangements of curves and surfaces. Many of the results obtained in those years are summarized in the book by Sharir and Agarwal [312] and in the survey papers [15] and [196]. From the mid nineties till the time of writing this chapter, a new more practical aspect of the study of arrangements has strengthened, emphasizing implementation and usage. The goal of robustly implementing algorithms for arrangements continues to raise numerous challenging technological and scientific problems. This chapter is devoted to the developments in this applied direction, with an emphasis on curves and surfaces. It should be noted however, that the appearance of a new topic of study in arrangements never replaced previous trends, and to this very day the theoretical study of arrangements of hyperplanes or of arrangements of algebraic curves is a thriving and fruitful domain.

Besides being interesting in their own right, arrangements are useful in a variety of applications. They have been used in solving problems in robot motion planning, computer vision, GIS (geographic information systems), computer-assisted surgery, statistics, and molecular biology, to mention just a few of the application domains. What makes arrangements such a useful structure is that they enable the accurate discretization of continuous problems, without compromising the exactness or completeness of the solution.

When coming to solve a problem using arrangements, we first need to cast the problem in “arrangement terms”. To this end, there is a large arsenal of techniques, most of which are rather simple. They include duality transforms (used to cast problems on point configurations as problems on arrangements of hyperplanes), Plücker coordinates [287], and the so-called locus method that analyzes criticalities in a problem and transforms the criticalities into hypersurfaces in the space where the problem is studied.

The next stage is to understand the combinatorial complexity of the relevant arrangement or of a portion thereof. Quite often, one does not need to construct the entire arrangement in order to solve a problem, and having only a substructure is sufficient (e.g., a single connected component of the ambient space often suffices in solving motion planning problems). This analysis gives a lower bound on the resources required by the algorithms and data structures that will be used in the solution.

Choosing or devising efficient algorithms and data structures to build the required (sub)arrangement is the next step of solving a problem using arrangements. This and the above two steps have been studied for decades.

Then comes the stage of effective implementation of the solution, which has various aspects to it. Sometimes asymptotically efficient algorithms are not necessarily practically the best. Precision and robustness of the solution is a central issue and raises questions such as: (i) how to cope with degeneracies, which are typically ignored in theory under the *general position* assumption; (ii) is the ready-made computer arithmetic sufficient or do we need to use more sophisticated machinery? These are the topics that this chapter focuses on.

The next section of the chapter gives a brief overview of the state-of-the-art in constructing arrangements. In Sect. 1.3 we survey the main advances in exact construction of planar arrangements, focusing mostly on the sweep-line approach, but explaining also what is needed for incremental construction. In Sect. 1.4 we review the software implementation details of these methods. The more recent work on the three-dimensional case is discussed in Sect. 1.5. Stepping away from exact computing is the topic of Sect. 1.6. A tour of implemented applications of curves and surfaces is given in Sect. 1.7. We conclude in Sect. 1.8 with suggestions for further reading and open problems.

1.2 Chronicles

In 1995, CGAL, the *Computational Geometry Algorithms Library*, was founded as a research project with the goal of making the large body of geometric algorithms developed in the field of computational geometry available for industrial applications with correct and efficient implementations [2, 222, 156]. It has since then evolved to an Open Source Project and is now representing the state-of-art in implementing computational geometry software in many areas. CGAL contains an elaborate and efficient implementation of arrangements that supports general types of curves.

The recent ECG project, which stands for *Effective Computational Geometry for Curves and Surfaces*, running from 2001 to 2004, extended the scope of implementation research towards curved objects.[1] Arrangements of curves and surfaces were an important theme in this project, and several different approaches to the topic were taken. This body of work is now collected and presented in a uniform manner in the following sections of the current chapter. In this brief section however, we present how the different results evolved.

The first branch of research, undertaken at Tel-Aviv University, Israel, is founded on the CGAL arrangement computation. Originally the CGAL arrangements package supported line segments, circular arcs and restricted types of parabolas. Wein [331] extended the CGAL implementation to ellipses and

2.4.3 Apollonius Diagrams

In this section, we present diagrams that are closely related to Möbius diagrams: namely, the Euclidean Voronoi diagrams of hyperspheres, also called Apollonius or Johnson-Mehl diagrams. Contrary to Möbius and anisotropic diagrams, the bisectors of Apollonius diagrams are not algebraic hypersurfaces since the bisector between two hyperspheres is only one sheet of a hyperboloid. As a consequence, Apollonius diagrams cannot be linearized in the same way as Möbius and anisotropic diagrams. Nevertheless, another linearization scheme can be applied, leading to interesting combinatorial and algorithmic results.

Definition of Apollonius Diagrams

Let us consider a finite set of weighted points $\mathcal{S} = \{\sigma_0, \sigma_1, \ldots, \sigma_n\}$ where $\sigma_i = (p_i, r_i)$, $p_i \in \mathbb{R}^d$ and $r_i \in \mathbb{R}$. We define the distance from x to σ_i as

$$\delta_i(x) = \|x - p_i\| - r_i.$$

This distance is also called the *additively weighted* distance from x to the weighted point σ_i. The minimization diagram of the distance functions δ_i, $i = 1, \ldots, n$, is called the additively weighted Voronoi diagram, or the Apollonius diagram of $\mathcal{S}$. We denote it by $\mathrm{Apo}(\mathcal{S})$ (see Fig. 2.8).

The Apollonius region $A(\sigma_i)$ of σ_i is defined as

$$A(\sigma_i) = \{x \in \mathbb{R}^d, \delta_i(x) \leq \delta_j(x)\}.$$

It is easy to see that $A(\sigma_i)$ is either empty or star-shaped from p_i. The boundary of $A(\sigma_i)$ may have a complicated structure. In fact, as we will see, the boundary of $A(\sigma_i)$ has the same combinatorial structure as a Möbius diagram in $\mathbb{R}^{d-1}$.

Since the diagram is not changed if we replace all r_i by $r_i + r$ for any $r \in \mathbb{R}$, we can assume, without loss of generality, that all r_i are non negative. The weighted points are then hyperspheres and the distance to a weighted point is the signed Euclidean distance to the corresponding hypersphere, counted positively outside the hypersphere and negatively inside the hypersphere.

Observe that, in the plane, a vertex of an Apollonius diagram is the center of a circle tangent to three circles of $\mathcal{S}$ (assuming all r_i non negative). Computing such a point is known as Apollonius' Tenth Problem, hence the name of the diagram.

Apollonius Diagrams and Power Diagrams

The graph of the distance function $\delta_i(x)$ is the half-cone of revolution $\mathcal{C}_i$ of equation

$$\mathcal{C}_i : x_{d+1} = \|x - p_i\| - r_i, \quad x_{d+1} + r_i \geq 0$$

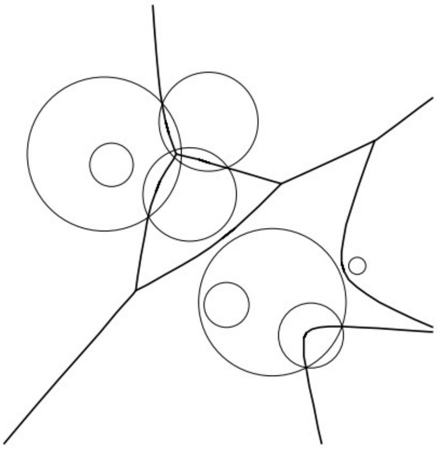

Fig. 2.8. The Apollonius diagram of a set of circles. Compare with the power diagram of the same set of circles in Fig. 2.6

The bisector of two hyperspheres of $\mathcal{S}$ is thus the projection of the intersection of two half-cones. This intersection is a quadratic hypersurface (in fact, a sheet of a two sheet hyperboloid) contained in a hyperplane. Indeed, we have

$$\begin{aligned} \mathcal{C}_1 &: (x_{d+1}+r_1)^2 = (x-p_1)^2, \;\; x_{d+1}+r_1 > 0, \\ \mathcal{C}_2 &: (x_{d+1}+r_2)^2 = (x-p_2)^2, \;\; x_{d+1}+r_2 > 0. \end{aligned}$$

The intersection of the two half-cones is contained in the hyperplane h_{12} whose equation is obtained by subtracting the two sides of the above equations:

$$h_{12} \quad : \quad -2(p_1-p_2)\cdot x - 2(r_1-r_2)x_{d+1} + p_1^2 - r_1^2 - p_2^2 + r_2^2 = 0.$$

This shows that there exists a correspondence between the diagram $\mathrm{Apo}(\mathcal{S})$ and the power diagram of the hyperspheres Σ_i in $\mathbb{R}^{d+1}$ $(i = 1, \ldots, n)$, where Σ_i is centered at (p_i, r_i) and has radius $r_i\sqrt{2}$. More precisely, $A(\sigma_i)$ is the projection of the intersection of the half-cone $\mathcal{C}_i$ with the power region $L(\Sigma_i)$. Indeed, x is in $A(\sigma_i)$ if and only if the projection X_i of x onto $\mathcal{C}_i$ has a smaller x_{d+1}-coordinate than the projections of x onto the other half-cones $\mathcal{C}_j$, $j \neq i$. In other words, the coordinates (x, x_{d+1}) of X_i must obey

$$\begin{aligned} &(x_{d+1}+r_i)^2 = (x-p_i)^2 \\ &(x_{d+1}+r_j)^2 \leq (x-p_j)^2 \quad \text{for any} \;\; j \neq i, \end{aligned}$$

and by subtracting both sides, it follows that $\Sigma_i(X_i) \leq \Sigma_j(X_i)$ for all j.

Algorithm 2 Construction of Apollonius diagrams

```
INPUT: a set of hyperspheres $\mathcal{S}$
1. Compute $\Sigma_i$, for $i = 1, \ldots, n$;
2. Compute the power diagram of the $\Sigma_i$'s;
3. For all $i = 1, \ldots, n$, project vertically the intersection of the power region $L(\Sigma_i)$
   with the half-cone $\mathcal{C}_i$.
OUTPUT: the Apollonius diagram of $\mathcal{S}$.
```

The Apollonius diagram of $\mathcal{S}$ can be computed using the following algorithm:

The power diagram of the Σ_i can be computed in time $O(n^{\lfloor \frac{d}{2} \rfloor+1} \log n)$. The intersection involved in Step 3 can be computed in time proportional to the number of faces of the power diagram of the Σ_i's, which is $O(n^{\lfloor \frac{d}{2} \rfloor+1})$. We have thus proved the following theorem due to Aurenhammer [35]:

Theorem 10. *The Apollonius diagram of a set of n hyperspheres in $\mathbb{R}^d$ has complexity $O(n^{\lfloor \frac{d}{2} \rfloor+1})$ and can be computed in time $O(n^{\lfloor \frac{d}{2} \rfloor+1} \log n)$.*

This result is optimal in odd dimensions, since the bounds above coincide with the corresponding bounds for the Voronoi diagram of points under the Euclidean distance. It is not optimal in dimension 2 (see Exercise 20). We also conjecture that it is not optimal in any even dimension.

Computing a Single Apollonius Region

We now establish a correspondence, due to Boissonnat and Karavelas [63], between a single Apollonius region and a Möbius diagram on a hypersphere.

To give the intuition behind the result, we consider first the case where one of the hyperspheres, say σ_0, is a hyperplane, i.e. a hypersphere of infinite radius. We take for σ_0 the hyperplane $x_d = 0$, and assume that all the other hyperspheres lie the half-space $x_d > 0$. The distance $\delta_0(x)$ from a point $x \in \mathbb{R}^d$ to σ_0 is defined as the Euclidean distance.

The points that are at equal distance from σ_0 and σ_i, $i > 0$, belong to a paraboloid of revolution with vertical axis. Consider such a paraboloid as the graph of a $(d-1)$-variate function ϑ_i defined over $\mathbb{R}^{d-1}$. If follows from Sect. 2.4.1 that the minimization diagram of the ϑ_i, $i = 1, \ldots, n$, is a Möbius diagram (see Fig. 2.9).

Easy computations give the associated weighted points. Write $p_i = (p'_i, p''_i)$, $p'_i \in \mathbb{R}^{d-1}$, $p''_i \in \mathbb{R}$, $i > 0$ and let $\Omega = \{\omega_1, \ldots, \omega_n\}$ be the set of Möbius sites of $\mathbb{R}^d$ where $\omega_i = \{p'_i, \lambda_i, \mu_i\}$, and

$$\lambda_i = \frac{1}{r_i + p''_i}, \qquad \mu_i = r_i - p''_i, \qquad i > 0.$$

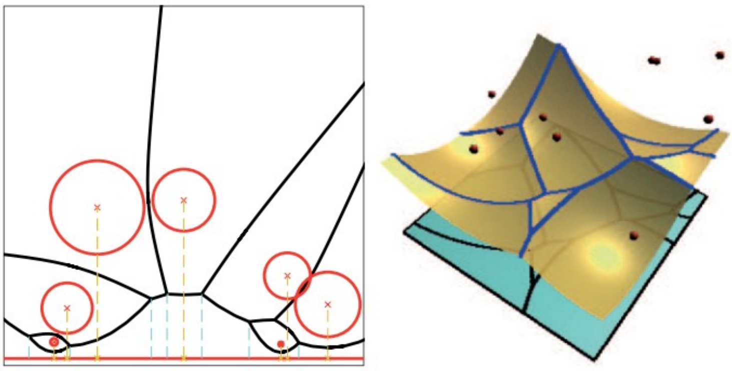

Fig. 2.9. A cell in an Apollonius diagram of hyperspheres projects vertically onto a Möbius diagram in σ_0

We let as an exercise to verify that the vertical projection of the boundary of the Apollonius region $A(\sigma_0)$ of σ_0 onto σ_0 is the Möbius diagram of ω.

We have assumed that one of the hyperspheres was a hyperplane. We now consider the case of hyperspheres of finite radii. The crucial observation is that the radial projection of $A(\sigma_0) \cap A(\sigma_i) \cap A(\sigma_j)$ onto σ_0, if not empty, is a hypersphere. It follows that the radial projection of the boundary of $A(\sigma_0)$ onto σ_0 is a Möbius diagram on σ_0.

Such a Möbius diagram on σ_0 can be computed by constructing the restriction of the power diagram of n hyperspheres of $\mathbb{R}^d$ with the hypersphere σ_0 (see Exercise 14).

Theorem 11. *Let $\mathcal{S}$ be a set of n hyperspheres in $\mathbb{R}^d$. The worst-case complexity of a single Apollonius region in the diagram of n hyperspheres of $\mathbb{R}^d$ is $\Theta(n^{\lfloor \frac{d+1}{2} \rfloor})$. Such a region can be computed in optimal time $\Theta(n \log n + n^{\lfloor \frac{d+1}{2} \rfloor})$.*

Exercise 17. Show that the cell of hypersphere σ_i in the Apollonius diagram of $\mathcal{S}$ is empty if and only if σ_i is inside another hypersphere σ_j.

Exercise 18. The predicates required to construct an Apollonius region are multivariate polynomials of degree at most 8 and 16 when $d = 2$ and 3 respectively. Detail these predicates [62].

Exercise 19. Show that the convex hull of a finite number of hyperspheres can be deduced from the restriction of a power diagram to a unit hypersphere [62].

Exercise 20. Prove that the combinatorial complexity of the Apollonius diagram of n circles in the plane has linear size.

Exercise 21 (Open problem). Give a tight bound on the combinatorial complexity of the Apollonius diagram of n hyperspheres of $\mathbb{R}^d$ when d is even.

2.5 Linearization

In this section, we introduce abstract diagrams, which are diagrams defined in terms of their bisectors. We impose suitable conditions on these bisectors so that any abstract diagram can be built as the minimization diagram of some distance functions, thus showing that the class of abstract diagrams is the same as the class of Voronoi diagrams.

Given a class of bisectors, such as affine or spherical bisectors, we then consider the inverse problem of determining a small class of distance functions that allows to build any diagram having such bisectors. We use a linearization technique to study this question.

2.5.1 Abstract Diagrams

Voronoi diagrams have been defined (see Sect. 2.2) as the minimization diagram of a finite set of continuous functions $\{\delta_1, \ldots, \delta_n\}$. It is convenient to interpret each δ_i as the distance function to an abstract object o_i, $i = 1, \ldots, n$. We define the bisector of two objects o_i and o_j of $\mathcal{O} = \{o_1, \ldots, o_n\}$ as

$$b_{ij} = \{x \in \mathbb{R}^d, \delta_i(x) = \delta_j(x)\}.$$

The bisector b_{ij} subdivides $\mathbb{R}^d$ into two open regions: one, b_{ij}^i, consisting of the points of $\mathbb{R}^d$ that are closer to o_i than to o_j, and the other one, b_{ij}^j, consisting of the points of $\mathbb{R}^d$ that are closer to o_j than to o_i. We can then define the Voronoi region of o_i as the intersection of the regions b_{ij}^i for all $j \neq i$. The union of the closures of these Voronoi regions covers $\mathbb{R}^d$. Furthermore, if we assume that the bisectors are $(d-1)$-manifolds, the Voronoi regions then have disjoint interiors and we can define the closed region associated to b_{ij}^i as $\bar{b}_{ij}^i = b_{ij}^i \cup b_{ij}$.

In a way similar to Klein [230], we now define diagrams in terms of bisectors instead of distance functions. Let $B = \{b_{ij}, i \neq j\}$ be a set of closed $(d-1)$-manifolds without boundary. We always assume in the following that $b_{ij} = b_{ji}$ for all $i \neq j$. We assume further that, for all distinct i, j, k, the following incidence condition (I.C.) holds:

$$b_{ij} \cap b_{jk} = b_{jk} \cap b_{ki} \quad (I.C.)$$

This incidence condition is obviously needed for B to be the set of bisectors of some distance functions.

By Jordan's theorem, each element of B subdivides $\mathbb{R}^d$ into at least two connected components and crossing a bisector b_{ij} implies moving into another

cities a few days later, then once a few days have passed we know that one of those two predictions was wrong. If we thought of the probability distribution as a physical thing, it would seem insane to suddenly change it in Galveston, because we see a storm hitting New Orleans. Bayes' rule of conditional probability tells us this is exactly the right thing to do.

Bayes' rule is not in general applicable in QM, because probabilities only add when interference terms are negligible. If we want to understand *why* the interference terms suddenly become negligible when we put a detector near one of the slits, then we have to understand more about the properties of the detector than Feynman's discussion supplies. We will see in Chapter 10 that the crucial property is that the detector is a complicated system, made of many atoms, with a huge number of microscopic atomic states corresponding to each position of the "needle on the detector's dial." As a consequence, the interference terms in the probability distribution for seeing the detector's dial either register a hit or not, are unimaginably small, and Bayes' rule is approximately valid. This is a general lesson: *the quantum rules for the probabilities that refer to macroscopic objects differ from the rules of a classical statistical theory, which satisfies Bayes' rule, by amounts which are of order* e^{-cN} *where* N *is the number of atoms out of which the object is composed.* These differences are so small that they are impossible to measure, even in principle.

The fact that the rule for computing probabilities of future events depends on whether the detector is there or not is not mysterious. Indeed, we are describing very different experiments in the two cases. In the first, we ask for a prediction of the probability of getting a hit on the screen. In the second, we are asking for probabilities of hits, *conditioned on the detector's behaving a certain way at an intermediate time.* As we will see, the fact that the violation of Bayes' rule for observations done on the macroscopic detector is vanishingly small, completely accounts for the difference in the predictions.

4.6 A WORKED EXERCISE

Exercise 4.6 As we will see in the next chapter, the generalization of the Schrödinger equation to particles moving under the influence of a force is simply to add the potential energy $V(x)$ to the Hamiltonian operator. In the following exercises, we will consider potentials, which are locally constant, so that we can use free particle solutions to solve the equation. To begin, solve the Schrödinger equation for a step function potential $V(x) = V_0\theta(x+a)\theta(a-x)$. The real line divides into three intervals, in each of which the equation reduces to that of a free particle. By taking the integral of the Schrödinger equation in small intervals around the points of discontinuity, you can figure out how to join the solutions in the three regions and impose the condition of normalizability. For one sign of V_0, you should find only delta function normalizable eigenstates, whereas for the other, you will find both delta function normalizable and truly normalizable eigenfunctions. Show that the spectrum of the latter is discrete and describe how it depends on V_0 and a. The normalizable wave functions are called bound states. Show that the bound state spectrum depends only on the parameter $s_0 \equiv \frac{a}{\hbar}\sqrt{2mV_0}$. By examining the equation for bound states graphically, show that the number of such states is finite, but goes to infinity as $s_0 \to \infty$. For small s_0, show that there is only a single bound state. Now find the eigenfunctions for $E > 0$. There are two linearly independent solutions, which can be characterized by saying that the associated time-dependent solution moves toward or away from the center, near $+\infty$. Alternatively, we can characterize the solutions as incoming or outgoing at $-\infty$. There must be two linear relations between these four solutions, since only two of them can be linearly independent. Compute the 2×2 *Scattering matrix* or S-matrix, which expresses the two outgoing solutions in terms of the two incoming solutions.

Exercise 4.7 Consider the square well potential of Exercise 4.6. For the case of the normalizable wave functions, show that they decrease exponentially for large $|x|$. Think about classical mechanics with the same potential, and show that motion in the region where the quantum wave function is exponentially decreasing is simply not allowed. The fact that there is nonzero probability for the particle to be found in this region is called *quantum tunneling through a barrier*. We will study it more extensively in Chapter 17 on the JWKB approximation. Show that the equation for bound states depends only on the parameter s_0.

Exercise 4.8 For the continuum (i.e., scattering) wave functions in Exercise 4.6, we have two possible behaviors $e^{\pm ikx}$ for positive k in each of the asymptotic regions $x \to \pm\infty$. By considering the time-dependent Schrödinger equation show that the choices of the sign of k correspond to left and right moving waves in the two regions. Argue that the two different signs in a given asymptotic region, correspond to two linearly independent solutions of the second order ordinary differential equation for fixed k^2. Argue that there are exactly two linearly independent solutions. Thus, there must be linear relations between the four possible asymptotic behaviors. Using your exact solutions, find these linear relations. Your tool for finding these relations is continuity of the wave function and its derivative at the points where the potential, and thus the *second* derivative of ψ is discontinuous.

Answer to Exercises 4.6–4.8: The solution to the Schrödinger equation with energy E is

$$\psi_E = e^{\pm\sqrt{\frac{2m}{\hbar^2}(V(x)-E)}x}, \tag{4.34}$$

where $V(x) = V_0\theta(a-x)\theta(x+a)$. Integrating the Schrödinger equation near the discontinuities in $V(x)$, we find that the wave function and its first derivative must be continuous there Figure 4.2. If $E > 0$, we have delta function normalizable solutions, while if $E < 0$, we can get normalizable bound state solutions by picking only the falling exponential as $x \to \pm\infty$. The problem is invariant under reflections, so for the bound states, we can choose to look at even and odd solutions. We can impose the continuity conditions only at $x = a$ and they

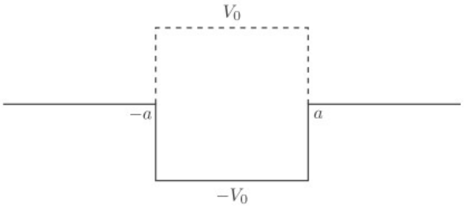

Figure 4.2 The potential for Exercises 4.6–4.8.

will automatically be satisfied for negative x. In the region near the origin, the wave function depends on the crucial quantity

$$ik_0 = \frac{\sqrt{2m(V_0 - E)}}{\hbar}, \tag{4.35}$$

which gives k_0 imaginary. The imaginary part of ak_0 is equal to the classical action in units of $\hbar$ of a particle traveling from $-a$ to a, if $E - V_0 > 0$. When the opposite inequality holds, k_0 is imaginary. In either case, we define k_0 with the positive (imaginary) square root. We define

$$ik = \frac{\sqrt{-2mE}}{\hbar}. \tag{4.36}$$

In addition, define $r \equiv \frac{k_0}{k}$. In the region $|x| > a$, the wave function grows or falls exponentially if $E < 0$. We must choose the falling solution at both positive and negative values of x, to obtain a normalizable wave function. The continuity conditions for even and odd wave functions at $x = a$ are:

$$A\cosh(|k_0|a) = Be^{-|k|a}, \quad Ar\sinh(|k_0|a) = -Be^{-|k|a}, \tag{4.37}$$

$$A\sinh(|k_0|a) = Be^{-|k|a}, \quad Ar\cosh(|k_0|a) = -Be^{-|k|a}, \tag{4.38}$$

when k_0 is imaginary. The hyperbolic sine and cosine are both positive, and these equations have no solution. Thus, we must have the intuitively obvious condition $E - V_0 > 0$, which implies a potential well rather than a barrier and asymptotic energy less than the depth of the well, in order to have a bound state. For k_0 real, the matching conditions become

$$A\cos(|k_0|a) = Be^{-|k|a}, \quad Ar\sin(|k_0|a) = Be^{-|k|a}, \tag{4.39}$$

$$A\sin(|k_0|a) = Be^{-|k|a}, \quad Ar\cos(|k_0|a) = -Be^{-|k|a}. \tag{4.40}$$

Motivated by the bound on E, we define $E = yV_0$, with $0 \leq y \leq 1$. The conditions become

$$\sqrt{\frac{y}{1-y}} = -\tan(s_0\sqrt{1-y}). \tag{4.41}$$

$$\sqrt{\frac{y}{1-y}} = -\cot(s_0\sqrt{1-y}). \tag{4.42}$$

These depend only on a single parameter $s_0 \equiv a\sqrt{\frac{-2mV_0}{\hbar^2}}$. When s_0 is small, we can expand the trigonometric functions. The equation for odd solutions becomes $y = 1/s_0^2$, which is inconsistent with $0 \leq y \leq 1$. The even solution is $y = s_0^2$ and is consistent. There is a single bound state. When s_0 is large, we can satisfy the equation with $s_0\sqrt{1-y} \sim \frac{n\pi}{2}$, where n is odd for even solutions and vice versa, as long as $\frac{n\pi}{2s_0} < 1$. The point is that the tangent and cotangent take on any large value in the vicinity of their poles, so that as long as y is sufficiently close to 1 we can match. These explicit formulae are only valid for large n, but there are bound states for every value of n satisfying the inequality. As s_0 goes to infinity, we get an infinite number of states and the explicit formula becomes more exact. In this limit, after adding a constant to make all the energies positive, the spectrum approaches that of the infinite square well. Note, however, that s_0 can be large for a shallow, but very broad, well also. In that situation, we would still have continuum eigenstates.

Turning now to $E > 0$, we define

$$\psi^+ = A^+_{out}e^{ikx} + A^+_{in}e^{-ikx}, \quad x > a, \tag{4.43}$$

$$\psi^+ = A^-_{out}e^{-ikx} + A^-_{in}e^{ikx}, \quad x < -a. \tag{4.44}$$

The subscripts *in* and *out* refer to the fact that, when multiplied by $e^{-i\frac{\hbar^2k^2}{2m}t}$, the relevant part of the solution becomes a traveling incoming or outgoing wave. Note that the sign of the exponential changes when we compare an incoming (outgoing) wave on the left and right. To write the continuity conditions at $x = \pm a$ compactly, it is convenient to define $z_0 = e^{ik_0a}$, $z = e^{ika}$, and $r^\pm = 1 \pm r$. Then we have

$$A^-_{in}z^{-1} + A^-_{out}z = Az_0^{-1} + Bz_0, \tag{4.45}$$

$$A^-_{in}z^{-1} - A^-_{out}z = r(Az_0^{-1} - Bz_0), \tag{4.46}$$

$$A^+_{out}z + A^+_{in}z^{-1} = Az_0 + Bz_0^{-1}, \tag{4.47}$$

$$A^+_{out}z - A^+_{in}z^{-1} = r(Az_0^{-1} - Bz_0). \tag{4.48}$$

These are equivalent to a pair of 2×2 matrix equations expressing the vectors

$$A_{in/out} \equiv \begin{pmatrix} A^-_{in/out} \\ A^+_{in/out} \end{pmatrix}$$

in terms of the vector

$$A_m \equiv \begin{pmatrix} A \\ B \end{pmatrix}$$

$$A_{in} = \frac{z}{2}[\frac{r_+}{z_0} + r_- z_0 \sigma_1] A_m, \tag{4.49}$$

$$A_{out} = \frac{1}{2z}[\frac{r_-}{z_0} + r_+ z_0 \sigma_1] A_m. \tag{4.50}$$

The *Scattering matrix* or S-matrix is the transformation that takes A_{in} into A_{out}, so we have

$$S = \frac{1}{2z}[\frac{r_-}{z_0} + r_+ z_0 \sigma_1] \frac{2}{z}[\frac{r_+}{z_0} + r_- z_0 \sigma_1]^{-1}, \tag{4.51}$$

These equations reflect the fact that there are only two linearly independent solutions of the Schrödinger equation. The *in* and *out* states represent two independent bases for the Hilbert space. These equations tell us how to transform between them.

Note that the two factors in the formula for the S-matrix commute with each other. Thus, since $S = S_+ S_-^{-1}$, we have $S^\dagger S = S_+^\dagger S_+ [S_-^\dagger S_-]^{-1}$. Now compute

$$S_+^\dagger S_+ = \frac{1}{4}[r_- z_0 + r_+ z_0^{-1} \sigma_1][\frac{r_-}{z_0} + r_+ z_0 \sigma_1] = \frac{1}{4}[r_+^2 + r_-^2 + r_+ r_- (z_0^2 + z_0^{-2})], \tag{4.52}$$

$$S_- S_-^\dagger = \frac{1}{4}[\frac{r_+}{z_0} + r_- z_0 \sigma_1][\frac{r_+}{z_0} + r_- z_0^{-1} \sigma_1] = \frac{1}{4}[r_+^2 + r_-^2 + r_+ r_- (z_0^2 + z_0^{-2})]. \tag{4.53}$$

Therefore, $S^\dagger S = 1$. The S-matrix is a unitary transformation between two bases of the Hilbert space. Of course, the states of fixed k are not normalizable states in the Hilbert space, but this calculation guarantees that the mapping of normalizable incoming wave packet states into normalizable outgoing wave packet states, defined as superpositions of the fixed k states, is a genuine unitary operator in the Hilbert space.

We can write the eigenvalues of the unitary S-matrix as $e^{2i\delta_\pm(k)}$ where $\delta_\pm$ are called the phase shifts.

$$e^{2i\delta_\pm} = z^2 \frac{(r_- z_0^{-1} \pm r_+ z_0)}{(r_- z_0^{-1} \pm r_- z_0)}. \tag{4.54}$$

They are analytic functions of k, which will have poles whenever the denominator has a linear zero. The equation for the poles is

$$\frac{r_+}{r_-} = -z_0^2. \tag{4.55}$$

For real k, there are no solutions of this equation because the left-hand side is a real number greater than 1 and the right-hand side is a phase. For imaginary k, the left-hand side is also a phase. If $k = il$ the equation for a pole is

$$r_- = \pm z_0^2 r_+. \tag{4.56}$$

Some simple algebra shows that this is identical to the equation for bound states, and has solutions only when $V_0 < 0$. The fact that the S-matrix is an analytic function of energy, with poles at the bound state energies, is a very general result of immense importance.

4.7 FURTHER EXERCISES

4.4 Consider the Fourier transform of a smooth function $f(x)$ (see Appendix B for a definition of smooth).

$$\tilde{f}(k) = \int dx\ f(x)e^{ikx},$$

for large values of k. Show that smoothness implies that the Fourier transform falls off faster than any power of k. Compute the Fourier transform of $(x^2 + a^2)^{-b}$ for those values of b for which the function is square integrable. How does the falloff in wave number space depend on b?

4.5 Compute the Fourier transform of a step function, $\theta(a - x)\theta(a + x)$, where $\theta(x)$ is 1 for $x > 0$ and 0 for negative x, and demonstrate the relation between the width of the interval over which the function is nonzero and the falloff in wave number space. Use this to calculate the time evolution of a wave function that is initially confined in a fixed interval.

4.9 Consider the plane wave normalizable solutions for the potential of Exercises 4.6–4.8, in the case where there is no left moving or incoming wave in the region of large positive x. Thus, $\psi = A^+_{out}e^{ikx}$ in this region. For $x < -a$ we have

$$\psi = A^-_{in}e^{ikx} + A^-_{out}e^{-ikx}.$$

A^-_{in} is called the incident amplitude. It is a wave moving toward the barrier from the left. A^-_{out} is called the reflected amplitude. A^+_{out} is the transmitted amplitude. The *transmission coefficient*,

$$T = |\frac{A^+_{out}}{A^-_{in}}|^2,$$

gives us the probability of transmission through the barrier. Calculate it, for all values of V_0, E, and a. Also *define* and calculate the *reflection coefficient* R and show that $R+T = 1$. Show that T oscillates as a function of E and that there are values of E for which it is equal to 1. That is, there are discrete energies for which the barrier becomes completely transparent! This is called the Ramsauer–Townsend effect, and has been observed in the laboratory.

4.10 Consider the potential $V = -a^2\theta(x)$. Consider a particle of mass m and energy E traveling to the right from large negative x. Assume that for $x > 0$ there is no left

(-& .- - -/ ' ! - * + ($! ! 8 2

axis. Hence the problem of approximating the medial axis of Ω boils down to sampling the boundary of Ω, a problem that is closely related to mesh generation (see Chap. 5). Other informations on the medial axis can be found in Chap. 6.

2.7.1 Medial Axis and Lower Envelope

The *medial axis* of an open set Ω, denoted by $\mathcal{M}(\Omega)$, is defined as the the set of points of Ω that have more than one nearest neighbor on the boundary of Ω. Nearest refers in this section to the Euclidean distance although the results may be extended to other distance functions. A *medial sphere* σ is a sphere centered at a point c of the medial axis and passing through the nearest neighbors of c on $\partial\Omega$. Those points where σ is tangent (in the sense that σ does not enclose any point of $\partial\Omega$) to $\partial\Omega$ are called the *contact points* of σ.

The concept of medial axis can be considered as an extension of the notion of Voronoi diagram to infinite sets. Let o be a point of the boundary of Ω and δ_o be the distance function to o defined over Ω

$$\forall x \in \Omega : \ \delta_o(x) = \|x - o\|.$$

The *lower envelope* of the infinite set of functions δ_o is defined as

$$\Delta^- = \inf_{o \in \partial\Omega} \delta_o.$$

Following what we did for Voronoi diagrams (Sect. 2.2), we define, for any point $x \in \Omega$, its index set $I(x)$ as the set of all o such that $\Delta^-(x) = \delta_o(x)$. The set of points x such that $|I(x)| > 1$ constitutes the medial axis of Ω.

Computing the medial axis is difficult in general. If Ω is defined as a semi-algebraic set, i.e. a finite collection of algebraic equations and inequalities, $\mathcal{M}(\Omega)$ is also a semi-algebraic set that can therefore be computed using techniques from real algebraic geometry [32, 44]. This general approach, however, leads to algorithms of very high complexity. Theorem 1 can also be used but, still, working out the algebraic issues is a formidable task. Effective implementations are currently limited to simple objects. If Ω is a planar domain bounded by line segments and circular arcs, one can apply the results of Sect. 2.6. Further results can be found in [159].

An alternative and more practical approach consists in departing from the requirement to compute the medial axis exactly. In Sect. 2.7.2, we describe a method that approximates the medial axis of an object by first sampling its boundary, and then computing and pruning the Voronoi diagram of the sample.

2.7.2 Approximation of the Medial Axis

Approximating the medial axis of a set is a non trivial issue since sets that are close for the Hausdorff distance may have very different medial axes. This is illustrated in Fig. 2.13. Let S be a closed curve, $\Omega = \mathbb{R}^2 \setminus S$ and $\mathcal{P}$ be a finite set of points approximating S. As can be seen on the figure, the skeleton of the Voronoi diagram of $\mathcal{P}$ is far from the medial axis of Ω since there are many long branches with no counterpart in $\mathcal{M}(\Omega)$. These branches are Voronoi edges whose dual Delaunay edges are small (their lengths tend to 0 when the sampling density increases). In other words, the medial axis is not continuous under the Hausdorff distance. Notice however that if we remove the long branches in Fig. 2.13, we obtain a good approximation of the medial axis of S. This observation will be made precise in Lemma 10 below. It leads to an approximate algorithm that first sample S and extract from the Euclidean Voronoi diagram of the sample a sub-complex that approximates the medial axis of S.

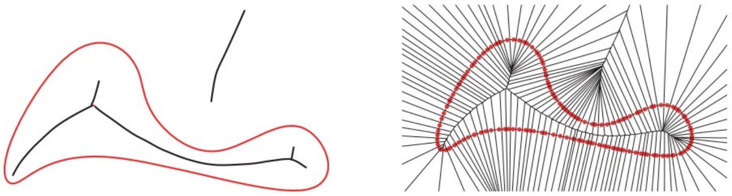

Fig. 2.13. On the left side, a closed curve S and the medial axis of $\Omega = \mathbb{R}^2 \setminus S$. On the right side, a dense sample E of points and its Voronoi diagram. The medial axis of $\mathbb{R}^2 \setminus E$ (which is the 1-skeleton of $\mathrm{Vor}(E)$) is very different from the medial axis of Ω

Given an open set Ω and a point x on the medial axis of Ω, we define $D(x)$ as the diameter of the smallest closed ball containing the contact points of the medial sphere centered at x. We define the λ-medial axis of Ω, denoted $\mathcal{M}_\lambda(\Omega)$ as the subset of the medial axis of Ω consisting of points x such that $D(x) \geq \lambda$.

Let Ω and Ω' be two open sets and let S and S' denote their boundaries. We assume that S and S' are compact and that their Hausdorff distance $d_H(S, S')$ is at most ε: any point of S is at distance at most ε from a point of S' and vice versa. Notice that we do not specify S nor S' to be finite or infinite point sets. For convenience, we rename medial axis of S (resp. S') and write $\mathcal{M}(S)$ (resp. $\mathcal{M}(S')$) the medial axis of $\mathbb{R}^3 \setminus S$. Similarly, we rename medial axis of S' and write $\mathcal{M}(S')$) the medial axis of $\mathbb{R}^3 \setminus S$.

The following lemma says that the λ-medial axis of S is close to the medial axis of S', provided that λ is sufficiently large. It should be emphasized that close here refers to the one-sided Hausdorff distance: the medial axis of S' is not necessarily close to the λ-medial axis of S although, by exchanging the roles of S and S', the lemma states that the λ'-medial axis of S' is close to the medial axis of S for a sufficiently large λ'. We will go back to this point later.

We say that a ball is S-empty if its interior does not intersect S. The sphere bounding a S-empty ball is called a S-empty sphere.

Lemma 10. *Let σ be a S-empty sphere centered at c, of radius r, intersecting S in two points x and y. If $\varepsilon < \frac{r}{2}$ and $l \overset{\text{def}}{=} \frac{\|x-y\|}{4} \geq \sqrt{\varepsilon r(1-\frac{\varepsilon}{r})}$, there exists an S'-empty sphere tangent to S' in two points whose center c' and radius r' are such that $|1-\frac{r'}{r}|$ and $\frac{\|c'-c\|}{r}$ are at most $\delta = \frac{\varepsilon r}{l^2-\varepsilon r+\varepsilon^2}$.*

Proof. Let σ'' be the maximal S'-empty sphere centered at c and let r'' be its radius (see Fig. 2.14). The Hausdorff distance between S and S' being at most ε, we have $|r-r''| \leq \varepsilon$. Let y' be a point of $\sigma'' \cap S'$.

Let σ' be the maximal S'-empty sphere tangent to σ'' at y'. σ' is tangent to S' at at least two points. Let c' be its center and r' its radius.

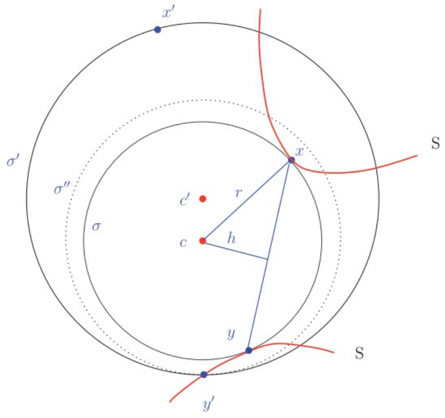

Fig. 2.14. S is the continuous curve. x' and y' belong to S'

Noting $h = \sqrt{r^2 - \frac{1}{4}\|x-y\|^2} = \sqrt{r^2-4l^2}$ the distance from c to line xy, we have

$$\begin{aligned} d(c', S) &\leq \min(\|c'-x\|, \|c'-y\|) \\ &\leq \sqrt{(\|c-c'\|+h)^2 + \frac{1}{4}\|x-y\|^2} \\ &= \sqrt{r^2 + \|c-c'\|^2 + 2h\|c-c'\|}. \end{aligned}$$

On the other hand,

$$d(c', S') = \|c' - y'\| = \|c - c'\| + r'' \geq \|c - c'\| + r - \varepsilon.$$

From these two inequalities, we deduce

$$\|c - c'\| + r - \varepsilon \leq d(c', S') \leq d(c', S) + \varepsilon \leq \sqrt{r^2 + \|c - c'\|^2 + 2h\|c - c'\|} + \varepsilon.$$

and, since, by assumption, $r > 2\varepsilon$, we get $\|c - c'\|\,(r - 2\varepsilon - h) \leq 2\varepsilon(r - \varepsilon)$. Moreover, by assumption, $l \geq \sqrt{\varepsilon r(1 - \frac{\varepsilon}{r})}$ which implies $r - 2\varepsilon - h \geq 0$. Indeed,

$$h = \sqrt{r^2 - 4l^2} \leq \sqrt{r^2 - 4\varepsilon r + 4\varepsilon^2} = r - 2\varepsilon.$$

We then deduce

$$\|c - c'\| \leq \frac{2\varepsilon(r - \varepsilon)}{r - h - 2\varepsilon} \leq \frac{2\varepsilon r}{r - \sqrt{r^2 - 4l^2} - 2\varepsilon}.$$

We then get

$$\frac{\|c - c'\|}{r} \leq \frac{2\varepsilon(r + \sqrt{r^2 - 4l^2} - 2\varepsilon)}{(r - 2\varepsilon)^2 - (r^2 - 4l^2)} \leq \frac{\varepsilon r}{l^2 - \varepsilon r + \varepsilon^2}.$$

The same bound plainly holds for $|1 - \frac{r'}{r}|$.

We consider the case where S is a surface of $\mathbb{R}^3$ and S' is a finite set of points on S at Hausdorff distance at most ε from S. To avoid confusion, we rename S' as $\mathcal{P}$. As already noticed, $\mathcal{M}(\mathcal{P})$ is the 1-skeleton of the Voronoi diagram $\mathrm{Vor}(\mathcal{P})$, called simply the Voronoi diagram of $\mathcal{P}$ in this section. The set of contact points of a medial sphere centered at a point $c \in \mathcal{M}(\mathcal{P})$ is the set of closest points of c in $\mathcal{P}$. Any point in the relative interior of a face of $\mathrm{Vor}(\mathcal{P})$ has the same closest points in $\mathcal{P}$. It follows that the λ-medial axis of $\mathcal{P}$ is the subset of the faces of $\mathrm{Vor}(\mathcal{P})$ whose contact points cannot be enclosed in a ball of diameter λ.

Lemma 10 then says that any Delaunay sphere of $\mathrm{Del}(\mathcal{P})$ passing through two sample points that are sufficiently far apart, is close to a medial sphere of S (for the Hausdorff distance). We have therefore bounded the *one-sided* Hausdorff distance from the λ-medial axis (Voronoi diagram) of an ε-sample $\mathcal{P}$ of S to the medial axis of S, when λ is sufficiently large with respect to ε. If we apply the lemma the other way around, we see that, for sufficiently large λ', $\mathcal{M}_{\lambda'}(S)$ is close to $\mathcal{M}(\mathcal{P})$. However, as observed above (Fig. 2.13), we cannot hope to bound the two-sided Hausdorff distance between $\mathcal{M}(S)$ and $\mathcal{M}(\mathcal{P})$.

The above lemma can be strengthened as recently shown by Chazal and Lieutier [83, 32]. They proved that the λ-medial axis of S is close to the λ'-medial axis of $\mathcal{P}$ for a sufficiently large λ and some positive λ' that depends on λ and ε. More precisely, let D be the diameter of S and k'' a positive constant. They showed that there exist three functions of ε, $k(\varepsilon) = 15\sqrt{2}\,\sqrt[4]{D^3\varepsilon}$, $k'(\varepsilon) = 10\sqrt{3}\,\sqrt[4]{D^3\varepsilon}$ and $k''(\varepsilon) = k''\,\sqrt[4]{D^3\varepsilon}$, such that

$$\mathcal{M}_{k(\varepsilon)}(S) \subset \mathcal{M}_{k'(\varepsilon)}(\mathcal{P}) \oplus B_{2\sqrt{D\varepsilon}} \subset \mathcal{M}_{k''(\varepsilon)}(S) \oplus B_{4\sqrt{D\varepsilon}}.$$

Here, B_r denotes the ball centered at the origin of radius r, and $\oplus$ the Minkowski sum.

Consider now a family of point sets $\mathcal{P}_\varepsilon$ parametrized by ε such that $d_H(S, \mathcal{P}_\varepsilon) \leq \varepsilon$ and let ε tends to 0. Because $\mathcal{M}_\eta(S)$ tends to $\mathcal{M}(S)$ when η tends to 0, we deduce from the above inequalities, that

$$\lim_{\varepsilon \to 0} d_H(\mathcal{M}(S), \mathcal{M}_{10\sqrt[4]{9D^3\varepsilon}}(\mathcal{P}_\varepsilon)) = 0.$$

The above discussion provides an algorithm to approximate the medial axis of S within any specified error (see Algorithm 5).

Algorithm 5 Approximation of the Medial Axis

```
INPUT: A surface $S$ and a positive real $\varepsilon$
1. Sample $S$ so as to obtain a sample $\mathcal{P}$ such that $d_H(S, \mathcal{P}) \leq \varepsilon$;
2. Construct the Voronoi diagram of $\mathcal{P}$;
3. Remove from the diagram the faces for which the diameter of the set of contact
   points is smaller than $10\sqrt[4]{9D^3\varepsilon}$.
OUTPUT: A PL approximation of $\mathcal{M}(S)$
```

The main issue is therefore to compute a sample of points on S (step 1). If S is a surface of $\mathbb{R}^3$, one can use a surface mesh generator to mesh S and take for $\mathcal{P}$ the vertices of the mesh. Various algorithms can be found in Chap. 5 and we refer to that chapter for a thorough description and analysis of these algorithms. Especially attractive in the context of medial axis approximation, are the algorithms that are based on the 3-dimensional Delaunay triangulation since we get the Voronoi diagram of the sample points (step 2) at no additional cost. An example obtained with the surface mesh generator of Boissonnat and Oudot [65] is shown in Fig. 2.15.

Exercise 31. Let O be a bounded open set. Show that $\mathcal{M}(O)$ is a retract of O (and therefore has the same homotopy type as O) [243].

2.8 Voronoi Diagrams in CGAL

The Computational Geometry Algorithms Library CGAL [2] offers severals packages to compute Voronoi diagrams. Euclidean Voronoi diagrams of points and power diagrams are represented through their dual Delaunay and regular triangulations. CGAL provides Delaunay and regular triangulations in $\mathbb{R}^2$ and $\mathbb{R}^3$. The implementation is based on a randomized incremental algorithm

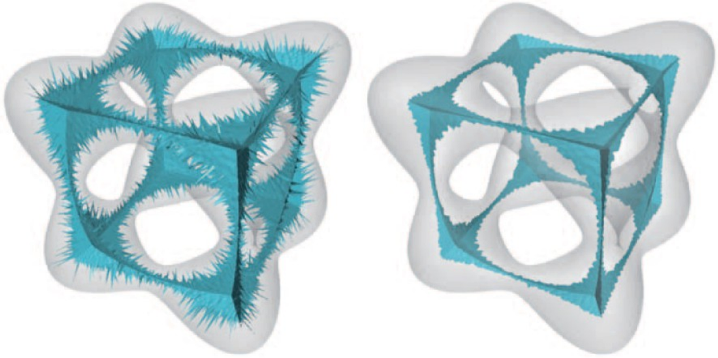

Fig. 2.15. Two λ-medial axes of the same shape, with λ increasing from left to right, computed as a subset of the Voronoi diagram of a sample of the boundary (courtesy of Steve Oudot)

using a variant of the Voronoi hierarchy described in Sect. 2.6. Delaunay triangulations are also provided in higher dimensions.

The library also contains packages to compute Voronoi diagrams of line segments [215] and Apollonius diagrams in $\mathbb{R}^2$ [216]. Those packages implement the incremental algorithm described in Sect. 2.6. A prototype implementation of Möbius diagrams in $\mathbb{R}^2$ also exists. This prototype computes the Möbius diagram as the projection of the intersection of a 3-dimensional power diagram with a paraboloid, as described in Sect. 2.4.1. This prototype also serves as the basis for the developement of a CGAL package for 3-dimensional Apollonius diagrams, where the boundary of each cell is computed as a 2-dimensional Möbius diagram, following the results of Sect. 2.4.3 [62]. See Fig. 2.8.

2.9 Applications

Euclidean and affine Voronoi diagrams have numerous applications we do not discuss here. The interested reader can consult other chapters of the book, most notably Chap. 5 on surface meshing and Chap. 6 on reconstruction. Other applications can be found in the surveys and the textbooks mentionned in the introduction.

Additively and multiplicatively weighted distances arise when modeling growing processes and have important applications in biology, ecology and other fields. Consider a number of crystals, all growing at the same rate, and all starting at the same time : one gets a number of growing circles. As these circles meet, they draw a Euclidean Voronoi diagram. In reality, crystals start

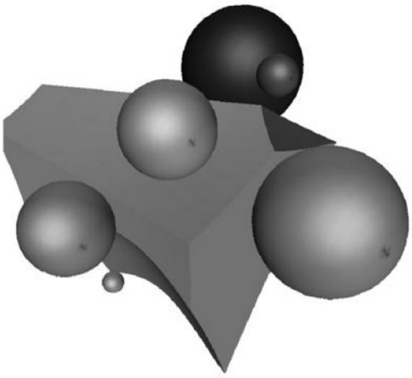

Fig. 2.16. A cell in an Apollonius diagram of spheres

growing at different times. If they still grow at the same rate, they will meet along an Apollonius diagram. This growth model is known as the Johnson-Mehl model in cell biology. In other contexts, all the crystals start at the same time, but grow at different rates. Now we get what is called the multiplicatively weighted Voronoi diagram, a special case of Möbius diagrams.

Spheres are common models for a variety of objects such as particles, atoms or beads. Hence, Apollonius diagrams have been used in physics, material sciences, molecular biology and chemistry [245, 339, 227, 228]. They have also been used for sphere packing [246] and shortest paths computations [256].

Euclidean Voronoi diagrams of non punctual objects find applications in robot motion planning [237, 197]. Medial axes are used for shape analysis [160], for computing offsets in Computer-Aided Design [118], and for mesh generation [290, 289, 316]. Medial axes are also used in character recognition, road network detection in geographic information systems, and other applications.

Acknowledgments

We thank D. Attali, C. Delage and M. Karavelas with whom part of the research reported in this chapter has been conducted. We also thank F. Chazal and A. Lieutier for fruitful discussions on the approximation of the medial axis.

3.6 Jamin-Lebedeff Interference Contrast Microscopy

Using specialized microscopic illumination techniques, spectacularly beautiful photographs of diatoms may be made. Combining darkfield with polarized light techniques can reveal beautiful but subtle interference colors at medium power magnification. Phase contrast images of diatoms may be manipulated using digital editing programs to bring out latent colors which are the product of refraction and interference, but no technique really compares to images which can be created using Jamin-Lebedeff interference contrast equipment with white light. A number of English and German microscope manufacturers made this equipment early in the 20th century, but the equipment is rare, often mishandled and thus unusable, and at best it is difficult to use. The polarized illuminating beam of light from the condenser is split into two parallel light bundles by a calcite plate in the condenser, one passing adjacent to the diatom and the other passing through the frustule. The two beams are recombined in the objective, which is fitted with an identical but opposite calcite plate, and the resulting image can be manipulated to generate interference colors which vary according to the optical path length of the part of the diatom being illuminated. The second author of this article has made a specialty of imaging diatom using this

2. If g is holomorphic, then calculate that

$$\triangle(f \circ g) = (\triangle f \circ g) \cdot |g'|^2.$$

3. If f is holomorphic, then calculate that

$$\triangle(f \circ g) = (f' \circ g) \triangle g + (f'' \circ g)[(D_x g)^2 + (D_y g)^2].$$

3. Isometries

In any mathematical subject there are morphisms: functions which preserve the relevant properties being studied. In linear algebra these are invertible linear maps, in Euclidean geometry these are rigid motions, and in Riemannian geometry these are "isometries." We now define the concept of isometry.

Definition 1. Let Ω_1 and Ω_2 be planar domains and let

$$f : \Omega_1 \to \Omega_2$$

be a continuously differentiable mapping with isolated zeros. Assume that Ω_2 is equipped with a metric ρ. We define the *pullback* of the metric ρ under the map f to be the metric on Ω_1 given by

$$f^*\rho(z) = \rho(f(z)) \cdot \left|\frac{\partial f}{\partial z}\right|.$$

Remark. The particular form that we use to define the pullback is motivated by the way that f induces mappings on tangent and cotangent vectors, but this motivation is irrelevant for us here.

It should be noted that the pullback of any metric under a conjugate holomorphic f will be the zero metric. Thus we have designed our definition of pullback so that holomorphic pullbacks will be the ones of greatest interest. This assertion will be made substantive in Proposition 3 below. ∎

Definition 2. Let Ω_1, Ω_2 be planar domains equipped with metrics ρ_1 and ρ_2, respectively. Let

$$f : \Omega_1 \to \Omega_2$$

be an onto, holomorphic mapping. If

$$f^*\rho_2(z) = \rho_1(z)$$

for all $z \in \Omega_1$ then f is called an *isometry* of the pair (Ω_1, ρ_1) with the pair (Ω_2, ρ_2).

The differential definition of isometry (Definition 2) is very natural from the point of view of differential geometry, but it is not intuitive. The next proposition relates the notion of isometry to more familiar ideas.

Proposition 3. *Let Ω_1, Ω_2 be domains and ρ_1, ρ_2 be metrics on these respective domains. If*

$$f : \Omega_1 \to \Omega_2$$

is an isometry of (Ω_1, ρ_1) to (Ω_2, ρ_2), then the following three properties hold:

(a) *If $\gamma : [a, b] \to \Omega_1$ is a continuously differentiable curve, then so is the push-forward $f_*\gamma \equiv f \circ \gamma$ and*

$$\ell_{\rho_1}(\gamma) = \ell_{\rho_2}(f_*\gamma).$$

(b) *If P, Q are elements of Ω_1 then*

$$d_{\rho_1}(P, Q) = d_{\rho_2}(f(P), f(Q)).$$

(c) *Part (b) implies that the isometry f is one-to-one. Then f^{-1} is well defined and f^{-1} is also an isometry.*

Proof. Assertion (b) is an immediate consequence of (a). Also (c) is a formal exercise in definition chasing. Therefore we shall prove (a).

By definition,

$$\begin{aligned}\ell_{\rho_2}(f_*\gamma) &= \int_a^b \left\|(f_*\gamma)'(t)\right\|_{\rho_2, f_*\gamma(t)}\, dt \\ &= \int_a^b \left\|\frac{\partial f}{\partial z}(\gamma(t)) \cdot \dot{\gamma}(t)\right\|_{\rho_2, f_*\gamma(t)} dt.\end{aligned}$$

With elementary manipulations, we see that the integrand equals

$$\begin{aligned}\left|\frac{\partial f}{\partial z}(\gamma(t))\right| \cdot \|\dot{\gamma}(t)\|_{\rho_2, f_*\gamma(t)} &= \left|\frac{\partial f}{\partial z}(\gamma(t))\right| \cdot |\dot{\gamma}(t)| \cdot \rho_2(f(\gamma(t))) \\ &= \|\dot{\gamma}(t)\|_{f^*\rho_2, \gamma(t)} \\ &= \|\dot{\gamma}(t)\|_{\rho_1, \gamma(t)},\end{aligned}$$

since f is an isometry. Substituting this back into the formula for the length of $f_*\gamma$ gives

$$\ell_{\rho_2}(f_*\gamma) = \int_a^b \|\dot{\gamma}(t)\|_{\rho_1, \gamma(t)}\, dt = \ell_{\rho_1}(\gamma).$$

This ends the proof. ■

It is not difficult to see that any positively oriented rigid motion of the Euclidean plane—rotations, translations, and their compositions (but *not* reflections, because they are conjugate holomorphic)—is an isometry of the Euclidean metric. In the next section we shall consider the isometries of the Poincaré metric on the disc.

If you have previously studied metric space theory or Banach space theory then you may have already encountered the term “isometry.” The essential notion is that an isometry should preserve distance. In fact, you can prove as an exercise that if f is a holomorphic mapping of (Ω_1, ρ_1) onto (Ω_2, ρ_2) that preserves distance then f is an isometry according to Definition 2. (Hint: compose f with a curve and differentiate.)

We close this section by noting an important technical fact about isometries:

Proposition 4. *Let ρ_j be metrics on the domains Ω_j, $j = 1, 2, 3$, respectively. Let $f : \Omega_1 \to \Omega_2$ and $g : \Omega_2 \to \Omega_3$ be isometries. Then $g \circ f$ is an isometry of the metric ρ_1 to the metric ρ_3.*

Proof. We calculate that

$$\rho_3(g([f(z)]) \cdot |g'(f(z))| = \rho_2(f(z))$$

hence

$$\rho_3(g([f(z)]) \cdot |g'(f(z))| \cdot |f'(z)| = \rho_2(f(z)) \cdot |f'(z)| = \rho_1(z).$$

In other words,

$$\rho_3(g \circ f(z)) \cdot |(g \circ f)'(z)| = \rho_1(z),$$

as required by the definition of an isometry. ∎

4. The Poincaré Metric

The Poincaré metric on the disc has occurred in many of the examples in previous sections. This metric is the paradigm for much of what we want to do in this book, and we want to treat it in some detail here. The Poincaré metric on the disc D is given by

$$\rho(z) = \frac{1}{1 - |z|^2}.$$

(For the record, we note that there is no agreement in the literature as to what constant goes in the numerator; many references use a factor of $\sqrt{2}$ or $1/\sqrt{2}$.)

In this and succeeding sections, we shall use the phrase "conformal map" to refer to a holomorphic mapping of one planar region to another which is both one-to-one and onto.

Proposition 1. *Let ρ be the Poincaré metric on the disc D. Let $h : D \to D$ be a conformal self-map of the disc. Then h is an isometry of the pair (D, ρ) with the pair (D, ρ).*

Proof. We have that

$$h^*\rho(z) = \rho(h(z)) \cdot |h'(z)|.$$

Because of Theorem 3 of Section 0.2 (and using Proposition 4 of Section 1.3), we now have two cases:

(i) If h is a rotation, then $h(z) = \mu \cdot z$ for some unimodular constant $\mu \in \mathbb{C}$. So $|h'(z)| = 1$ and

$$h^*\rho(z) = \rho(h(z)) = \rho(\mu z) = \frac{1}{1 - |\mu z|^2} = \frac{1}{1 - |z|^2} = \rho(z)$$

as desired.

(ii) If h is a Möbius transformation (these were defined in Section 0.2, following Theorem 2), then

$$h(z) = \frac{z - a}{1 - \overline{a}z}, \qquad \text{some constant } a \in D.$$

But then

$$|h'(z)| = \frac{1 - |a|^2}{|1 - \overline{a}z|^2}$$

and

$$\begin{aligned} h^*\rho(z) &= \rho\left(\frac{z-a}{1-\overline{a}z}\right) \cdot |h'(z)| \\ &= \frac{1}{1 - \left|\frac{z-a}{1-\overline{a}z}\right|^2} \cdot \frac{1 - |a|^2}{|1 - \overline{a}z|^2} \\ &= \frac{1 - |a|^2}{|1 - \overline{a}z|^2 - |z - a|^2} \\ &= \frac{1 - |a|^2}{1 - |z|^2 - |a|^2 + |a|^2|z|^2} \\ &= \frac{1}{1 - |z|^2} \\ &= \rho(z). \end{aligned}$$

Since any conformal self-map of D is a composition of maps of the form (i) or (ii), the proposition is proved. ■

We know from this result and from Proposition 3 in Section 3 that conformal self-maps of the disc preserve Poincaré distance. To understand what this means, consider the Möbius transformation

$$\phi(z) = \frac{z+a}{1+\overline{a}z}.$$

Then ϕ maps the disc to the disc conformally. It does not preserve Euclidean distance, but it *does* preserve Poincaré distance. See Figure 1.

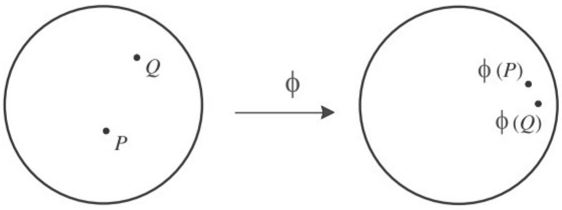

Figure 1.

We can use what we have learned so far to calculate the Poincaré metric explicitly.

Proposition 2. *If P and Q are points of the disc D, then the Poincaré distance of P to Q is*

$$d_\rho(P,Q) = \frac{1}{2}\log\left(\frac{1+\left|\frac{P-Q}{1-\overline{P}Q}\right|}{1-\left|\frac{P-Q}{1-\overline{P}Q}\right|}\right).$$

Proof. In case $P = 0$ and $Q = R + i0$, the result was already noted in Section 1. In the general case, note that we may define

$$\phi(z) = \frac{z-P}{1-\overline{P}z},$$

a Möbius transformation of the disc. Then, by Proposition 1,

$$d_\rho(P, Q) = d_\rho(\phi(P), \phi(Q)) = d_\rho(0, \phi(Q)).$$

Next we have

$$d_\rho(0, \phi(Q)) = d_\rho(0, |\phi(Q)|) \tag{$*$}$$

since there is a rotation of the disc taking $\phi(Q)$ to $|\phi(Q)| + i0$. Finally,

$$|\phi(Q)| = \left| \frac{P - Q}{1 - \overline{P}Q} \right|,$$

so that $(*)$ together with the special case treated in the the first sentence gives the result. ■

One of the reasons that the Poincaré metric is so useful is that it induces the same topology as the usual Euclidean metric topology. That is our next result.

Proposition 3. *The topology induced on the disc by the Poincaré metric is the usual planar topology.*

Proof. A neighborhood basis for the topology of the Poincaré metric at the origin is given by the balls

$$\mathbf{B}(0, r) = \{z : d_\rho(0, z) < r\}.$$

However, a calculation using Proposition 2 yields that these balls are the same as the Euclidean discs

$$\left\{ z : |z| < \frac{e^{2r} - 1}{e^{2r} + 1} \right\}.$$

These discs form a neighborhood basis for the origin in the Euclidean topology. Thus we find that the two topologies are the same at the origin. Now the origin can be moved to any other point $a \in D$ by the Möbius transformation

$$z \longmapsto \frac{z+a}{1+\overline{a}z}.$$

Since the Poincaré metric is invariant under Möbius transformations, and since Möbius transformations take circles to circles (after all, they are linear fractional), the two topologies are the same at every point.

■

One of the most striking facts about the Poincaré metric on the disc is that it turns the disc into a *complete* metric space. How could this be? The boundary is missing! The reason that the disc is complete in the Poincaré metric is the same as the reason that the plane is complete in the Euclidean metric—the boundary is infinitely far away. We now prove this assertion.

Proposition 4. *The unit disc D, when equipped with the Poincaré metric, is a complete metric space.*

Proof. Let p_j be a sequence in D that is Cauchy in the Poincaré metric. Then the sequence is bounded in that metric. So there is a positive, finite M such that

$$d_\rho(0, p_j) \leq M, \quad \text{all } j.$$

With Proposition 2 this translates to

$$\frac{1}{2}\log\left(\frac{1+|p_j|}{1-|p_j|}\right) \leq M.$$

Solving for $|p_j|$ gives

$$|p_j| \leq \frac{e^{2M}-1}{e^{2M}+1} < 1.$$

Thus our sequence is contained in a relatively compact subset of the disc. A similar calculation yields that the sequence must in fact be Cauchy in the Euclidean metric. Therefore it converges to a limit point in the disc, as required for completeness. ■

In the proof of Proposition 2 and in the subsequent remarks we used the fact, whose verification was sketched earlier, that the curve of least length (in the Poincaré metric) connecting 0 to a point of the form $R+i0$ is in fact a Euclidean segment. More generally, the shortest path from 0 to any point w is a rotation of the shortest path from 0 to $|w|+i0$, which is a segment. Let us now calculate the "curve of least length" connecting any two given points P and Q in the disc.

Proposition 5. *Let* P, Q *be elements of the unit disc. The "curve of least Poincaré length" connecting* P *to* Q *is*

$$\gamma_{P,Q}(t) = \frac{t\frac{Q-P}{1-Q\overline{P}} + P}{1 + t\overline{P}\cdot\frac{Q-P}{1-Q\overline{P}}}, \qquad 0 \leq t \leq 1.$$

Proof. Define the Möbius transformation

$$\phi(z) = \frac{z-P}{1-\overline{P}z}.$$

By what we already know about shortest paths emanating from the origin, the curve $\tau(t) \equiv t\cdot\phi(Q)$ is the shortest curve from $\phi(P)=0$ to $\phi(Q)$, $0 \leq t \leq 1$. Applying the isometry

$$\phi^{-1}(z) = \frac{z+P}{1+\overline{P}z}$$

to τ we obtain that

$$\phi^{-1}\circ\tau(t) = \frac{(t\phi(Q)+P)}{(1+\overline{P}t\phi(Q))}$$

is the shortest path from P to Q. Since $\phi^{-1}\circ\tau = \gamma_{P,Q}$, we are done.

■

Let us analyze the curves discovered in Proposition 5. First notice that, since the curve $\gamma_{P,Q}$ is the image under a linear fractional transformation of a part of a line, the trace of $\gamma_{P,Q}$ is, therefore, either a line segment or an arc of a circle. In fact, if P and Q are collinear with 0, then the formula for $\gamma_{P,Q}$ quickly reduces to that for a segment; otherwise $\gamma_{P,Q}$ traces an arc of a Euclidean circle. Which circle is it?

Matters are simplest if we let t range over the entire real line and look for the whole circle. We find that $t = \infty$ corresponds to the point $1/\overline{P}$. It is now a simple, but tedious, calculation to determine the Euclidean center and radius of the circle determined by the three points P, Q, $1/\overline{P}$ (note that, by symmetry, the circle will also pass through $1/\overline{Q}$). The circle is depicted in Figure 2. Notice that since the segment $\{t + i0 : -1 \leq t \leq 1\}$ is orthogonal to ∂D at the endpoints 1 and -1, conformality dictates that the circular arcs of least length provided by Proposition 5 are orthogonal to ∂D at the points of intersection. Some of these "geodesic arcs" are exhibited in Figure 3.

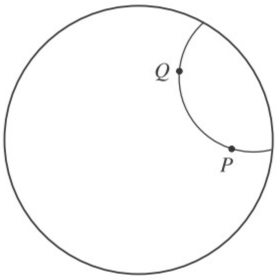

Figure 2.

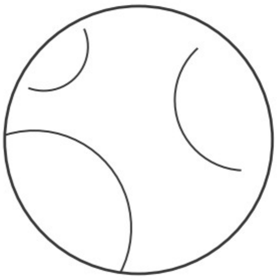

Figure 3.

A final note on this matter is that geodesics are particularly easy to calculate in the upper-half-plane realization $\mathcal{U}$ of the disc. For the geodesic circles will then have their centers on the boundary (i.e., the real line). If $\widetilde{P}$, $\widetilde{Q}$ are points of $\mathcal{U}$, then the perpendicular bisector of the segment connecting these points will intersect the real axis at the center C of the circular arc that forms the geodesic through $\widetilde{P}$ and $\widetilde{Q}$. See Figure 4.

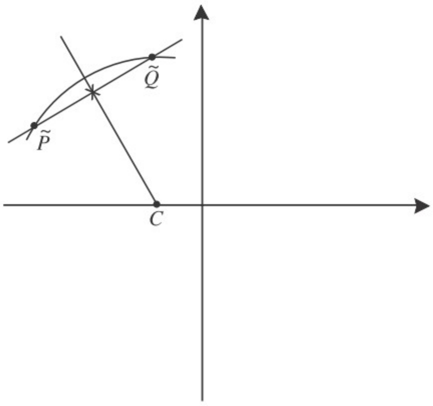

Figure 4.

We next see that the Poincaré metric is characterized by its property of invariance under conformal maps.

Proposition 6. *If* $\widetilde{\rho}(z)$ *is a metric on* D *which is such that every conformal map of the disc is an isometry of the pair* $(D, \widetilde{\rho})$ *with the pair* $(D, \widetilde{\rho})$*, then* $\widetilde{\rho}$ *is a constant multiple of the Poincaré metric* ρ*.*

Proof. The hypothesis guarantees that if $z_0 \in D$ is fixed and

$$h(z) = \frac{z + z_0}{1 + \overline{z}_0 z}$$

then

$$h^*\widetilde{\rho}(0) = \widetilde{\rho}(0).$$

Writing out the left-hand side gives

$$|h'(0)|\widetilde{\rho}(h(0)) = \widetilde{\rho}(0)$$

or

$$\widetilde{\rho}(z_0) = \frac{1}{1 - |z_0|^2} \cdot \widetilde{\rho}(0) = \widetilde{\rho}(0) \cdot \rho(z_0).$$

Thus we have exhibited $\widetilde{\rho}$ as the constant $\widetilde{\rho}(0)$ times ρ. ■

Now that we know that the Poincaré metric is the right metric for complex analysis on the disc, a natural next question is to determine which other maps preserve the Poincaré metric.

Proposition 7. *Let $f : D \to D$ be continuously differentiable and let ρ be the Poincaré metric. If f pulls back the pair (D, ρ) to the pair (D, ρ), then f is holomorphic and is one-to-one. We may conclude then that f is the composition of a Möbius transformation and a rotation (see Theorem 3 of Section 0.2).*

Proof. First suppose that $f(0) = 0$. For $R > 0$ let C_R be the set of points in D that have Poincaré distance R from 0. Since the Poincaré metric is invariant under rotations (after all, rotations are holomorphic self-maps), it follows that C_R is a Euclidean circle (however this circle will have Euclidean radius $(e^{2R}-1)/(e^{2R}+1)$, not R). Since $f(0) = 0$ and f preserves the metric, it follows that $f(C_R) = C_R$. The fact that f is distance-preserving then shows that f is one-to-one on each C_R. As a result, f is globally one-to-one.

Let $P \in C_R$. Then

$$\frac{|f(P) - f(0)|}{|P - 0|} = \frac{|f(P)|}{|P|} = 1.$$

Letting $R \to 0^+$ we conclude that f is conformal at the origin (that is, f preserves length infinitesimally). Since f pulls back the metric ρ, we can be sure that $\partial\rho/\partial z \neq 0$ at the origin.

Now we drop the special hypothesis that $f(0) = 0$. Pick an arbitrary $z_0 \in D$ and set $w_0 = f(z_0)$. Define

$$\phi(z) = \frac{z + z_0}{1 + \overline{z}_0 z}, \qquad \psi(z) = \frac{z - w_0}{1 - \overline{w}_0 z}.$$

Also define

$$g = \psi \circ f \circ \phi.$$

Then $g(0) = 0$ and g is an isometry (since ψ, f, and ϕ are); therefore the argument in the last paragraph applies and g is conformal at the origin. It follows as before that $\partial g/\partial z \neq 0$ at the origin.

We conclude that f is conformal at every point—since ψ and ϕ are—and $\partial f/\partial z \neq 0$ at every point. Therefore f is holomorphic. ■

Propositions 1 and 7 demonstrate that there are plenty of isometries of the unit disc in the Poincaré metric. On the other hand, isometries are very rigid objects. They are completely determined by their first-order behavior at just one point. While a proof of this assertion in general is beyond us at this point, we can certainly prove the result for the Poincaré metric on the disc.

Proposition 8. *Let ρ be the Poincaré metric on the disc. Let f be an isometry of the pair (D, ρ) with the pair (D, ρ). If $f(0) = 0$ and $\partial f/\partial z(0) = 1$ then $f(z) \equiv z$.*

Proof. By Proposition 7, f must be holomorphic. Since f preserves the origin and is one-to-one and onto, f must be a rotation. Since $f'(0) = 1$, it follows that f is the identity. ■

Corollary 8.1. *Let f and g be isometries of the pair (D, ρ) with the pair (D, ρ). Let $z_0 \in D$ and suppose that $f(z_0) = g(z_0)$ and $(\partial f/\partial z)(z_0) = (\partial g/\partial z)(z_0)$. Then $f(z) \equiv g(z)$.*

Proof. We noted in Section 2 that g^{-1} is an isometry. If ψ is a Möbius transformation that takes 0 to z_0, then $\psi^{-1} \circ g^{-1} \circ f \circ \psi$ satisfies the hypothesis of the Proposition. As a result $\psi^{-1} \circ g^{-1} \circ f \circ \psi(z) \equiv z$ or $g(z) \equiv f(z)$. ■

5. The Schwarz Lemma

One of the important facts about the Poincaré metric is that it can be used to study not just conformal maps (as in Section 1.4) but all holomorphic maps of the disc. The key to this assertion is the classical Schwarz lemma. We begin with an elegant geometric interpretation of the Schwarz–Pick lemma (see Section 0.2).

Proposition 1. *Let $f : D \to D$ be holomorphic. Then f is distance-decreasing in the Poincaré metric ρ. That is, for any $z \in D$,*

$$f^*\rho(z) \leq \rho(z).$$

The integrated form of this assertion is that if $\gamma : [0, 1] \to D$ is a continuously differentiable curve then

$$\ell_\rho(f_*\gamma) \leq \ell_\rho(\gamma).$$

Therefore, if P and Q are elements of D, we may conclude that

$$d_\rho(f(P), f(Q)) \leq d_\rho(P, Q).$$

Proof. Now

$$f^*\rho(z) \equiv |f'(z)|\rho(f(z)) = |f'(z)| \cdot \frac{1}{1 - |f(z)|^2}$$

and

$$\rho(z) = \frac{1}{1 - |z|^2}$$

20.1 COORDINATES

Distance Formula

Distance between $A(x_1, y_1, z_1)$ and $B(x_2, y_2, z_2)$ is given by

$$AB = \sqrt{(x_2 - x_1)^2 + (y_2 - y_1)^2 + (z_2 - z_1)^2}.$$

Section Formulae

The coordinates of the point P which divides the join of $A(x_1, y_1, z_1)$ and $B(x_2, y_2, z_2)$ in the ratio $m : n$ are

$$\left(\frac{mx_2 + nx_1}{m+n}, \frac{my_2 + ny_1}{m+n}, \frac{mz_2 + nz_1}{m+n}\right)$$

By taking $m = n$, we find the coordinates of the mid-point of AB as

$$\left(\frac{x_1 + x_2}{2}, \frac{y_1 + y_2}{2}, \frac{z_1 + z_2}{2}\right)$$

Coordinates of any point on the join of two points $A(x_1,y_1,z_1)$ and $B(x_2,y_2,z_2)$ are $\left(\frac{\lambda x_2 + x_1}{\lambda + 1}, \frac{\lambda y_2 + y_1}{\lambda + 1}, \frac{\lambda z_2 + z_1}{\lambda + 1}\right)$ where $\lambda \neq -1$. If λ takes only positive real values, we get the coordinates of the points on the segment AB (except A and B).

Volume of a Tetrahedron

If $A_i(x_i, y_i, z_i)$, $i = 1, 2, 3, 4$ are the vertices of a tetrahedron, its volume is equal to

$$\frac{1}{6}\left|\begin{vmatrix} x_1 & y_1 & z_1 & 1 \\ x_2 & y_2 & z_2 & 1 \\ x_3 & y_3 & z_3 & 1 \\ x_4 & y_4 & z_4 & 1 \end{vmatrix}\right|$$

Direction-Cosines

If α, β, γ are the angles that a given directed line makes with the positive directions $X'OX$, $Y'OY$, $Z'OZ$ of the coordinate axes, then $\cos \alpha$, $\cos \beta$, $\cos \gamma$ are called the *direction-cosines* of the line.

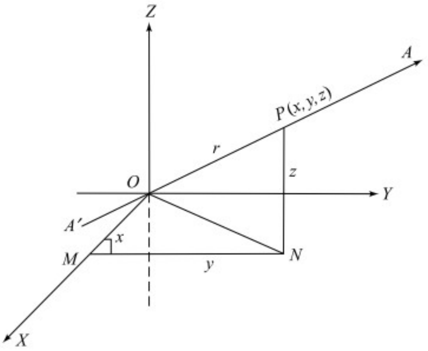

Fig. 20.1

Let $P(x, y, z)$ be any point on $A'OA$, and let the measure of OP be r. Let PN be the perpendicular from P on the plane XOY, and NM be the perpendicular from N on OX. Then $PN = z$, $NM = y$, $OM = x$

$$x = r \cos \alpha,\ y = r \cos \beta,\ z = r \cos \gamma.$$

and $$\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma = 1.$$

Direction-Ratios

If l, m, n be the direction-cosines of a line OP and a, b, c be numbers proportional to l, m, n respectively, then a, b, c are called the direction ratios of OP. If l, m, n be the direction-cosines of a line and k ($\neq 0$) be any number, then kl, km, kn are the direction-ratios of OP.

If a, b, c are the direction-ratios of a line, the actual direction-cosines $\cos \alpha$, $\cos \beta$, $\cos \gamma$ are obtained from the relations

$$\frac{\cos \alpha}{a} = \frac{\cos \beta}{b} = \frac{\cos \gamma}{c}$$

$$= \pm\frac{\sqrt{\cos^2 \alpha + \cos^2 \beta + \cos^2 \gamma}}{\sqrt{a^2 + b^2 + c^2}} = \frac{\pm 1}{\sqrt{a^2 + b^2 + c^2}}$$

If P be the point (a, b, c), and $\cos\alpha$, $\cos\beta$, $\cos\gamma$ are the direction cosines of the directed line OP, then

$$\cos\alpha = \frac{a}{\sqrt{(a^2+b^2+c^2)}},\ \cos\beta = \frac{b}{\sqrt{(a^2+b^2+c^2)}},$$

$$\cos\gamma = \frac{c}{\sqrt{(a^2+b^2+c^2)}}$$

The direction-cosines of PO are

$$-\frac{a}{\sqrt{(a^2+b^2+c^2)}}, -\frac{b}{\sqrt{(a^2+b^2+c^2)}}, -\frac{c}{\sqrt{(a^2+b^2+c^2)}}$$

Illustration 1

Find the direction cosines of the line whose direction ratios are 12, 4, – 18.

Solution: Direction cosines of the given line are

$$\frac{12}{\sqrt{(12)^2+(4)^2+(-18)^2}}, \frac{4}{\sqrt{(12)^2+(4)^2+(-18)^2}}, \frac{-18}{\sqrt{(12)^2+(4)^2+(-18)^2}}$$

$$\text{or } \frac{12}{22}, \frac{4}{22}, \frac{-18}{22}$$

$$\text{or } \frac{6}{11}, \frac{2}{11}, \frac{-9}{11}.$$

Angle Between Two Lines

(a) If θ is an angle between two lines whose direction-cosines are (l_1, m_1, n_1) and (l_2, m_2, n_2) then

$$\cos\theta = l_1l_2 + m_1m_2 + n_1n_2.$$

The expressions for $\sin\theta$, $\tan\theta$ are given below:

$$\sin^2\theta = \begin{vmatrix} m_1 & n_1 \\ m_2 & n_2 \end{vmatrix}^2 + \begin{vmatrix} n_1 & l_1 \\ n_2 & l_2 \end{vmatrix}^2 + \begin{vmatrix} l_1 & m_1 \\ l_2 & m_2 \end{vmatrix}^2$$

and $\tan\theta = \pm\,[\Sigma\,(l_1 m_2 - l_2 m_1)^2]^{1/2}/(l_1l_2 + m_1m_2 + n_1n_2)$

The lines are parallel to each other if and only if

$$l_1/l_2 = m_1/m_2 = n_1/n_2.$$

Also the lines are perpendicular to each other provided

$$l_1l_2 + m_1m_2 + n_1n_2 = 0.$$

(b) Angle θ between two lines whose direction-ratios are a_1, b_1, c_1 and a_2, b_2, c_2 is given by

$$\cos\theta = \pm\frac{a_1a_2 + b_1b_2 + c_1c_2}{\sqrt{a_1^2+b_1^2+c_1^2}\,\sqrt{a_2^2+b_2^2+c_2^2}}$$

$$\sin\theta = \pm\frac{[(a_1b_2-a_2b_1)^2+(b_1c_2-b_2c_1)^2+(c_1a_2-c_2a_1)^2]^{1/2}}{\sqrt{a_1^2+b_1^2+c_1^2}\,\sqrt{a_2^2+b_2^2+c_2^2}}$$

$$\tan\theta = \pm\frac{[(a_1b_2-a_2b_1)^2+(b_1c_2-b_2c_1)^2+(c_1a_2-c_2a_1)^2]^{1/2}}{a_1a_2+b_1b_2+c_1c_2}$$

The lines are parallel to each other if and only if

$$\frac{a_1}{a_2} = \frac{b_1}{b_2} = \frac{c_1}{c_2}$$

Also, the lines are perpendicular to each other if and only if

$$a_1a_2 + b_1b_2 + c_1c_2 = 0.$$

Illustration 2

Direction ratios of a line L_1, are 1, –1, 1 and of L_2 are 1, 0, λ. Find the value of λ so that L_1 and L_2 are perpendicular to each other.

Solution: The line L_1 and L_2 are perpendicular if the angle θ between them is 90°

$$\Rightarrow \cos\theta = \frac{1(1)+(-1)(0)+(1)(\lambda)}{\sqrt{(1)^2+(-1)^2+(1)^2}\,\sqrt{1^2+0+\lambda^2}} = \cos 90° = 0$$

$$\Rightarrow \lambda = -1$$

20.2 THE PLANE

Equation of a Plane

A plane is represented by an equation of the first degree i.e. by $ax + by + cz + d = 0$. Conversely, every equation of the first degree in x, y, z represents a plane.

(a) Equation of the yz-plane is $x = 0$.

(b) Equation of the zx-plane is $y = 0$.

(c) Equation of the xy-plane is $z = 0$.

(d) If l, m, n be the direction cosines of the normal to a plane and p be the length of the perpendicular from the origin on the plane, then an equation of the plane is $lx + my + nz = p$.

Illustration 3

Find the direction cosines of the normal to the plane $4x - 3y + 5z = 25$ and the length of the perpendicular from the origin on this plane

Solution: Direction ratios of the normal to the plane are 4, –3, 5. So direction cosines are

$$l = \frac{4}{\sqrt{4^2+(-3)^2+5^2}},\ m = \frac{-3}{\sqrt{4^2+(-3)^2+5^2}},\ n = \frac{5}{\sqrt{4^2+(-3)^2+5^2}}$$

$$\text{or } l = \frac{4}{5\sqrt{2}},\ m = \frac{-3}{5\sqrt{2}},\ n = \frac{5}{5\sqrt{2}}$$

We can write the equation of the plane as

$$\frac{4}{5\sqrt{2}}x - \frac{3}{5\sqrt{2}}y + \frac{5}{5\sqrt{2}}z = \frac{25}{5\sqrt{2}}$$

or $lx + my + nz = p$ where $p = \dfrac{25}{5\sqrt{2}} = \dfrac{5}{\sqrt{2}}$

is the required distance of the plane from the origin.

(e) If a plane makes intercepts a, b, c on the axes of x, y, z respectively its equation is

$$\frac{x}{a} + \frac{y}{b} + \frac{z}{c} = 1.$$

Systems of Planes

An equation of a plane contains three independent constants, as such a plane is uniquely determined by three independent conditions. If we consider a plane satisfying just two given conditions, its equation will contain one arbitrary constant. If we consider a plane satisfying one given condition, its equation will contain two arbitrary constants.

We give below the equations of some well-known systems of planes:

(i) The equation $ax + by + cz + k = 0$ represents a system of planes parallel to the plane $ax + by + cz + d = 0$, k being a parameter.

(ii) The equation $ax + by + cz + k = 0$, represents a system of planes perpendicular to the line $\dfrac{x}{a} = \dfrac{y}{b} = \dfrac{z}{c}$.

(iii) The equation $(a_1x + b_1y + c_1z + d_1) + k\,(a_2x + b_2y + c_2z + d_2) = 0$ represents a system of planes passing through the intersection of the planes $a_1x + b_1y + c_1z + d_1 = 0$ and $a_2x + b_2y + c_2z + d_2 = 0$, k being a parameter.

Illustration 4

Find the equation of the plane passing through the intersection of the planes $3x + 4y + 7z + 5 = 0$ and $2x - 3y + 4z - 6 = 0$ and making an intercept of 1 unit on the axis of x.

Solution: Equation of any plane through the intersection of the given planes is

$3x + 4y + 7z + 5 + \lambda\,(2x - 3y + 4z - 6) = 0$

Intercept on x-axis $= \dfrac{6\lambda - 5}{3 + 2\lambda} = 1 \Rightarrow \lambda = 2$

So the required equation of the plane is

$7x - 2y + 15z - 7 = 0$

(iv) The equation $A(x - x_1) + B(y - y_1) + C(z - z_1) = 0$. represents a system of planes passing through the point (x_1, y_1, z_1), the ratios of A, B, C being the two parameters.

It may be noted that (i)–(iii) above are examples of one-parameter family of planes and (iv) is an example of a two-parameter family of planes.

Angle Between Two Planes

Angle θ between the planes $a_1x + b_1y + c_1z + d_1 = 0$, $a_2x + b_2y + c_2z + d_2 = 0$, is given by

$$\cos\theta = \pm\frac{a_1a_2 + b_1b_2 + c_1c_2}{\sqrt{(a_1^2 + b_1^2 + c_1^2)}\,\sqrt{(a_2^2 + b_2^2 + c_2^2)}}$$

Parallelism and Perpendicularity of Two Planes

The planes $a_1x + b_1y + c_1z + d_1 = 0$, $a_2x + b_2y + c_2z + d_2 = 0$ are parallel if and only if

$$\frac{a_1}{a_2} = \frac{b_1}{b_2} = \frac{c_1}{c_2};$$

and perpendicular if and only if

$$a_1a_2 + b_1b_2 + c_1c_2 = 0.$$

Two Sides of a Plane

Two points $P(x_1, y_1, z_1)$ and $Q(x_2, y_2, z_2)$ lie on the same or different sides of the plane $ax + by + cz + d = 0$ according as $ax_1 + by_1 + cz_1 + d$ and $ax_2 + by_2 + cz_2 + d$ are of the same or of different signs.

Length of the Perpendicular from a Point to a Plane

The perpendicular distance of the point (x_1, y_1, z_1) from the plane $lx + my + nz = p$ is $|p - lx_1 - my_1 - nz_1|$, where l, m, n are direction cosines of the normal to the plane and p is the length of the perpendicular to the plane from the origin.

The perpendicular distance of the point (x_1, y_1, z_1) from the plane $ax + by + cz + d = 0$ is

$$\frac{|\,ax_1 + by_1 + cz_1 + d\,|}{\sqrt{(a^2 + b^2 + c^2)}}$$

Bisectors of the Angles between Two Planes

(A) Let $a_1x + b_1y + c_1z + d_1 = 0$ and $a_2x + b_2y + c_2z + d_2 = 0$ be the equations of two planes, written in such a way that d_1 and d_2 are both positive. Then

$$\frac{a_1x + b_1y + c_1z + d_1}{\sqrt{(a_1^2 + b_1^2 + c_1^2)}} = \frac{a_2x + b_2y + c_2z + d_2}{\sqrt{(a_2^2 + b_2^2 + c_2^2)}}$$

is the equation of the plane bisecting that angle between the given planes which contains the origin, and

$$\frac{a_1x + b_1y + c_1z + d_1}{\sqrt{(a_1^2 + b_1^2 + c_1^2)}} = -\frac{a_2x + b_2y + c_2z + d_2}{\sqrt{(a_2^2 + b_2^2 + c_2^2)}}$$

is the equation of the plane bisecting that angle between the given planes which does not contain the origin.

Illustration 5

Find the angle between the planes $x + y + z + 1 = 0$ and $x - y + z - 1 = 0$. Also find the equation of the plane bisecting the angle between these planes which contain the origin.

Solution: If θ is the angle between these planes, then

$$\Rightarrow \cos\theta = \frac{(1)\times(1)+(1)(-1)+(1)(1)}{\sqrt{1^2+1^2+1^2}\sqrt{(1)^2+(-1)^2+(1)^2}} = \frac{1}{3}$$

$$\Rightarrow \theta = \cos^{-1}(1/3)$$

Equation of the required plane bisecting the angle between the given planes is

$$\frac{x+y+z+1}{\sqrt{1^2+1^2+1^2}} = \frac{-x+y-z+1}{\sqrt{(1)^2+(-1)^2+(1)^2}}$$

$$\Rightarrow x+z=0$$

(B) The equations of the planes bisecting the angles between the planes $a_1x + b_1y + c_1z + d_1 = 0$ and $a_2x + b_2y + c_2z + d_2 = 0$ are

$$\frac{a_1x+b_1y+c_1z+d_1}{\sqrt{\left(a_1^2+b_1^2+c_1^2\right)}} = \pm\frac{a_2x+b_2y+c_2z+d_2}{\sqrt{\left(a_2^2+b_2^2+c_2^2\right)}}$$

Of these two planes one makes angle less than 45° with both the given planes and the other makes angles greater than 45° with both the given planes.

The bisector of the acute angle between the given planes is the one which makes angles less than 45° with both the given planes.

20.3 THE STRAIGHT LINE

Equations of a Line

An equation of the first degree represents a plane. Two equations of the first degree are satisfied by the coordinates of every point on the line of intersection of the planes represented by them. Therefore, the two equations together represent that line. Therefore $ax + by + cz + d = 0$ and $a'x + b'y + c'z + d' = 0$ together represent a straight line.

The Equations to the Axes of Coordinates

(a) Equations to the x-axis are $y = 0, z = 0$.
(b) Equations to the y-axis are $x = 0, z = 0$.
(c) Equations to the z-axis are $x = 0, y = 0$.

Symmetrical form of the Equation of a Line

If a straight line passes through a given point (x_1, y_1, z_1) and has direction cosines l, m, n, then the coordinates of any point on it satisfy the equations

$$\frac{x-x_1}{l} = \frac{y-y_1}{m} = \frac{z-z_1}{n} \; (= r)$$

These equations enable us to write down the coordinates of any point (x, y, z) on the line in terms of its distance r from the point (x_1, y_1, z_1) in the form:

$$x = x_1 + lr,\; y = y_1 + mr,\; z = z_1 + nr.$$

This form is called the *distance form* of the equation of a line.

Illustration 6

P and Q are two points on a line whose direction ratios are 3, 5, 1. If the coordinates of P are $(1, -4, 2)$ and $(PQ)^2 = 35$. Find the coordinates of Q.

Solution: Direction cosines of the line are

$$\frac{3}{\sqrt{3^2+5^2+1^2}},\quad \frac{5}{\sqrt{3^2+5^2+1^2}},\quad \frac{1}{\sqrt{3^2+5^2+1^2}}$$

or $\frac{3}{\sqrt{35}}, \frac{5}{\sqrt{35}}, \frac{1}{\sqrt{35}}$

So the equation of the line can be written as

$$\frac{x-1}{3/\sqrt{35}} = \frac{y+4}{5/\sqrt{35}} = \frac{z-2}{1/\sqrt{35}} = r = \sqrt{35} = PQ\,.$$

and the coordinates of Q are.

$(3 + 1, 5 - 4, 1 + 2) = (4, 1, 3)$

If l, m, n are only direction-ratios of the line and not the actual direction cosines, even then the equations represent a straight line, but in this case r is only a parameter, it is *not* the distance of (x, y, z) from (x_1, y_1, z_1).

Conversely, the equations

$$\frac{x-a}{l} = \frac{y-b}{m} = \frac{z-c}{n},$$

represent a straight line passing through the point (a, b, c) and having direction ratios l, m, n.

Equation of Line through two Given Points

If $A(x_1, y_1, z_1)$, $B(x_2, y_2, z_2)$ be two given points, an equation of the line AB is

$$\frac{x-x_1}{x_2-x_1} = \frac{y-y_1}{y_2-y_1} = \frac{z-z_1}{z_2-z_1}$$

The coordinates of a variable point on AB can be expressed in terms of a parameter λ in the form

$$x = \frac{\lambda x_2 + x_1}{\lambda+1},\; y = \frac{\lambda y_2 + y_1}{\lambda+1},\; z = \frac{\lambda z_2 + z_1}{\lambda+1},$$

λ being any real number different from -1. In fact, (x, y, z) are the coordinates of the point which divides the join of A and B in the ratio $\lambda : 1$.

Changing unsymmetrical form to symmetrical form

The unsymmetrical form of a line

$$ax + by + cz + d = 0,$$

$$a'x + b'y + c'z + d' = 0.$$

can be changed to symmetrical form as follows:

$$\frac{x - \dfrac{bd' - b'd}{ab' - a'b}}{bc' - b'c} = \frac{y - \dfrac{da' - d'a}{ab' - a'b}}{ca' - c'a} = \frac{z}{ab' - a'b}$$

Illustration 7

Find the direction ratios of the line $x + 2y - z = 3$, $2x - y + z = 1$ and its equation in a symmetrical form.

Solution: Direction ratios of the line are

$$\begin{vmatrix} 2 & -1 \\ -1 & 1 \end{vmatrix}, \; -\begin{vmatrix} 1 & -1 \\ 2 & 1 \end{vmatrix}, \; \begin{vmatrix} 1 & 2 \\ 2 & -1 \end{vmatrix}$$

or 1, –3, –5

For any point on the line, let $x = 0$, then $x = y = 1$ and the equation of the line in the symmetrical form is

$$\frac{x-1}{1} = \frac{y-1}{-3} = \frac{z-0}{-5} \qquad (1)$$

Verification Any point on the line is

$r + 1, -3r + 1, -5r$

$r + 1 + 2(-3r + 1) - (-5r) = 3$ for all r

and $2(r + 1) - (-3r + 1) + (-5r) = 1$ for all r.

showing that each point on the line satisfies the given equations of the line. (1)

Number of Constants in the Equation of a Line

The equation $\dfrac{x-a}{l} = \dfrac{y-b}{m} = \dfrac{z-c}{n}$,

of a line can be written as $x = (l/n)\, z + a - (lc/n)$,

$y = (m/n)\, z + b - (mc/n)$,

which are of the form $x = Az + B,\ y = Cz + D$

Therefore the *equation of a line contains four arbitrary constants.*

A Plane and a Straight Line

Let the equations

$$ax + by + cz + d = 0,\ \frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n},$$

represent a given plane and a straight line respectively.

(i) The line is perpendicular to the plane if and only if

$$\frac{a}{l} = \frac{b}{m} = \frac{c}{n},$$

(ii) The line is parallel to the plane if and only if $al + bm + cn = 0$.

(iii) The line lies in the plane if and only if

$$al + bm + cn = 0 \text{ and } a\alpha + b\beta + c\gamma + d = 0.$$

Angle between a Line and a Plane

The angle θ between the line

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n},$$

and the plane $ax + by + cz + d = 0$, is given by

$$\sin\theta = \frac{al + bm + cn}{\sqrt{(a^2 + b^2 + c^2)}\sqrt{(l^2 + m^2 + n^2)}}$$

Coplanar Lines

The lines $\dfrac{x-\alpha}{l} = \dfrac{y-\beta}{m} = \dfrac{z-\gamma}{n}$,

and $\dfrac{x-\alpha'}{l'} = \dfrac{y-\beta'}{m'} = \dfrac{z-\gamma'}{n'}$

are coplanar if and only if

$$\begin{vmatrix} \alpha - \alpha' & \beta - \beta' & \gamma - \gamma' \\ l & m & n \\ l' & m' & n' \end{vmatrix} = 0$$

In case the above condition is satisfied, the equation of the plane containing the lines is

$$\begin{vmatrix} x - \alpha & y - \beta & z - \gamma \\ l & m & n \\ l' & m' & n' \end{vmatrix} = 0.$$

Illustration 8

Find the value of λ, so that the lines

$\dfrac{x-1}{1} = \dfrac{y-2}{2} = \dfrac{z+\lambda}{3}$ and

$\dfrac{x+1}{2} = \dfrac{y-1}{3} = \dfrac{z-3}{1}$ are coplanar

Also find the equation of the plane containing them.

Solution: Given lines are coplanar if

$$\begin{vmatrix} 1+1 & 2-1 & -\lambda-3 \\ 1 & 2 & 3 \\ 2 & 3 & 1 \end{vmatrix} = 0 \Rightarrow \lambda = 6$$

and the equation of the plane containing the coplanar lines is

$$\begin{vmatrix} x-1 & y-2 & z+6 \\ 1 & 2 & 3 \\ 2 & 3 & 1 \end{vmatrix} = 0$$

or $7x - 5y + z + 9 = 0$

General Equation of a Plane Containing a Line

The general equation of the plane containing the line

$$\frac{x-\alpha}{l} = \frac{y-\beta}{m} = \frac{z-\gamma}{n},$$

is $$A(x-\alpha)+B(y-\beta)+C(z-\gamma)=0,$$
where $Al+Bm+Cn=0.$

Length of the Perpendicular from a Point to a Line

The length p of the perpendicular from a given point $P(x_1, y_1, z_1)$ to a given line $\dfrac{x-\alpha}{l}=\dfrac{y-\beta}{m}=\dfrac{z-\gamma}{n}$ (l, m, n are direction cosines of the line), is given by $p^2=(x_1-\alpha)^2+(y_1-\beta)^2+(z_1-\gamma)^2-[l(x_1-\alpha)+m(y_1-\beta)+n(z_1-\gamma)]^2$. Another expression for p^2 is given by

$$p^2=\begin{vmatrix} x_1-\alpha & y_1-\beta \\ l & m \end{vmatrix}^2+\begin{vmatrix} y_1-\beta & z_1-\gamma \\ m & n \end{vmatrix}^2+\begin{vmatrix} z_1-\gamma & x_1-\alpha \\ n & l \end{vmatrix}^2$$

Illustration 9

Find the perpendicular distance of the point (2, 1, 3) from the line
$$\frac{x-1}{3}=\frac{y-3}{1}=\frac{z-4}{-5}$$

Solution: Let $P(2, 1, 3)$ be the given point $A(1, 3, 4)$ is a point on the given line $p=PM$, be the perpendicular from P on the line.

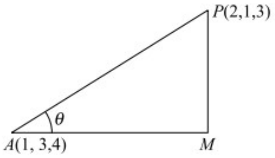

Fig. 20.2

Let $\lfloor\underline{PAM}=\theta$ then
$p^2=(PM)^2=(AP)^2-(AM)^2=(AP)^2-(AP\cos\theta)^2$
$\Rightarrow p^2=(AP)^2\sin^2\theta$
Direction ratios of AP are $2-1, 1-3, 3-4$
or $1, -2, -1$ and of the given line are $3, 1, -5$

$$\text{so } \cos\theta=\frac{(1)(3)+(-2)(1)+(-1)(-5)}{\sqrt{(1)^2+(-2)^2+(-1)^2}\sqrt{(3)^2+(1)^2+(-5)^2}}$$

$$=\frac{6}{\sqrt{6}\sqrt{35}}=\sqrt{\frac{6}{35}}$$

$(AP)^2=(2-1)^2+(1-3)^2+(3-4)^2=6$

Hence $p^2=6\times\dfrac{29}{35}\Rightarrow p=\sqrt{\dfrac{174}{35}}$

Equation of a Line through the Intersection of Given Lines

If $L_1=0=L_2$ and $L_3=0=L_4$, where $L_K=a_kx+b_ky+c_kz+d_k$, $k=1, 2, 3, 4$; are equations of two intersecting lines then for all values of λ and μ the equation $L_1+\lambda L_2=0=L_3+\mu L_4$ represents a line through their intersection.

20.4 VECTORIAL EQUATIONS

1. Parametric vectorial equation of the line through a point with position vector **a** and parallel to the vector **b** is
   $\mathbf{r}=\mathbf{a}+t\mathbf{b}$
   where t, is a scalar parameter.
2. Parametric vectorial equation of the line through two points with position vectors **a** and **b** is
   $\mathbf{r}=(1-\text{t})\mathbf{a}+t\mathbf{b}$
   where t, is a scalar parameter.
3. Parametric vectorial equation of a plane which passes through the point with position vector **a** and which is parallel to the vectors **b** and **c** is
   $\mathbf{r}=\mathbf{a}+t\mathbf{b}+p\mathbf{c}$
   where, t and p are scalar parameters.
4. Parametric vectorial equation of a plane passing through two given points with position vectors **a** and **b** and parallel to the vectors **c** is
   $\mathbf{r}=\mathbf{a}+t(\mathbf{b}-\mathbf{a})+p\mathbf{c}=(1-t)\,\mathbf{a}+t\mathbf{b}+p\mathbf{c}$
   where t and p are scalar parameters.
5. Equation of the plane passing through three points with position vectors **a**, **b**, **c** is
   $\text{r}\cdot(\mathbf{b}\times\mathbf{c}+\mathbf{c}\times\mathbf{a}+\mathbf{a}\times\mathbf{b})=[\mathbf{a}\ \mathbf{b}\ \mathbf{c}].$
6. *Normal form of the vector equation of a plane* $\mathbf{r}\cdot\mathbf{n}=p$ is vector equation of a plane, such that **n** is the unit vector normal to the plane and p is the length of the perpendicular from the origin to the plane.
7. $(\mathbf{r}-\mathbf{a})\cdot\mathbf{N}=0$ is vector equation of a plane normal to the vector **N** and passing through a point with position vector **a**.

Illustration 10

Find the vectorial equation of the plane passing through the point (2, 5, –3) and perpendicular to the line with direction ratios 3, 7, 5.

Solution: Let $\mathbf{a}=2\mathbf{i}+5\mathbf{j}-3\mathbf{k}$

and $\mathbf{N}=3\mathbf{i}+7\mathbf{j}+5\mathbf{k}$

Required equation of the plane is

$(\mathbf{r}-\mathbf{a})\cdot\mathbf{N}=0$

or $[\mathbf{r} - (2\mathbf{i} + 5\mathbf{j} - 3\mathbf{k})]\,(3\mathbf{i} + 7\mathbf{j} + 5\mathbf{k}) = 0$

8. *Angle between two planes* $\mathbf{r} \cdot \mathbf{N}_1 = p_1$ and $\mathbf{r} \cdot \mathbf{N}_2 = p_2$ is $\cos^{-1} \dfrac{\mathbf{N}_1 \cdot \mathbf{N}_2}{|\mathbf{N}_1||\mathbf{N}_2|}$
9. *Angle between a line and a plane* whose vectorial equations are $\mathbf{r} = \mathbf{a} + \mathbf{b}t$ and $\mathbf{r} \cdot \mathbf{N} = q$ respectively is $\sin^{-1} \dfrac{\mathbf{N} \cdot \mathbf{b}}{|\mathbf{N}||\mathbf{b}|}$.
10. *The perpendicular distance* of a point with position vector **a** from the plane $\mathbf{r} \cdot \mathbf{N} = q$ is $\dfrac{|q - \mathbf{a} \cdot \mathbf{N}|}{|\mathbf{N}|}$.
11. Equation of the plane containing two coplanar lines $\mathbf{r} = \mathbf{a} + t\mathbf{b}$ and $\mathbf{r} = \mathbf{c} + p\mathbf{d}$ is
    $(\mathbf{r} - \mathbf{a}) \cdot \mathbf{b} \times \mathbf{d} = 0$
    $\Rightarrow \quad \mathbf{r} \cdot \mathbf{b} \times \mathbf{d} = \mathbf{a} \cdot \mathbf{b} \times \mathbf{d}$.
12. Condition for the lines $\mathbf{r} = \mathbf{a} + t\mathbf{b}$ and $\mathbf{r} = \mathbf{c} + p\mathbf{d}$ to be *coplanar* is $[\mathbf{cbd}] = [\mathbf{abd}]$.
13. The line LM of shortest distance between the lines $\mathbf{r} = \mathbf{a} + t\mathbf{b}$ and $\mathbf{r} = \mathbf{c} + p\mathbf{d}$ is parallel to the vector $\mathbf{b} \times \mathbf{d}$. Length of LM is the projection of the line joining the points with position vectors **a** and **c** on **LM**.

    Thus $LM = \dfrac{|(\mathbf{c} - \mathbf{a}) \cdot (\mathbf{b} \times \mathbf{d})|}{|\mathbf{b} \times \mathbf{d}|} = \dfrac{|[\mathbf{cbd}] - [\mathbf{abd}]|}{|\mathbf{b} \times \mathbf{d}|}$

    Also, the line of shortest distance is the line of intersection of the two planes through the given lines and the line LM. The equations of these planes are
    $(\mathbf{r} - \mathbf{a}) \cdot \mathbf{b} \times (\mathbf{b} \times \mathbf{d}) = 0$,
    $(\mathbf{r} - \mathbf{c}) \cdot \mathbf{d} \times (\mathbf{b} \times \mathbf{d}) = 0$
    The line of intersection of these planes is the required line of shortest distance between the given lines.

Illustration 11

Find an equation of the line of shortest distance between the lines

$\mathbf{r} = \lambda(\mathbf{i} - \mathbf{j} + \mathbf{k})$ and $\mathbf{r} = (\mathbf{i} - \mathbf{j}) + \mu(-2\mathbf{j} + \mathbf{k})$

In the vectorial notation and Cartesian notation. Also find the shortest distance between them.

Solution: $\mathbf{a} = \mathbf{0}, \quad \mathbf{b} = \mathbf{i} - \mathbf{j} + \mathbf{k}$

$\mathbf{c} = \mathbf{i} - \mathbf{j}, \quad \mathbf{d} = -2\mathbf{j} + \mathbf{k}$

Then equation of the line of shortest distance is

$(\mathbf{r} - \mathbf{a}) \cdot \mathbf{b} \times (\mathbf{b} \times \mathbf{d}) = 0, (\mathbf{r} - \mathbf{c}) \cdot \mathbf{d} \times (\mathbf{b} \times \mathbf{d}) = 0$

$(\mathbf{b} \times \mathbf{d}) = \mathbf{i} - \mathbf{j} - 2\mathbf{k}$

$\mathbf{b} \times (\mathbf{b} \times \mathbf{d}) = 3\mathbf{i} + 3\mathbf{j}$

$\mathbf{d} \times (\mathbf{b} \times \mathbf{d}) = 5\mathbf{i} + \mathbf{j} + 2\mathbf{k}, \mathbf{c} \cdot [\mathbf{d} \times (\mathbf{b} \times \mathbf{d})] = 4$

So equation of the required line is

$\mathbf{r} \cdot (3\mathbf{i} + 3\mathbf{j}) = 0, \mathbf{r} \cdot (5\mathbf{i} + \mathbf{j} + 2\mathbf{k}) = 4$

$\mathbf{r} = (\mathbf{i} - \mathbf{j})$. satisfies both the equations.

So the line of shortest distance is

$\mathbf{r} = (\mathbf{i} - \mathbf{j}) + \lambda(\mathbf{i} - \mathbf{j} - 2\mathbf{k})$

Or $\dfrac{x-1}{1} = \dfrac{y+1}{-1} = \dfrac{z}{-2}$

Required shortest distance is $\dfrac{|(\mathbf{c} - \mathbf{a}) \cdot (\mathbf{b} \times \mathbf{d})|}{|\mathbf{b} \times \mathbf{d}|}$

$$= \frac{|(\mathbf{i} - \mathbf{j}) \cdot (\mathbf{i} - \mathbf{j} - 2\mathbf{k})|}{\sqrt{(1)^2 + (-1)^2 + (-2)^2}} = \frac{2}{\sqrt{6}}$$

SOLVED EXAMPLES

SINGLE CORRECT ANSWER TYPE QUESTIONS

Example 1 Let P be the image of the point (3, 1, 7) with respect to the plane $x - y + z = 3$. Then equation of the plane through P and containing the straight line $\dfrac{x}{1} = \dfrac{y}{2} = \dfrac{z}{1}$ is

(a) $x + y - 3z = 0$ (b) $3x + z = 0$
(c) $x - 4y + 7z = 0$ (d) $2x - y = 0$

Ans. (c)

Solution: An equation of normal to plane $x - y + z = 3$ and passing through $A(3, 1, 7)$ is

$\dfrac{x-3}{1} = \dfrac{y-1}{-1} = \dfrac{z-7}{1} = r$ (say)

Let the coordinates of P be $(r + 3, -r + 1, r + 7)$

Mid-point M of AP is $\left(\dfrac{r}{2}+3, -\dfrac{r}{2}+1, \dfrac{r}{2}+7\right)$ and lies on $x - y + z = 3$

$$\Rightarrow \quad \frac{r}{2}+3+\frac{r}{2}-1+\frac{r}{2}+7 = 3 \Rightarrow r = -4$$

Thus coordinates of P are $(-1, 5, 3)$

Now equation of the plane through P and containing the line $\dfrac{x}{1} = \dfrac{y}{2} = \dfrac{z}{1}$ is $\begin{vmatrix} x & y & z \\ -1 & 5 & 3 \\ 1 & 2 & 1 \end{vmatrix} = 0$

$\Rightarrow x - 4y + 7z = 0$

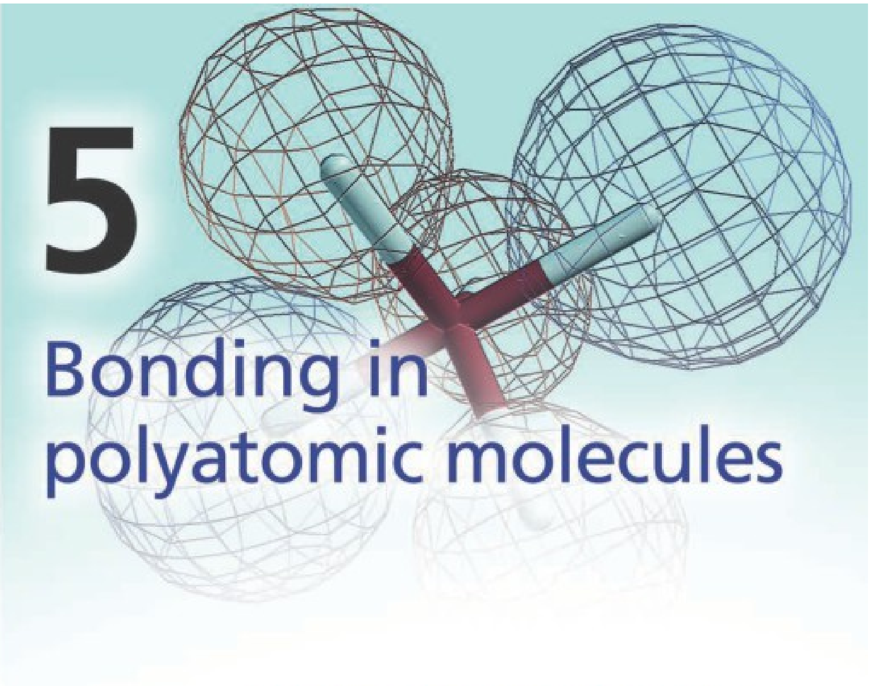
Bonding in polyatomic molecules



5.1 Introduction

In Chapter 2, we considered three approaches to the bonding in diatomic molecules:

- Lewis structures;
- valence bond (VB) theory;
- molecular orbital (MO) theory.

In this chapter we extend the discussion to polyatomic molecules (i.e. those containing three or more atoms). Within the valence bond model, treatment of a molecule XY_n ($n \geq 2$) raises the question of compatibility (or not) between the positions of the Y atoms and the directionalities of the atomic orbitals on the central atom X. Although an s atomic orbital is spherically symmetric, other atomic orbitals possess directional properties (see Section 1.6). Consider H_2O: Fig. 5.1 illustrates that, if the atoms of the H_2O molecule lie in (for example) the yz plane, the directionalities of the $2p_y$ and $2p_z$ atomic orbital of oxygen are not compatible with the directionalities of the two O–H bonds. Although we could define the z axis to coincide with one O–H bond, the y axis could not (at the same time) coincide with the other O–H bond. Hence, there is a problem in trying to derive a localized bonding scheme in terms of an atomic orbital basis set (see Section 2.3). The next section describes a bonding model within valence bond (VB) theory that overcomes this problem. After we have considered how VB theory views the bonding in a range of XY_n species, we move on to the problems of applying molecular orbital theory to polyatomic species.

A ***polyatomic species*** contains three or more atoms.

5.2 Valence bond theory: hybridization of atomic orbitals

What is orbital hybridization?

The word 'hybridization' means 'mixing' and when used in the context of atomic orbitals, it describes a way of deriving *spatially directed orbitals* which may be used within VB theory. Like all bonding theories, *orbital hybridization is a model*, and should *not* be taken to be a real phenomenon.

Hybrid orbitals may be formed by mixing the characters of atomic orbitals that are close in energy. The character of a hybrid orbital depends on the atomic orbitals involved and their percentage contributions. The labels given to hybrid orbitals reflect the contributing atomic orbitals, e.g. an sp hybrid possesses equal amounts of s and p orbital character.

Hybrid orbitals are generated by mixing the characters of atomic orbitals.

The reason for creating a set of hybrid orbitals is to produce a convenient bonding scheme for a particular molecular species. An individual hybrid orbital points along a given internuclear axis within the framework of the molecule under consideration, and use of a set of hybrid orbitals provides a bonding picture in terms of *localized σ-bonds*. In working through the rest of this section, notice that each hybridization scheme for an atom X in a molecule XY_n is appropriate only for a particular shape, the shape being defined by the number of attached groups and any lone pairs.

A set of hybrid orbitals provides a bonding picture for a molecule in terms of ***localized σ-bonds***.

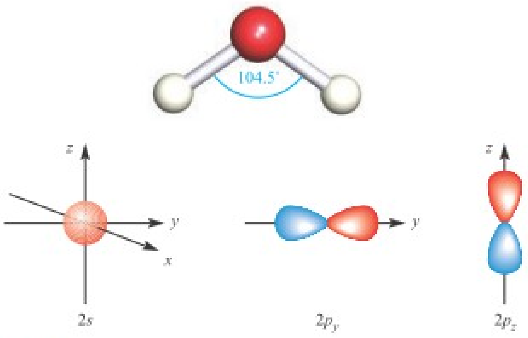


Fig. 5.1 A comparison of the shape of the H_2O molecule (the framework of which is taken as lying in the yz plane) with the spatial properties of the $2s$, $2p_y$ and $2p_z$ atomic orbitals of oxygen.

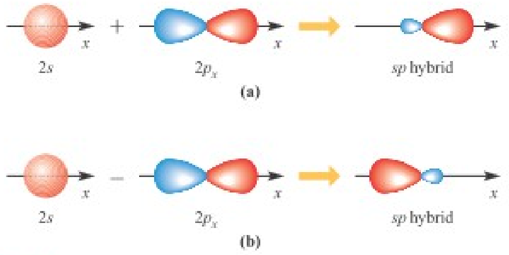

Fig. 5.2 The formation of two sp hybrid orbitals from one $2s$ atomic orbital and one $2p$ atomic orbital.

sp Hybridization: a scheme for linear species

The notation ***sp*** means that one s atomic orbital and one p atomic orbital mix to form a set of two hybrid orbitals with different directional properties.

One possible combination of a $2s$ atomic orbital and $2p_x$ atomic orbital is shown in Fig. 5.2a. In the figure, the colour of the orbital lobe corresponds to a particular phase (see Section 1.6) and the addition of the $2s$ component reinforces one lobe of the $2p_x$ atomic orbital but diminishes the other. Equation 5.1 represents the combination mathematically. The wavefunction $\psi_{sp\,\text{hybrid}}$ describes a normalized (see Section 2.2) sp hybrid orbital which possesses 50% s and 50% p character. Although eq. 5.1 and Fig. 5.2a refer to the combination of $2s$ and $2p_x$ atomic orbitals, this could just as well be $2s$ with $2p_y$ or $2p_z$, or $3s$ with $3p_x$, and so on.

$$\psi_{sp\,\text{hybrid}} = \frac{1}{\sqrt{2}}(\psi_{2s} + \psi_{2p_x}) \tag{5.1}$$

Now comes an important general rule: *if we begin with n atomic orbitals, we must end up with n orbitals after hybridization.* Figure 5.2b and eq. 5.2 show the second possibility for the combination of a $2s$ and a $2p_x$ atomic orbital. The sign change for the combination changes the phase of the $2p_x$ orbital and so the resultant hybrid points in the opposite direction to the one shown in Fig. 5.2a. (Remember that p atomic orbitals have vector properties.)

$$\psi_{sp\,\text{hybrid}} = \frac{1}{\sqrt{2}}(\psi_{2s} - \psi_{2p_x}) \tag{5.2}$$

Equations 5.1 and 5.2 represent two wavefunctions which are equivalent in every respect *except for their directionalities* with respect to the x axis. Although the orbital energies of the initial $2s$ and $2p_x$ atomic orbitals were different, mixing leads to two hybrid orbitals of equal energy.

The model of sp hybridization can be used to describe the σ-bonding in a linear molecule such as $BeCl_2$ in which the Be−Cl bonds are of equal length. The ground state electronic configuration of Be is $[He]2s^2$ and the valence shell contains the $2s$ atomic orbital and three $2p$ atomic orbitals (Fig. 5.3). If we use two of these atomic orbitals,

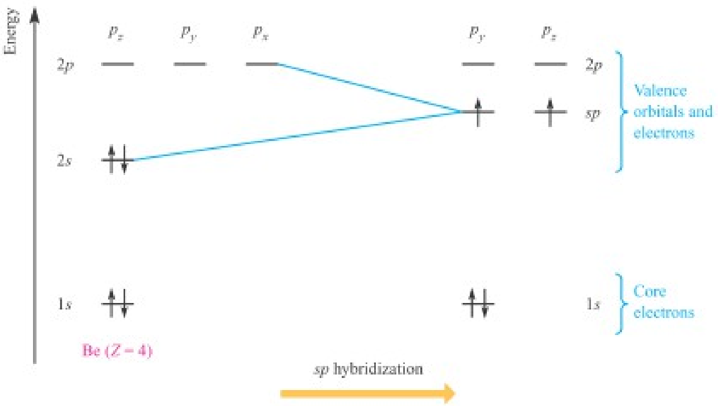

Fig. 5.3 Scheme to show the formation of the sp hybridized valence state of a beryllium atom from its ground state. This is a formalism and is not a 'real' observation, e.g. the valence state *cannot* be observed by spectroscopic techniques. The choice of using the $2p_x$ orbital for hybridization is arbitrary.

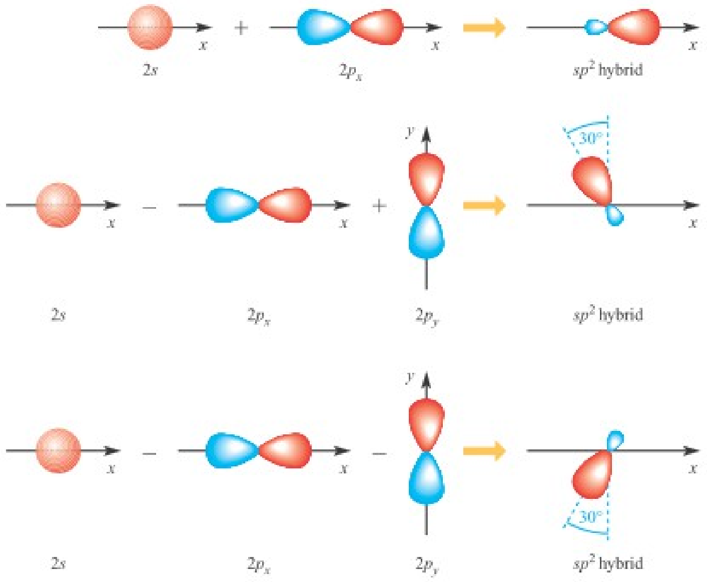

Fig. 5.4 The formation of three sp^2 hybrid orbitals from one 2*s* atomic orbital and two 2*p* atomic orbitals. The choice of p_x and p_y is arbitrary. (If we started with $2p_x$ and $2p_z$ atomic orbitals, the hybrids would lie in the *xz* plane; using the $2p_y$ and $2p_z$ atomic orbitals gives hybrid orbitals in the *yz* plane.) The directionalities of the hybrid orbitals follow from the relative contributions of the atomic orbitals (see eqs. 5.3–5.5).

treating them separately, to form two localized Be−Cl bonds, we cannot rationalize the bond equivalence. However, if we take the 2*s* atomic orbital and one 2*p* atomic orbital, mix their characters to form *sp* hybrids, and use one hybrid orbital to form one Be−Cl interaction and the other hybrid orbital for the second interaction, then the equivalence of the Be−Cl interactions is a natural consequence of the bonding picture. Effectively, we are representing the valence state of Be in a linear molecule as consisting of two degenerate *sp* hybrids, each containing one electron; this is represented by the notation $(sp)^2$. Figure 5.3 represents the change from the ground state electronic configuration of Be to an *sp* valence state. This is a *theoretical state* which can be used to describe σ-bonding in a linear molecule.

sp^2 Hybridization: a scheme for trigonal planar species

The notation $\boldsymbol{sp^2}$ means that one *s* and two *p* atomic orbitals mix to form a set of three hybrid orbitals with different directional properties.

Let us consider the combination of 2*s*, $2p_x$ and $2p_y$ atomic orbitals. The final hybrid orbitals must be equivalent in every way except for their directional properties; sp^2 hybrids must contain the same amount of *s* character as each other and the same amount of *p* character as one another. We begin by giving one-third of the 2*s* character to each sp^2 hybrid orbital. The remaining two-thirds of each hybrid orbital consists of 2*p* character, and the normalized wavefunctions are given in eqs. 5.3 to 5.5.

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} + \sqrt{\frac{2}{3}}\psi_{2p_x} \tag{5.3}$$

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} - \frac{1}{\sqrt{6}}\psi_{2p_x} + \frac{1}{\sqrt{2}}\psi_{2p_y} \tag{5.4}$$

$$\psi_{sp^2\ \text{hybrid}} = \frac{1}{\sqrt{3}}\psi_{2s} - \frac{1}{\sqrt{6}}\psi_{2p_x} - \frac{1}{\sqrt{2}}\psi_{2p_y} \tag{5.5}$$

Figure 5.4 gives a pictorial representation of the way in which the three sp^2 hybrid orbitals are constructed. Remember that a change in sign for the atomic wavefunction means a change in phase. The resultant directions of the lower two hybrid orbitals in Fig. 5.4 are determined by resolving the vectors associated with the $2p_x$ and $2p_y$ atomic orbitals.

The model of sp^2 hybridization can be used to describe the σ-bonding in trigonal planar molecules such as BH_3. The valence state of the B atom is $(sp^2)^3$ (i.e. three sp^2 hybrid orbitals, each with one electron) and the equivalence of the B−H interactions follows by considering that each interaction is formed by the overlap of one B sp^2 hybrid orbital with the 1*s* atomic orbital of an H atom (Fig. 5.5). Each H atom contributes one electron to the bonding scheme and, so, each B−H σ-bond is a localized 2c-2e interaction (see Section 2.2). A diagram similar to that shown in Fig. 5.3 can be constructed to show the formation of a valence state for the trigonal planar B atom.

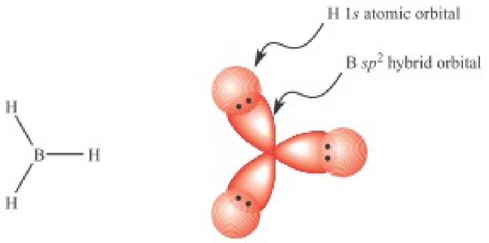

Fig. 5.5 The bonding in trigonal planar BH_3 can be conveniently described in terms of the interactions between a set of sp^2 hybrid orbitals centred on the B atom and three H 1s atomic orbitals. Three pairs of electrons are available (three electrons from B and one from each H) to give three 2c-2e σ-bonds.

sp^3 Hybridization: a scheme for tetrahedral and related species

The notation sp^3 means that one s and three p atomic orbitals mix to form a set of four hybrid orbitals with different directional properties.

A similar scheme to those described above can be derived to generate four sp^3 hybrid orbitals from one 2s and three 2p atomic orbitals. The sp^3 hybrid orbitals are described by the normalized wavefunctions in eqs. 5.6–5.9 and are shown pictorially in Fig. 5.6a. Each sp^3 hybrid orbital possesses 25% s character and 75% p character, and the set of four equivalent orbitals defines a tetrahedral framework.

$$\psi_{sp^3\text{ hybrid}} = \tfrac{1}{2}(\psi_{2s} + \psi_{2p_x} + \psi_{2p_y} + \psi_{2p_z}) \qquad (5.6)$$

$$\psi_{sp^3\text{ hybrid}} = \tfrac{1}{2}(\psi_{2s} + \psi_{2p_x} - \psi_{2p_y} - \psi_{2p_z}) \qquad (5.7)$$

$$\psi_{sp^3\text{ hybrid}} = \tfrac{1}{2}(\psi_{2s} - \psi_{2p_x} + \psi_{2p_y} - \psi_{2p_z}) \qquad (5.8)$$

$$\psi_{sp^3\text{ hybrid}} = \tfrac{1}{2}(\psi_{2s} - \psi_{2p_x} - \psi_{2p_y} + \psi_{2p_z}) \qquad (5.9)$$

Figure 5.6b illustrates how the tetrahedral structure of CH_4 relates to a cubic framework. This relationship is important because it allows you to describe a tetrahedron in terms of a Cartesian axis set. Within valence bond theory, the bonding in CH_4 can conveniently be described in terms of an sp^3 valence state for C, i.e. four degenerate orbitals, each containing one electron. Each hybrid orbital overlaps with the 1s atomic orbital of one H atom to generate one of four equivalent, localized 2c-2e C–H σ-interactions.

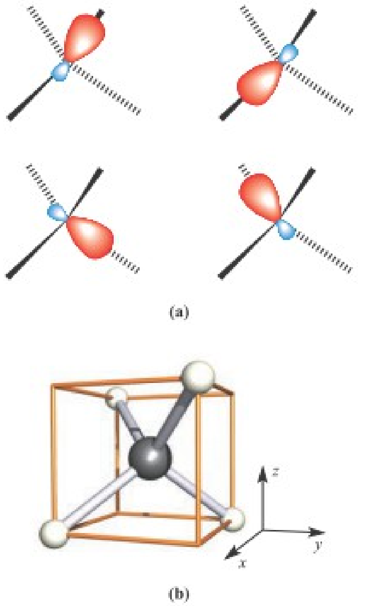

Fig. 5.6 (a) The directions of the orbitals that make up a set of four sp^3 hybrid orbitals correspond to a tetrahedral array. (b) The relationship between a tetrahedron and a cube; in CH_4, the four H atoms occupy alternate corners of a cube, and the cube is easily related to a Cartesian axis set.

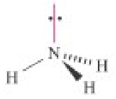
Worked example 5.1 Hybridization scheme for the nitrogen atom in NH_3

Use the VSEPR model to account for the structure of NH_3, and suggest an appropriate hybridization scheme for the N atom.

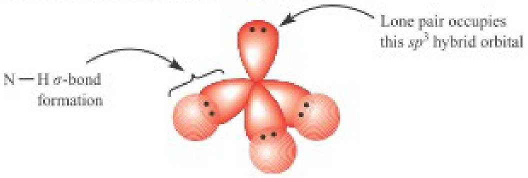
The ground state electronic configuration of N is $[He]2s^22p^3$.

Three of the five valence electrons are used to form three N–H single bonds, leaving one lone pair.

The structure is trigonal pyramidal, derived from a tetrahedral arrangement of electron pairs:



The N atom has four valence atomic orbitals: 2s, $2p_x$, $2p_y$ and $2p_z$. An sp^3 hybridization scheme gives a tetrahedral arrangement of hybrid orbitals, appropriate for accommodating the four pairs of electrons:



Self-study exercises

1. Use the VSEPR model to account for the tetrahedral structure of $[NH_4]^+$.

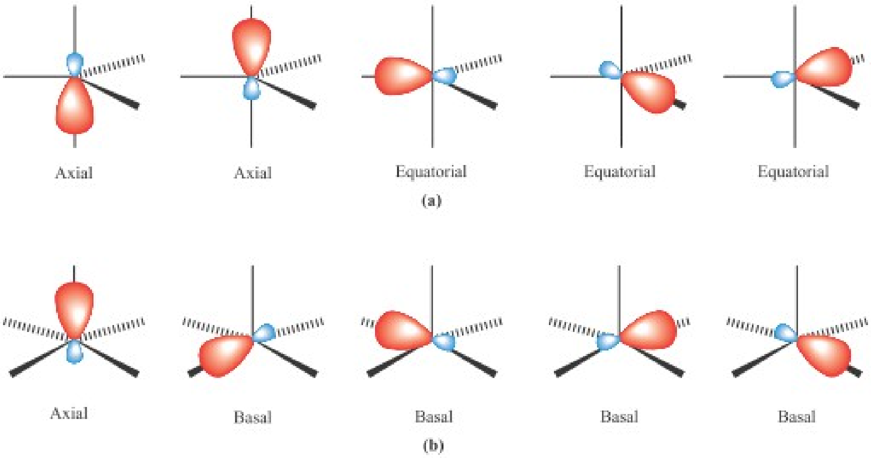


Fig. 5.7 A schematic representation of sp^3d hybridization. (a) A combination of s, p_x, p_y, p_z and d_{z^2} atomic orbitals gives a set of five sp^3d hybrid orbitals corresponding to a trigonal bipyramidal arrangement; the axial sp^3d hybrid orbitals are directed along the z axis. (b) A combination of s, p_x, p_y, p_z and $d_{x^2-y^2}$ atomic orbitals gives a set of five sp^3d hybrid orbitals corresponding to a square-based pyramidal arrangement; the axial sp^3d hybrid orbital is directed along the z axis.

2. Rationalize why H_2O is bent but XeF_2 is linear. Explain why an sp^3 hybridization scheme can be applied to H_2O, but not to XeF_2.
3. Give a suitable hybridization scheme for the central atom in each of the following: (a) $[NH_4]^+$; (b) H_2S; (c) BBr_3; (d) NF_3; (e) $[H_3O]^+$.
   [*Ans.* (a) sp^3; (b) sp^3; (c) sp^2; (d) sp^3; (e) sp^3]

Other hybridization schemes

For molecular species with other than linear, trigonal planar or tetrahedral-based structures, it is usual to involve d orbitals within valence bond theory. We shall see later that this is not necessarily the case within molecular orbital theory. We shall also see in Chapters 15 and 16 that the bonding in so-called *hypervalent compounds* such as PF_5 and SF_6, can be described without invoking the use of d-orbitals. One should therefore be cautious about using sp^nd^m hybridization schemes in compounds of p-block elements with apparently expanded octets around the central atom. *Real* molecules do not have to conform to simple theories of valence, nor must they conform to the sp^nd^m schemes that we consider in this book. Nevertheless, it is convenient to visualize the bonding in molecules in terms of a range of simple hybridization schemes.

The mixing of s, p_x, p_y, p_z and d_{z^2} atomic orbitals gives a set of five sp^3d hybrid orbitals, the mutual orientations of which correspond to a trigonal bipyramidal arrangement (Fig. 5.7a). The five sp^3d hybrid orbitals are *not* equivalent and divide into sets of two axial and three equatorial orbitals; the axial orbital lobes lie along the z axis.[†] The model of sp^3d hybridization can be used to describe the σ-bonding in 5-coordinate species such as $[Ni(CN)_5]^{3-}$ (see Section 21.11).

The σ-bonding framework in a square-pyramidal species may also be described in terms of an sp^3d hybridization scheme. The change in spatial disposition of the five hybrid orbitals from trigonal bipyramidal to square-based pyramidal is a consequence of the participation of a different d orbital. Hybridization of s, p_x, p_y, p_z and $d_{x^2-y^2}$ atomic orbitals generates a set of five sp^3d hybrid orbitals (Fig. 5.7b).

Hybridization of s, p_x, p_y, p_z, d_{z^2} and $d_{x^2-y^2}$ atomic orbitals gives six sp^3d^2 hybrid orbitals corresponding to an octahedral arrangement. The bonding in MoF_6 can be described in terms of sp^3d^2 hybridization of the central atom. If we remove the z-components from this set (i.e. p_z and d_{z^2}) and hybridize only the s, p_x, p_y and $d_{x^2-y^2}$ atomic orbitals, the resultant set of four sp^2d hybrid orbitals corresponds to a square planar arrangement, e.g. $[PtCl_4]^{2-}$.

Each set of hybrid orbitals is associated with a particular shape, although this may not coincide with the molecular shape if lone pairs also have to be accommodated:

• sp	linear
• sp^2	trigonal planar
• sp^3	tetrahedral
• sp^3d (d_{z^2})	trigonal bipyramidal
• sp^3d ($d_{x^2-y^2}$)	square-based pyramidal
• sp^3d^2	octahedral
• sp^2d	square planar

[†] Choice of coincidence between the z axis and the axial lobes is convenient and tends to be conventional.

Introduction

Quantum tunneling is a microscopic phenomenon where a particle can penetrate and in most cases pass through a potential barrier. The maximum height of the barrier is assumed to be higher than the kinetic energy of the particle, therefore such a motion is not allowed by the laws of classical dynamics. The simplest problems in quantum tunneling are one-dimensional and most of the research is done on these problems. But the extension of one-dimensional tunneling to higher dimensions is not straightforward. In addition there are certain characteristics that appear in two- or three-dimensional tunneling problems which do not show up in the one-dimensional motion.

In most of the one-dimensional systems we study the motion of a particle in a potential $V(x)$, where $V(x)$ has a finite (or infinite) number of maxima. As long as the height of the barriers remain finite, the motion of the particle will not be restricted and we may choose the energy of the particle E to be greater than the asymptotic value of the potential say at $x = -\infty$. Then the simplest case will be that of a particle with energy $E > V(-\infty)$ approaching the barrier from the left and then penetrating the barrier. Now depending on whether $E > V(\infty)$ or $E < V(\infty)$ the particle can pass through the potential or be reflected back and move to $x = -\infty$. The value of E is arbitrary as long as these conditions or inequalities are met.

The other possibility is the one where the potential is finite on one side and tends to infinity on the other, e.g. $V(-\infty) = \infty$ and $V(\infty)$ is finite. In addition the potential has at least one local maximum say at $x = a$. Then depending on the boundary conditions of the problem we can have two different possibilities:

(i) - If the particle moves from $x = \infty$ in the direction of $x = -\infty$, then there is the possibility that by tunneling the particle can enter the region between a and $-\infty$ and stays there for a finite time (a metastable state).

(ii) - If the initial condition states that the particle is in the region $-\infty < x < a$, then in the course of time by the process of tunneling the particle passes through the barrier and goes to $x = \infty$. This initial state has also a finite lifetime. In both of these cases there are characteristic energies for which the tunneling probability is large, whereas for other energies it is small.

(iii) -The third possibility appears in the case where the potential $V(x)$ is a confining potential, i.e. $V(x)$ tends to infinity on both sides of the central maximum (or maxima), $V(x) \to \infty$ as $x \to \pm\infty$. In this case the motion of the particle will be restricted to a part of the x-axis. Depending on the number of maxima of $V(x)$, we can have the eigenvalue problem for a double- or multi-well potential. The motion of the wave packet for double-wells, due to their importance in applied physics have received extensive treatment and will be discussed at length in this book.

A double-well can be symmetric or asymmetric. The motion of a wave packet which represents the particle in a symmetric double-well, under certain conditions, can be obtained from the superposition of the eigenfunctions of the two lowest states of the system. When this happens then the wave packet oscillates between the two wells with a well defined frequency, and it also preserves its shape after successive back and forth tunneling. This very important case is called quantum coherence. For an asymmetric double-well, if the motion from one well to the other takes place by tunneling, then we have a situation which we call quantum hopping.

In two or three dimensions when the barrier is only a function of the distance from the origin of the coordinate system, i.e. $\rho = \sqrt{x^2 + y^2}$ in cylindrical coordinates or $r = \sqrt{x^2 + y^2 + z^2}$, in spherical polar coordinates we can separate the variables in the Schrödinger equation and thus reduce the problem to a one-dimensional motion but now with the boundary conditions imposed at $\rho = 0$ or $r = 0$ and at ρ or r going to infinity. For instance in three dimensions if we assume that $V(r \to \infty) \to 0$ and that $V(r)$ has a maximum at $r = a$, then if the particle is originally confined in the region $0 \leq r < a$, it can tunnel through the barrier and go to infinity. These special cases of two- or three-dimensional tunneling can be regarded as one-dimensional but the potentials $V(\rho)$ and $V(r)$ are replaced by $V_{eff}(\rho)$ and $V_{eff}(r)$, with the boundary condition that the reduced radial wave function must vanish at the origin.

A Brief Review of the Contents of This Book — In the first chapter of this book we present a brief history of the subject of quantum tunneling and the role that a number of pioneers played in its development. In the second chapter we discuss the physics of tunneling and the solution to the problem of local kinetic energy provided by the uncertainty principle. Furthermore we show that the principles of wave mechanics imply that, in general, the decay of the system, either because of tunneling or by some other mechanism, is non-exponential. Following this argument, we consider a special solvable problem to show that the exponential decay law is a very good approximation except for very short initial time and also after a very long time, and only at these extremes there are departures from the exponential decay. In the next chapter (Chapter 3) we solve a number of simple problems for which analytic solutions are known, and we determine, in appropriate cases, the lifetime of the quasi-stationary states, and or the motion of the wave packets. Of special interest is the resonant tunneling from either two identical barriers or a group of barriers.

The time-dependence of the wave function in one-dimensional tunneling is

2.1 Tunneling and the Uncertainty Principle

At the first sight the tunneling of a particle looks like a paradoxical problem, since if the height of the barrier is greater than the total energy of the particle,

$$E = \frac{1}{2m}p^2 + V(x) \tag{2.1}$$

then in the range b where $V(x) > E$, the kinetic energy $\frac{1}{2m}p^2$ is negative and p is imaginary, but this simple picture is not correct.

At the root of this paradox is our assumption that at each instant we know both the kinetic and the potential energy separately, or in other words we can assign values to the coordinate x and the momentum p simultaneously and this is in violation of the uncertainty principle. Here we want to know whether it is possible to determine the position of the particle when it is moving under the barrier or not. For this we observe that the particle can be at the point x where $E < V(x)$ but then according to the uncertainty principle its momentum is uncertain by an amount $\sqrt{\overline{\Delta p^2}}$. Thus if we know the position of the particle to be x, then its total energy cannot be E.

Position-Momentum Uncertainty in Tunneling — Since the transmission amplitude during tunneling in WKB approximation is proportional to (see Chapters 5)

$$\exp\left[-\frac{1}{\hbar}\int_{x_0}^{x}\sqrt{2m(V(x)-E)}dx\right], \tag{2.2}$$

where x_0 is the classical turning point, then the probability of finding the particle which is coming from the left to be on the right of the barrier, i.e. $x_0 + b$ is proportional to the square of this amplitude or to the factor

$$\exp\left[-\frac{2}{\hbar}\int_{x_0}^{x_0+b}\sqrt{2m(V(x)-E)}dx\right]. \tag{2.3}$$

Now if we want a non-negligible probability then we must have

$$2\sqrt{2m(V_m-E)}\,b \approx \hbar. \tag{2.4}$$

where V_m is the maximum height of the potential. To find the position of the particle inside the barrier, we have to measure its coordinate with an accuracy $\Delta x < b$, therefore the uncertainty in momentum for this measurement is

$$\overline{\Delta p^2} = \frac{\hbar^2}{4(\Delta x)^2} = \frac{\hbar^2}{4b^2}. \tag{2.5}$$

By substituting b from (2.4) in (2.5) we find

$$\frac{\overline{\Delta p^2}}{2m} = V_m - E. \tag{2.6}$$

Thus the kinetic energy of the particle must be greater than the difference between the height of the barrier V_m and the total energy E [1].

Time-Energy Uncertainty in Tunneling — A result similar to (2.5) and (2.6) can be obtained from the time-energy uncertainty relation [11] i.e. from

$$\Delta E \Delta t \approx \frac{\hbar}{2}. \tag{2.7}$$

Again let us denote the energy of the incident particle by E. For a very short time Δt, the uncertainty in the energy is ΔE, and for sufficiently small Δt, the energy of the particle $E+\Delta E$ is greater than the height of the barrier V_m. Tunneling takes place if in the time Δt the particle can traverse the barrier. For a rectangular barrier of width b this time Δt is given by

$$\Delta t = \frac{b}{\sqrt{\left(\frac{2}{m}\right)\left(E+\Delta E - V_m\right)}}. \tag{2.8}$$

From Eqs. (2.7) and (2.8) we find ΔE to be the solution of the quadratic equation

$$(\Delta E)^2 - \frac{\hbar^2}{2mb^2}\Delta E + \frac{\hbar^2}{2mb^2}\left(V_m - E\right) = 0, \tag{2.9}$$

and the condition for ΔE to be real is given by

$$\frac{\hbar^2}{8mb^2} > V_m - E, \tag{2.10}$$

which is the same as Eq. (2.6).

The uncertainty principle can also be used to estimate the tunneling time, i.e. the time that takes a particle to tunnel through a barrier. In order for a particle moving with the energy E to surmount a square barrier of height V_m, $(V_m > E)$ it must acquire an amount of energy $V_m - E$, and this according to the uncertainty principle can be achieved in a time Δt where

$$\Delta t \approx \frac{\hbar}{V_m - E}, \tag{2.11}$$

The time Δt is a crude upper bound for the tunneling time. For a rectangular barrier of width b, the effective speed of the particle according to (2.11) is of the order $b\frac{(V_m - E)}{\hbar}$ [12]. Different definitions of quantum mechanical tunneling times and their meanings will be discussed in detail later (Chapters 18-20).

A similar argument based on the time-energy uncertainty can be found in ref. [13].

7' 5 % 6

where in this relation $\frac{\omega_0}{2\pi}$ is the frequency of the oscillation of the particle between $r = 0$ and $r = a$

$$\frac{\omega_0}{2\pi} = \frac{K_0}{2ma} = \frac{1}{T_0}, \tag{13.33}$$

and $|p(r)| = \sqrt{v(r) - K_0^2}$. This is similar to the result that we found in Chapters 6 and 11.

The formulation of path integral presented in the preceding section can be applied to one-dimensional problems or separable problems in two or three dimensions. However its usefulness in solving nonseparable multidimensional tunnelings has not been investigated except for a very limited number of systems [16].

13.2 Method of Euclidean Path Integral

In the part of space where tunneling takes place, the momentum of the particle is imaginary, but if we choose the time variable as an imaginary variable, (called Euclidean time), then the momentum becomes real and the motion, in the sense of classical dynamics, is possible.

The advantage of introducing "imaginary time" is that it allows us to determine the action and the escape path using the laws of motion of classical mechanics. In introducing this fictitious time parameter along the path we have to be careful about the interpretation of the results concerning the motion of the particle. For instance, since pure imaginary time is somehow orthogonal to the real time, one may be inclined to say that the tunneling happens instantaneously. Here nothing is said about the quantum observation and or coupling to a measuring apparatus, and thus it does not provide us with a correct account of the tunneling time [17]. The question of tunneling time will be discussed at length in Chapters 19 and 20.

Imaginary Time Formulation of the Path Integral — As an introduction to this technique, we try to solve a one-dimensional problem where we can write for the path integral in the form of [18]–[20]

$$\left\langle x_f \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right) \right| x_i \right\rangle = \mathcal{N} \int [\mathcal{D}(x)] \exp\left(-\frac{S}{\hbar}\right). \tag{13.34}$$

Here we have used $t = -i\mathcal{T}$ ($\mathcal{T}$ is a positive number called Euclidean time), H is the Hamiltonian operator of the particle, and $|x_i\rangle$ and $|x_f\rangle$ are the initial and final states of the particle. Now we expand $|x_i\rangle$ and $|x_f\rangle$ in terms of the energy eigenfunctions $|n\rangle$ of H and these are defined by the eigenvalue equation

$$H|n\rangle = E_n|n\rangle. \tag{13.35}$$

We also expand $|x_i\rangle$ and $|x_f\rangle$ in terms the eigenfunctions $|n\rangle$;

$$|x_i\rangle = \sum_n |n\rangle\langle n|x_i\rangle. \tag{13.36}$$

With the help of this expansion we write the left-hand side of (13.34) as

$$\left\langle x_f \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right) \right| x_i \right\rangle = \sum_n \exp\left(-\frac{E_n\mathcal{T}}{\hbar}\right) \langle x_f\,|n\rangle\,\langle n|\,x_i\rangle\,. \tag{13.37}$$

We observe that for large $\mathcal{T}$ in the right-hand side of (13.37) only the lowest energy state and its corresponding wave function will make the major contribution. Now let us study the integral in Eq. (13.34) in which $\mathcal{N}$ is the normalization constant and S is the Euclidean action

$$S = \int_{-\frac{\mathcal{T}}{2}}^{\frac{\mathcal{T}}{2}} \left[\frac{1}{2}\left(\frac{dx}{d\tau}\right)^2 + V(x)\right] d\tau, \tag{13.38}$$

where we have assumed that the particle has a unit mass. In Eq. (13.34), $[\mathcal{D}(x)]$ shows that the integral is over all paths $x(t)$ which satisfy the initial and final conditions

$$x\left(-\frac{\mathcal{T}}{2}\right) = x_i, \quad \text{and} \quad x\left(\frac{\mathcal{T}}{2}\right) = x_f. \tag{13.39}$$

To make this idea clearer, we can define the paths in the following way: Let us assume that $\bar{x}$ is a function of t which satisfies the conditions (13.39). Then a general set of functions which satisfies (13.39) can be written as

$$x(\tau) = \bar{x}(\tau) + \sum_n c_n x_n(\tau) \tag{13.40}$$

where $\{x_n\}$ s form a complete set of orthonormal states which vanish at the initial and final times, $\tau = -\frac{\mathcal{T}}{2}$ and $\tau = \frac{\mathcal{T}}{2}$,

$$\int_{-\frac{\mathcal{T}}{2}}^{\frac{\mathcal{T}}{2}} x_m(\tau)x_n(\tau)d\tau = \delta_{nm}, \tag{13.41}$$

and

$$x_n\left(\pm\frac{\mathcal{T}}{2}\right) = 0. \tag{13.42}$$

Now we define $[\mathcal{D}(x)]$ in the following way

$$[\mathcal{D}(x)] = \prod_n \frac{1}{\sqrt{2\pi\hbar}}\, dc_n. \tag{13.43}$$

Again we observe that we can calculate the right-hand side of (13.34) in the semiclassical limit of $\hbar \to 0$. In this case, as we have seen earlier, the major contribution to the path integral comes from the path(s) for which S is minimum. For simplicity we assume that there is a single path and we denote it by $\bar{x}$. The minimum of S with respect to the variation of path is found from the equation of motion (for imaginary time)

$$\frac{\delta S}{\delta \bar{x}} = -\frac{d^2\bar{x}}{d\tau^2} + V'(\bar{x}) = 0, \tag{13.44}$$

in which $V'(x) = \frac{dV(x)}{dx}$. In addition we take $\{x_n\}$ s to be the eigenfunctions of the second derivative of S with respect to path, i.e. $\frac{\delta^2 S}{\delta x^2}$ for $x = \bar{x}$,

$$-\frac{d^2 x_n}{d\tau^2} + V''(\bar{x})x_n = \lambda_n x_n. \tag{13.45}$$

With these assumptions, in the limit of $\hbar \to 0$, the path integral is expressible as a product of Gaussian integrals

$$\begin{aligned}\left\langle x_f \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right)\right| x_i \right\rangle &= \mathcal{N}\exp\left[-\frac{S(\bar{x})}{\hbar}\right]\prod_n \frac{1}{\sqrt{\lambda_n}}\left(1+\mathcal{O}(\hbar)\right)\\ &= \mathcal{N}\exp\left[-\frac{S(\bar{x})}{\hbar}\right]\left\{\det\left[-\frac{\partial^2}{\partial\tau^2}+V''(\bar{x})\right]\right\}^{-\frac{1}{2}}\\ &\quad\times\left(1+\mathcal{O}(\hbar)\right).\end{aligned} \tag{13.46}$$

For this derivation we have chosen all the eigenstates to be positive. Those cases where some of the eigenvalues are negative can be dealt with in a similar manner [20]. If there are a number of roots (or paths) for the equation $\frac{\delta S}{\delta x} = 0$ then we have to sum S over all of these paths.

Equation (13.45) is the equation of motion of a particle of unit mass in the potential $-V(x)$ for which the first integral is

$$E = \frac{1}{2}\left(\frac{d\bar{x}}{d\tau}\right)^2 - V(\bar{x}), \tag{13.47}$$

where E is a constant.

Euclidean Path Integral for a Potential with a Single Minimum — Let us apply these ideas to the motion where the potential is of the form shown in Fig. 13.3, and let us take $x_i = x_f = d$. Then $\bar{x} = 0$ is the only solution which satisfies the initial and the final conditions and for this solution $S = 0$. If we denote $V''(d) = \omega^2$, we want to show that

$$\mathcal{N}\left[\det\left(-\frac{\partial^2}{\partial\tau^2}+\omega^2\right)\right]^{-\frac{1}{2}} = \sqrt{\frac{\omega}{\pi\hbar}}\exp\left(-\frac{\omega\mathcal{T}}{2}\right). \tag{13.48}$$

To prove this relation we write Eq. (13.45) in the following way:

$$\left(-\frac{d^2}{d\tau^2}+\omega^2\right)x_n = \lambda_n x_n, \tag{13.49}$$

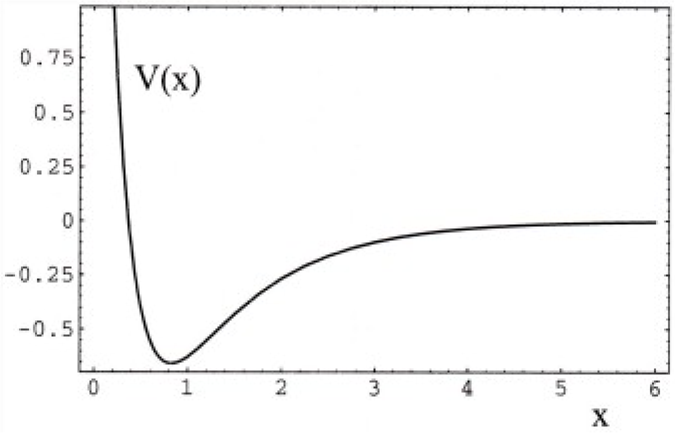

Figure 13.3: A potential with a single minimum at $x = d$.

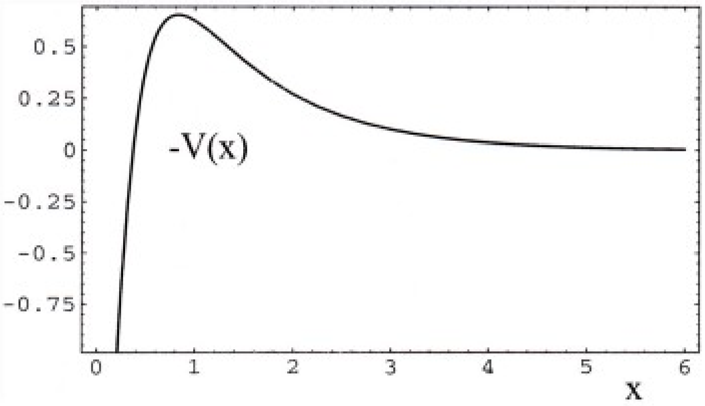

Figure 13.4: The negative of the potential shown in the previous figure.

where λ_n s are the characteristic values. The initial and final conditions for the path x_n is given by (13.42). From Eqs. (13.42) and (13.49) we conclude that

$$x_n = A_n \sin\left(\sqrt{\lambda_n - \omega^2}\,\tau\right), \tag{13.50}$$

in which

$$\lambda_n = \omega^2 + \left(\frac{n\pi}{\mathcal{T}}\right)^2. \tag{13.51}$$

Next we consider the product [7]

$$\mathcal{N} \lim_{N\to\infty} \prod_{n=1}^{N} \frac{1}{\sqrt{\omega^2 + \left(\frac{n\pi}{\mathcal{T}}\right)^2}}, \tag{13.52}$$

and write it as

$$\mathcal{N} \lim_{N\to\infty} \prod_{n=1}^{N} \frac{1}{\sqrt{\left(\frac{n\pi}{\mathcal{T}}\right)^2}} \prod_{n=1}^{N} \frac{1}{\sqrt{1+\left(\frac{\omega\mathcal{T}}{n\pi}\right)^2}}. \tag{13.53}$$

But the first product is independent of ω, therefore we choose $\mathcal{N}$ in such a way that

$$\mathcal{N} \lim_{N\to\infty} \prod_{n=1}^{N} \frac{1}{\sqrt{\left(\frac{n\pi}{\mathcal{T}}\right)^2}} = \frac{1}{\sqrt{2\pi\hbar\mathcal{T}}}, \tag{13.54}$$

Now we need to calculate the product

$$\mathcal{J} = \lim_{N\to\infty} \prod_{n=1}^{N} \frac{1}{\sqrt{1+\left(\frac{\omega\mathcal{T}}{n\pi}\right)^2}}. \tag{13.55}$$

To determine this infinite product, we start with another infinite product which can be written in closed form [23]

$$\left(1+\frac{z^2}{1^2}\right)\left(1+\frac{z^2}{2^2}\right)\left(1+\frac{z^2}{3^2}\right)\cdots = \frac{1}{\pi z}\sinh(\pi z). \tag{13.56}$$

By raising the two sides of (13.56) to the power of $(-\frac{1}{2})$ we find

$$\prod_{n=1}^{\infty} \frac{1}{\sqrt{1+\frac{z^2}{n^2}}} = \sqrt{\frac{\pi z}{\sinh(\pi z)}}. \tag{13.57}$$

Now we choose z to be $\frac{\omega\mathcal{T}}{\pi}$, then we get

$$\mathcal{J} = \sqrt{\frac{\omega\mathcal{T}}{\sinh(\omega\mathcal{T})}}, \tag{13.58}$$

therefore

$$\mathcal{N} \lim_{N\to\infty} \prod_{n=1}^{N} \frac{1}{\sqrt{\omega^2+\left(\frac{n\pi}{\mathcal{T}}\right)^2}} = \left(\frac{\omega}{2\pi\hbar}\right)^{\frac{1}{2}} \frac{1}{\sqrt{\sinh\omega\mathcal{T}}}. \tag{13.59}$$

For $\omega\mathcal{T} \gg 1$, this relation reduces to (13.48). The normalization constant $\mathcal{N}$ in (13.59) in the limit of $\omega \to 0$ is the same as the normalization constant for the motion of a free particle [7]. From Eqs. (13.46) and (13.48) it follows that the lowest energy eigenvalue is

$$E_0 = \frac{1}{2}\hbar\omega\left(1+\mathcal{O}(\hbar)\right). \tag{13.60}$$

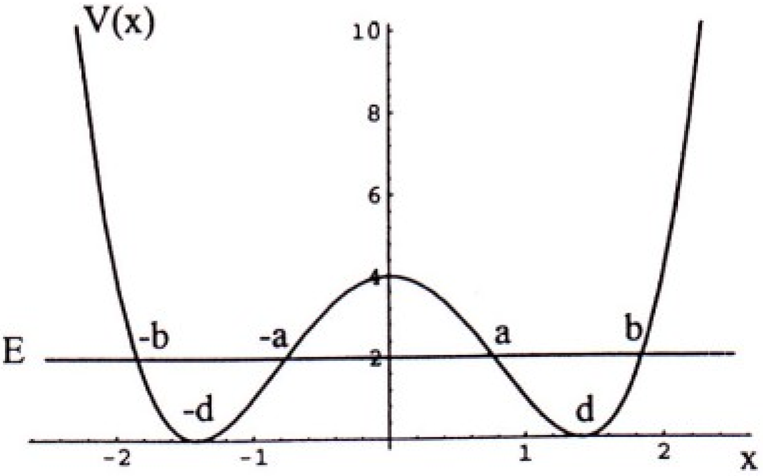

Figure 13.5: A symmetric double-well potential with minima at $x = -d$ and at $x = d$. For the energy E lower than $V(0)$, there are four turning points $-b$, $-a$, a and b.

13.3 Other Applications of the Path Integral Method in Tunneling

In Chapter 5, we studied tunneling in a symmetric double-well potential, and we found the splitting of levels for such a well as an application of WKB approximation. Now we apply the method of path integration to find the energy splitting between the two lowest states [20],[24].

Let us consider a symmetric double-well $V(x)$ shown in Fig. 13.5. The potential $V(x)$ is an even function of x, i.e. $V(x) = V(-x)$, and has two minima at $x = \pm d$. It is convenient to choose $V(x)$ so that $V(\pm d) = 0$. Here again we denote $V''(\pm d)$ by ω^2. First we want to calculate the two expectation values

$$\left\langle -d \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right)\right| -d \right\rangle = \left\langle d \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right)\right| d \right\rangle, \tag{13.61}$$

and

$$\left\langle d \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right)\right| -d \right\rangle = \left\langle -d \left| \exp\left(-\frac{H\mathcal{T}}{\hbar}\right)\right| d \right\rangle. \tag{13.62}$$

To this end we find these path integrals in their semiclassical limit of $\hbar \to 0$, exactly as we found Eq. (13.44). For this we need to solve Eq. (13.44) with proper initial and final conditions. The two solutions of this problem are obtained by placing the particle on one of the two maxima in the potential $-V(x)$ of Fig. 13.6. But there is another interesting solution for this problem, and that is when the particle starts its motion at the time $\tau = -\frac{1}{2}\mathcal{T}$ at $x = -d$ and reaches $x = d$ at $\tau = \frac{1}{2}\mathcal{T}$. Since at the end we want to consider the limit

Pág. XX(21)

In two or three dimensions when the barrier is only a function of the distance from the origin of the coordinate system, i.e. $\rho = \sqrt{x^2+y^2}$ in cylindrical coordinates or $r = \sqrt{x^2+y^2+y^2}$ in spherical polar coordinates we can separate the variables in the Schröndiger equation and thus reduce the problem to a one-dimensional motion but now with the boundary conditions imposed at $\rho = 0$ or $r = 0$ and at ρ or r going to infinity.

* For instance in three dimensions if we assume that $V(r \rightarrow \infty) \rightarrow 0$ and that $V(r)$ has a maximum at $r = a$, then if the particle is originally confined in the region $0 \leq r < a$, it can tunnel through the barrier and go to infinity.

These special cases of two- or three-dimensional tunneling can be regarded as one-dimensional but the potentials $V(\rho)$ and $V(r)$ are replaced by $V_{eff}(\rho)$ and $V_{eff}(r)$, with the boundary condition that the reduced radial wavefunction must vanish at the origin.

2.1. Tunneling and the Uncertainty Principle

At the first sight the tunneling of a particle looks like a paradoxical problem, since if the height of the barrier is greater that (than) the total energy of the particle

$$E = \frac{1}{2m} p^2 + V(x) \qquad (2.1)$$

then in the range b where $V(x) > E$, the kinetic energy

$\frac{1}{2m} p^2$ is negative and p is imaginary,

but this simple picture is not correct.

∴ particle can be at the point x where $E < V(x)$ but then according to the uncertainty principle its momentum is uncertain by an amount $\sqrt{\Delta p^2}$.

Thus if we know the position of the particle to be x, then its total energy cannot be E.

Position-Momentum Uncertainty in Tunneling (WKB approximation - Chapter 5)

$$\exp\left[-\frac{1}{\hbar}\int_{x_0}^{x}\sqrt{2m(V(x)-E)}\,dx\right] \qquad (2.2)$$

where x_0 is the classical turning point ...

Pág. 3 (17) Introduction

i is a certain solution to the polynomial equation $x^2 = -1$
obs: π → to see as an infinite sum.

i is a root of polynomial with rational coefficients, and the fact that π is not the root of a polynomial with rational coefficients – in other words, the fact that π is transcendental – means that the methods of studying i are very likely not going to be especially useful in studying π.

Approaching Galois theory, we choose to consider only those numbers that are roots of polynomials with rational number coefficients.

$1/7$ is root of $7x - 1$;
$\sqrt{2}$ is root of $x^2 - 2$;
$\sqrt[3]{-5}$ is a root of $x^3 + 5$;
$\sqrt[4]{20}$ is a root of $x^4 - 20$, and
$11 + 13/\sqrt{17}$ is a root of $x^2 - 22x + (1888/17)$.
We call a root of a polynomial with rational coefficients an algebraic number.

Theorem 1.3.2 (Angle Bisectors). *In any triangle, the lines which bisect the three interior angles meet in a common point.*

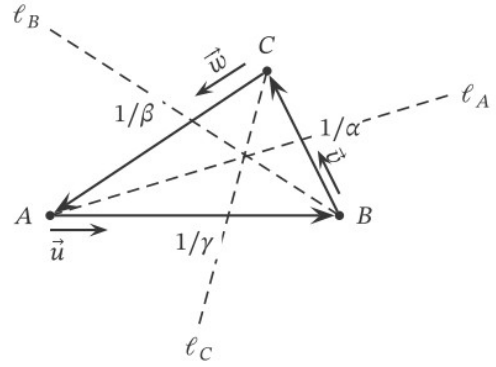

Figure 1.18. Theorem 1.3.2

Suppose the position vectors of the vertices A, B, and C are $\vec{a}$, $\vec{b}$, and $\vec{c}$, respectively.

(a) Show that the *unit* vectors pointing *counterclockwise* along the edges of the triangle (see Figure 1.18) are as follows:

$$\vec{u} = \gamma\vec{b} - \gamma\vec{a}, \quad \vec{v} = \alpha\vec{c} - \alpha\vec{b}, \quad \vec{w} = \beta\vec{a} - \beta\vec{c},$$

where

$$\alpha = \frac{1}{|BC|}, \quad \beta = \frac{1}{|AC|}, \text{ and } \gamma = \frac{1}{|AB|}$$

are the reciprocals of the lengths of the sides (each length is labelled by the Greek analogue of the name of the opposite vertex).

(b) Show that the line ℓ_A bisecting the angle $\angle A$ can be given as

$$\vec{p_A}(r) = (1 - r\beta - r\gamma)\vec{a} + r\gamma\vec{b} + r\beta\vec{c}$$

and the corresponding bisectors of $\angle B$ and $\angle C$ are

$$\vec{p_B}(s) = s\gamma\vec{a} + (1 - s\alpha - s\gamma)\vec{b} + s\alpha\vec{c}$$

$$\vec{p_C}(t) = t\beta\vec{a} + t\alpha\vec{b} + (1 - t\alpha - t\beta)\vec{c}.$$

(c) Show that the intersection of ℓ_A and ℓ_B is given by

$$r = \frac{\alpha}{\alpha\beta + \beta\gamma + \gamma\alpha}, \quad s = \frac{\beta}{\alpha\beta + \beta\gamma + \gamma\alpha}.$$

(d) Show that the intersection of ℓ_B and ℓ_C is given by

$$s = \frac{\beta}{\alpha\beta + \beta\gamma + \gamma\alpha}, \quad t = \frac{\gamma}{\alpha\beta + \beta\gamma + \gamma\alpha}.$$

(e) Conclude that all three lines meet at the point given by

$$\overrightarrow{p_A}\left(\frac{\alpha}{\alpha\beta+\beta\gamma+\gamma\alpha}\right) = \overrightarrow{p_B}\left(\frac{\beta}{\alpha\beta+\beta\gamma+\gamma\alpha}\right) = \overrightarrow{p_C}\left(\frac{\gamma}{\alpha\beta+\beta\gamma+\gamma\alpha}\right) = \frac{1}{\alpha\beta+\beta\gamma+\gamma\alpha}\left(\beta\gamma\vec{a}+\gamma\alpha\vec{b}+\alpha\beta\vec{c}\right).$$

(9) **Barycentric Coordinates:** Show that if $\vec{a}$, $\vec{b}$, and $\vec{c}$ are the position vectors of the vertices of a triangle $\triangle ABC$ in $\mathbb{R}^3$, then the position vector $\vec{p}$ of every point P in that triangle (lying in the plane determined by the vertices) can be expressed as a linear combination of $\vec{a}$, $\vec{b}$ and $\vec{c}$

$$v' = \lambda_1\vec{a} + \lambda_2\vec{b} + \lambda_3\vec{c} \qquad \text{with } 0 \le \lambda_i \le 1 \text{ for } i = 1,2,3 \text{ and } \lambda_1+\lambda_2+\lambda_3 = 1.$$

(*Hint:* (see Figure 1.19) Draw a line from vertex A through P, and observe where it meets the opposite side; call this point D. Use Remark 1.3.1 to show that the position vector $\vec{d}$ of D is a linear combination of $\vec{b}$ and $\vec{c}$, with coefficients between zero and one and summing to 1. Then use Remark 1.3.1 again to show that $\vec{p}$ is a linear combination of $\vec{d}$ and $\vec{a}$.)

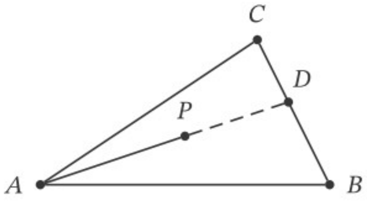

Figure 1.19. Barycentric Coordinates

The numbers λ_i are called the **barycentric coordinates** of P with respect to A, B, and C. Show that P lies on an edge of the triangle precisely if one of its barycentric coordinates is zero.

Barycentric coordinates were introduced (in a slightly different form) by August Möbius (1790-1860) in his book *Barycentrische Calcul* (1827). His name is more commonly associated with “Möbius transformations” in complex analysis and with the “Möbius band” (the one-sided surface that results from joining the ends of a band after making a half-twist) in topology.[12]

(10) Find a line that lies entirely in the set defined by the equation $x^2+y^2-z^2=1$.

History note:

(11) Heath [28, pp. 85-88] points out that the proof of Proposition 4, Book IV of the *Elements* contains the following implicit proof of Theorem 1.3.2 (see Figure 1.20). This was proved by vector methods in Exercise 8.

---

[12] The “Möbius band” was independently formulated by Johann Listing (1808-1882) at about the same time—in 1858, when Möbius was 68 years old. These two are often credited with beginning the study of topology. [32, p. 1165]

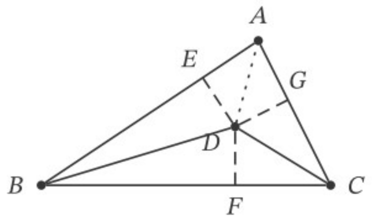

Figure 1.20. Euclid's proof of Theorem 1.3.2

(a) The lines bisecting $\angle B$ and $\angle C$ intersect at a point D above BC because of Book I, Postulate 5 (known as the **Parallel Postulate**):

> That, if a straight line falling on two straight lines make the interior angles on the same side less than two right angles, the two straight lines, if produced indefinitely, meet on that side on which are the angles less than the two right angles.

Why do the interior angles between BC and the two angle bisectors add up to less than a right angle? (*Hint:* What do you know about the angles of a triangle?)

(b) Drop perpendiculars from D to each edge of the triangle, meeting the edges at E, F, and G.
Show that the triangles $\triangle BFD$ and $\triangle BED$ are congruent. (*Hint:* ASA—angle, side, angle!)

(c) Similarly, show that the triangles $\triangle CFD$ and $\triangle CGD$ are congruent.

(d) Use this to show that $|DE| = |DF| = |DG|$.

(e) Now draw the line DA. Show that the triangles $\triangle AGD$ and $\triangle AED$ are congruent. (*Hint:* Both are right triangles; compare one pair of legs and the hypotenuse.)

(f) Conclude that $\angle EAD = \angle GAD$—which means that AD bisects $\angle A$. Thus D lies on all three angle bisectors.

1.4 Projection of Vectors; Dot Products

Suppose a weight is set on a ramp which is inclined θ radians from the horizontal (Figure 1.21). The gravitational force $\vec{g}$ on the weight is directed downward, and some of this is countered by the structure holding up the ramp. The effective force on the weight can be found by expressing $\vec{g}$ as a sum of two (vector) forces, $\overrightarrow{g_{\perp}}$ *perpendicular* to the ramp, and $\overrightarrow{g_{\|}}$ *parallel* to the ramp. Then $\overrightarrow{g_{\perp}}$ is cancelled by the structural forces in the ramp, and the net unopposed force is $\overrightarrow{g_{\|}}$, the *projection* of $\vec{g}$ in the direction of the ramp.

$$\varepsilon = \varepsilon' - j\varepsilon'' = \varepsilon_0\varepsilon_r - j\frac{\sigma}{\omega}$$

In this complex expression, $j = \sqrt{-1}$ and ω is the angular frequency. The real part $\varepsilon' = \varepsilon_0\varepsilon_r$ accounts for the permittivity of the material (where ε_0 is the permittivity of vacuum and ε_r is the dielectric constant of the material, also designated as the relative permittivity). The permittivity measures the induced polarization of the material by units of electrical field, i.e. the extent to which the bound charge distributions can be distorted and polarized under the influence of the field, and the consequent energy stored within the material. For organic material, these charge distributions are mainly associated with double layer membrane proteins, with the surface of solvated macromolecules or with other polar molecules [129].

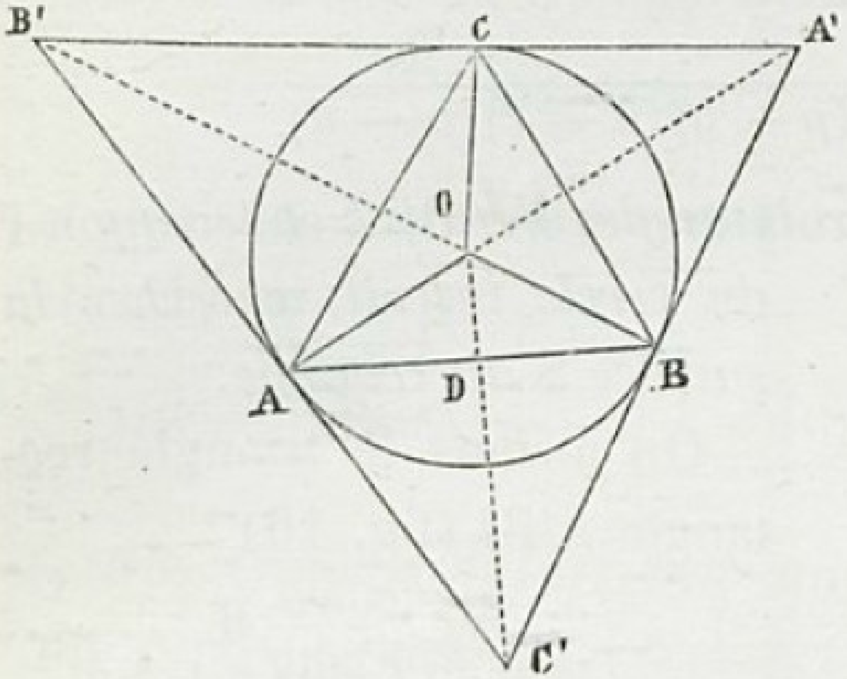
Fig. 15.



En multipliant par ordre (1) et (2), il viendra :

$$ab:(a+x)(b+x)=\sin\alpha\sin\gamma:\sin(\alpha+\beta)\sin(\beta+\gamma) \quad (3);$$

d'où $$x^2+(a+b)x+ab=\frac{ab\sin(\alpha+\beta)\sin(\beta+\gamma)}{\sin\alpha\sin\gamma}$$

et $$x=-\frac{1}{2}(a+b)\pm\frac{1}{2}\sqrt{(a-b)^2+\frac{4ab\sin(\alpha+\beta)\sin(\beta+\gamma)}{\sin\alpha\sin\gamma}}.$$

En posant $$\frac{4ab\sin(\alpha+\beta)\sin(\beta+\gamma)}{\sin\alpha\sin\gamma}=(a-b)^2\operatorname{tg}^2\omega' \quad (4),$$

on aura : $$x=-\frac{1}{2}(a+b)\pm\frac{1}{2}(a-b)\sqrt{1+\operatorname{tg}^2\omega'}$$

et enfin $$x=-\frac{a+b}{2}\pm\frac{(a-b)}{2\cos\omega'}.$$

L'angle auxiliaire ω' est déterminé par l'équation (4). On ne prendra des deux valeurs de x que celle qui est positive. Si l'une des deux autres distances a et b, a par exemple, était inconnue, on la regarderait comme telle et les deux autres x et b comme étant connues ; comme il est facile de le voir, l'équation serait du 1er degré.

Surface d'un triangle.

51. Soit ABC un triangle quelconque (fig. 8).

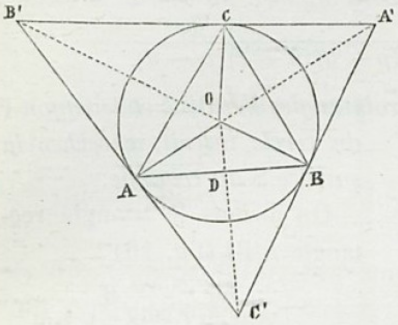
On sait, par la Géométrie, que la surface S de ce triangle est $S=\frac{AB\times CD}{2}$, CD étant la hauteur du triangle. Le triangle rectangle ACD donne :

$$CD=\frac{b\sin A}{R}; \quad \text{d'où} \quad S=\frac{bc\sin A}{2R}.$$

Connaissant les trois angles A, B, C et le rayon R du cercle circonscrit, on a aussi pour la surface S de ce triangle :

$$S=\overline{2R}^2\sin A\sin B\sin C.$$

Fig. 15.



En effet, soit O le centre du cercle circonscrit; désignons par R le rayon du cercle circonscrit, il viendra :

$$AB = c = 2R \sin C,$$

et pour la perpendiculaire abaissée du centre sur AB: $OD = R \cos C$; de sorte que la surface du triangle $AOB = \frac{R^2}{2} \sin 2C$; celle de $AOC = \frac{R^2}{2} \sin 2B$, et celle de $BOC = R^2 \sin A \cos A$. La surface totale

$$ABC = \frac{R^2}{2}(\sin 2A + \sin 2B + \sin 2C).$$

Mais on a vu (15) que

$$\sin 2A + \sin 2B + \sin 2C = 4 \sin A \sin B \sin C;$$

la surface cherchée est donc :

$$S = 2R^2 \sin A \sin B \sin C.$$

52. *Connaissant les quatre côtés* a, b, c, d *d'un quadrilatère inscrit* ABCD, *trouver la surface* Q *de ce quadrilatère.*

On a : $$Q = \left(\frac{ad + bc}{2}\right) \sin A,$$

a, b, c, d étant les côtés AB, BC, CD, AD.

Les deux triangles ABD, BCD donnent pour le côté BD:

$$\overline{BD}^2 = a^2 + d^2 - 2ad \cos A = b^2 + c^2 + 2bc \cos A;$$

d'où $$\cos A = \frac{a^2 + d^2 - b^2 - c^2}{2(ad + bc)}$$

et $$\sin A = \sqrt{1 - \frac{(a^2 + d^2 - b^2 - c^2)^2}{4(ad + bc)^2}}.$$

En remplaçant cette valeur de sin A dans l'expression de Q, il vient :

$$Q = \frac{ad + bc}{2} \sqrt{1 - \frac{(a^2 + d^2 - b^2 - c^2)^2}{4(ad + bc)^2}}$$

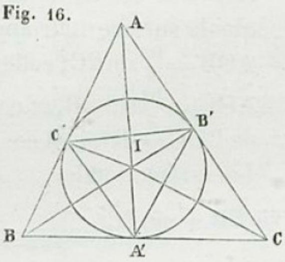
et $Q = \frac{1}{4}\sqrt{(b+c+d-a)(a+c+d-b)(a+b+d-c)(a+b+c-d)}$;

en désignant par $2p$ le périmètre du quadrilatère inscrit, on a :

$$Q = \sqrt{(p-a)(p-b)(p-c)(p-d)}.$$

53. *Connaissant les trois angles* A, B, C *et le rayon* r *du cercle inscrit, chercher la surface* S *du triangle.*

Fig. 16.



On a dans le triangle rectangle A'BI (fig. 16) :

$$A'B = r \operatorname{cotg}\frac{B}{2},$$

$$A'C = r \operatorname{cotg}\frac{C}{2};$$

le côté $BC = a = r\left(\operatorname{cotg}\frac{B}{2} + \operatorname{cotg}\frac{C}{2}\right) = r\frac{\cos\frac{A}{2}}{\sin\frac{B}{2}\sin\frac{C}{2}}.$

La surface du triangle BIC est donc :

$$BIC = \frac{r^2}{2}\left(\operatorname{cotg}\frac{B}{2} + \operatorname{cotg}\frac{C}{2}\right);$$

celle du triangle total ABC est :

$$S = r^2\left(\operatorname{cotg}\frac{A}{2} + \operatorname{cotg}\frac{B}{2} + \operatorname{cotg}\frac{C}{2}\right).$$

Mais on a vu que

$$\operatorname{cotg}\frac{A}{2} + \operatorname{cotg}\frac{B}{2} + \operatorname{cotg}\frac{C}{2} = \operatorname{cotg}\frac{A}{2}\operatorname{cotg}\frac{B}{2}\operatorname{cotg}\frac{C}{2};$$

d'où $$S = r^2 \operatorname{cotg}\frac{A}{2}\operatorname{cotg}\frac{B}{2}\operatorname{cotg}\frac{C}{2}.$$

54. *On connait les trois angles d'un triangle et le rayon* r *du cercle inscrit. Chercher l'aire du triangle qui joint les trois points de contact.*

Soient A', B', C' les trois points de contact et I le centre du cercle inscrit (fig. 16). L'angle au centre B'IC' est le supplément de l'angle A du triangle; de sorte que l'on a pour la surface du triangle B'IC' :

$$\text{surface } B'IC' = \frac{r^2}{2} \sin A,$$

et ainsi des autres. En ajoutant, on obtient pour la surface cherchée S :

$$S = \frac{r^2}{2}(\sin A + \sin B + \sin C) = 2r^2 \cos\frac{A}{2}\cos\frac{B}{2}\cos\frac{C}{2}.$$

55. *Connaissant les trois angles* A, B, C *et le rayon* R *du cercle circonscrit, trouver la surface* S *du triangle* A'B'C', *compris par les tangentes aux sommets du triangle* (fig. 15).

Le triangle rectangle A'BO donne :

$$A'B = R \operatorname{tg} A.$$

On a de même dans le triangle rectangle C'BO :

$$C'B = R \operatorname{tg} C;$$

de sorte que le côté $A'C' = R(\operatorname{tg} A + \operatorname{tg} C)$,

$$A'C' = \frac{R \sin B}{\cos A \cos C}.$$

L'aire du triangle $A'OC' = \frac{R^2}{2}(\operatorname{tg} A + \operatorname{tg} C)$.

La surface du triangle A'B'C' est :

$$S = R^2(\operatorname{tg} A + \operatorname{tg} B + \operatorname{tg} C),$$

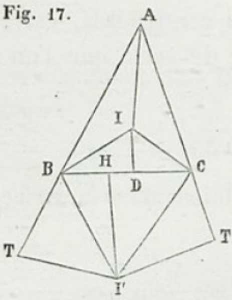
$$S = R^2 \operatorname{tg} A \operatorname{tg} B \operatorname{tg} C,$$

puisque $\operatorname{tg} A + \operatorname{tg} B + \operatorname{tg} C = \operatorname{tg} A \operatorname{tg} B \operatorname{tg} C$.

56. Soient α, β, γ les rayons des trois cercles ex-inscrits au triangle ABC; R, r les rayons des cercles circonscrit et inscrit, a, b, c les trois côtés et $2p$ le périmètre du triangle, I, I' étant les centres des cercles inscrit et ex-inscrit au côté $BC = a$; on aura (fig. 17) :

$$BH = \alpha \operatorname{tg}\frac{B}{2}$$

Fig. 17.



et $$CH = \alpha \operatorname{tg}\frac{C}{2};$$

$$a = \alpha\left(\operatorname{tg}\frac{B}{2} + \operatorname{tg}\frac{C}{2}\right).$$

En remplaçant $\operatorname{tg}\frac{B}{2}$ et $\operatorname{tg}\frac{C}{2}$ par leurs valeurs en fonction des côtés a, b, c du triangle, il viendra :

$$a = \alpha\left[\sqrt{\frac{(p-a)(p-c)}{p(p-b)}} + \sqrt{\frac{(p-a)(p-b)}{p(p-c)}}\right],$$

$$a = \alpha\left[\frac{(p-a)(p-c+p-b)}{\sqrt{p(p-a)(p-b)(p-c)}}\right] = \frac{\alpha(p-a)a}{\sqrt{p(p-a)(p-b)(p-c)}};$$

d'où $$\sqrt{p(p-a)(p-b)(p-c)} = \alpha(p-a);$$

donc, $$S = \alpha(p-a).$$

On aura de même :

$$S = \beta(p-b), \quad S = \gamma(p-c);$$

d'ailleurs, $$S = pr.$$

En ajoutant les valeurs inverses de α, β, γ, on obtiendra :

$$\frac{1}{\alpha} + \frac{1}{\beta} + \frac{1}{\gamma} = \frac{p-a+p-b+p-c}{S} = \frac{p}{S} = \frac{1}{r},$$

et, en multipliant :

$$S^2 = r\alpha\beta\gamma; \quad \text{d'où} \quad S = \sqrt{r\alpha\beta\gamma}.$$

En ajoutant les valeurs de α, β, γ et en retranchant de cette somme le rayon r, il vient :

$$\alpha + \beta + \gamma - r = \frac{abc}{S} \quad \text{ou} \quad \alpha + \beta + \gamma - r = 4R,$$

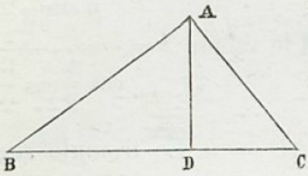
puisque l'on a :

$$abc = 4RS.$$

Ainsi, *la somme des rayons des cercles ex-inscrits est* *égale à quatre fois le rayon du cercle circonscrit plus le rayon du cercle inscrit.*

57. *Connaissant la hauteur* h, *la base* a *et l'angle* A *opposé à celle-ci, résoudre le triangle* (fig. 18).

Fig. 18.



Représentons DC par y et l'angle DAC par x, on aura :

$$\mathrm{BD} = a - y.$$

Les triangles rectangles BDA, ADC donnent :

$$y = h \operatorname{tg} x \quad (1), \quad a - y = h \operatorname{tg}(\mathrm{A} - x) \quad (2).$$

On tire de (1) :

$$\operatorname{tg} x = \frac{y}{h}; \quad \text{d'où} \quad \frac{a-y}{h} = \frac{\operatorname{tg}\mathrm{A} - \frac{y}{h}}{1 + \frac{y}{h}\operatorname{tg}\mathrm{A}}.$$

En résolvant cette équation, il vient :

$$y = \frac{a}{2} \pm \sqrt{\frac{a^2}{4} + h^2 - \frac{ah}{\operatorname{tg}\mathrm{A}}}.$$

Cherchons un carré $v^2 = \frac{\rho\, ah}{\operatorname{tg}\mathrm{A}}$, ρ étant le rayon des tables. On aura :

$$y = \frac{a}{2} \pm \sqrt{\frac{a^2}{4} + h^2 - v^2}.$$

On procédera de la même manière pour connaitre les autres côtés dans les triangles rectangles.

58. *Connaissant les trois angles et le périmètre* 2p, *résoudre le triangle et trouver sa surface.*

On a :
$$\frac{\sin\mathrm{A}}{a} = \frac{\sin\mathrm{B}}{b} = \frac{\sin\mathrm{C}}{c}$$

et
$$\frac{\sin\mathrm{A} + \sin\mathrm{B} + \sin\mathrm{C}}{2p} = \frac{\sin\mathrm{A}}{a}.$$

Mais on sait que

$$\sin A + \sin B + \sin C = 4 \cos \frac{A}{2} \cos \frac{B}{2} \cos \frac{C}{2}.$$

La proportion

$$\frac{\sin A}{\sin B} = \frac{a}{b} = \frac{p \sin \frac{A}{2}}{b \cos \frac{B}{2} \cos \frac{C}{2}} \text{ fournit la valeur } b = \frac{p \sin \frac{B}{2}}{\cos \frac{A}{2} \cos \frac{C}{2}}.$$

Menons la perpendiculaire AD $= h$. Le triangle rectangle ADC donne

$$h = b \sin C; \quad \text{d'où} \quad h = \frac{2p \sin \frac{B}{2} \sin \frac{C}{2}}{\cos \frac{A}{2}}.$$

La surface ABC $= \frac{bh}{2}$. On aura donc :

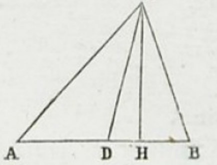
$$\text{surf. ABC} = \frac{p^2 \sin \frac{A}{2} \sin \frac{B}{2} \sin \frac{C}{2}}{\cos \frac{A}{2} \cos \frac{B}{2} \cos \frac{C}{2}} \text{ ou surf. ABC} = p^2 \operatorname{tg} \frac{A}{2} \operatorname{tg} \frac{B}{2} \operatorname{tg} \frac{C}{2}.$$

En rendant cette formule homogène, elle devient :

$$\text{surface ABC} = \frac{p^2 \operatorname{tg} \frac{A}{2} \operatorname{tg} \frac{B}{2} \operatorname{tg} \frac{C}{2}}{\rho^3}.$$

59. *Résoudre le triangle et trouver sa surface, connaissant les trois angles et la bissectrice* δ *de l'un d'eux* (fig. 19).

Fig. 19.



On aura :

$$\frac{\sin A}{\sin CDA} = \frac{\delta}{b};$$

mais

$$\sin CDA = \sin \left(A + \frac{C}{2}\right):$$

donc
$$\frac{\sin A}{\sin\left(A+\frac{C}{2}\right)}=\frac{\delta}{b}.$$

On tire de cette expression :
$$b=\frac{\delta\sin\left(A+\frac{C}{2}\right)}{\sin A}.$$

La proportion $\frac{\sin C}{\sin B}=\frac{c}{b}$ donne :
$$c=\frac{\delta\sin C\sin\left(A+\frac{C}{2}\right)}{\sin A\sin B}.$$

On sait que l'on a :
$$h=\delta\sin\left(A+\frac{C}{2}\right)\quad\text{et}\quad \text{surf. ABC}=\frac{ch}{2}:$$
$$\text{surface ABC}=\frac{\delta^2\sin^2\left(A+\frac{C}{2}\right)\sin C}{2\sin A\sin B}.$$

60. *Connaissant l'aire* t, *la hauteur* h *et un angle* A *à la base, résoudre le triangle.*

On a : $\frac{bh}{2}=t$; d'où $b=\frac{2t}{h}$.

De l'expression $h=c\sin A$, on tire :
$$c=\frac{h}{\sin A}.$$

Les côtés b et c sont donc connus. Il vient :
$$A+B+C=180°;\quad\text{d'où}\quad B+C=180°-A$$
et
$$\frac{1}{2}(B+C)=90°-\frac{A}{2}.$$

On connaîtra $\operatorname{tg}\frac{1}{2}(B-C)$ par la proportion
$$\frac{b+c}{b-c}=\frac{\operatorname{cotg}\frac{1}{2}A}{\operatorname{tg}\frac{1}{2}(B-C)};$$
par suite, on aura la valeur de $\frac{1}{2}(B-C)$.

On a déjà obtenu $\frac{1}{2}(B+C)$; connaissant la demi-somme et la demi-différence de deux angles, on sait trouver chacun d'eux. La valeur de B et de C étant déterminée, on cherchera a au moyen de

$$\frac{\sin A}{\sin B} = \frac{a}{b}.$$

61. *Résoudre le triangle connaissant deux côtés* a *et* b *et la différence* 2d *des angles opposés.*

On donne a et b, $A - B = 2d$;

d'où $\frac{1}{2}(A - B) = d$.

Il vient : $$\frac{a+b}{a-b} = \frac{\operatorname{cotg} \frac{1}{2} C}{\operatorname{tg} \frac{1}{2}(A-B)} = \frac{\operatorname{cotg} \frac{C}{2}}{\operatorname{tg} d};$$

d'où $$\operatorname{cotg} \frac{C}{2} = \frac{(a+b) \operatorname{tg} d}{a-b} = \operatorname{tg} \tfrac{1}{2}(A+B).$$

On connaît ainsi $\frac{1}{2}(A+B)$. D'un autre côté,

$$\tfrac{1}{2}(A - B) = d.$$

Au moyen de la demi-somme et de la demi-différence de deux angles, on peut déterminer chacun d'eux. On trouvera la valeur de c par la formule $\frac{\sin A}{\sin C} = \frac{a}{c}$, sin A, sin C, a étant connus.

62. *Connaissant un angle* A, *le côté opposé* a *et le rectangle* K^2 *des deux autres côtés, résoudre le triangle.*

On a les équations :

$$bc = K^2, \quad a^2 = b^2 + c^2 - 2bc \cos A;$$

d'où $$b^2 + c^2 = a^2 + 2K^2 \cos A.$$

En complétant le carré, il vient :

$$b + c = \sqrt{a^2 + 4K^2 \cos^2 \frac{A}{2}}.$$

On a de même :

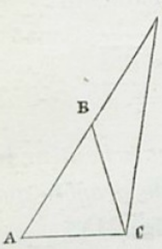
$$b - c = \sqrt{a^2 - 4K^2 \sin^2 \frac{A}{2}}.$$

On fera $\frac{K^2 \cos^2 \frac{A}{2}}{\rho^2} = u^2, \qquad \frac{K^2 \sin^2 \frac{A}{2}}{\rho^2} = v^2 :$

les côtés b et c seront déterminés.

63. *Résoudre le triangle connaissant l'angle* B, *le côté* b *et la somme* a + c = S *des deux autres côtés* (fig. 20).

Fig. 20.



Prolongeons le côté c d'une quantité égale à a. On aura $AI = S$, $AC = b$. Puisque $IBC = 180° - B$, $BIC + ICB = B$. Le triangle IBC étant isoscèle donne :

$$ICB = BIC = \frac{B}{2}.$$

Dans AIC on connaît b, S et l'angle I;

il vient : $\sin \frac{B}{2} : b = \sin \left(C + \frac{B}{2}\right) : S;$

d'où $\sin \left(C + \frac{B}{2}\right) = \frac{S \sin \frac{B}{2}}{b}.$

Dans cette équation, il n'y a d'autre inconnue que l'angle C, la valeur de $\frac{B}{2}$ permettant de trouver B.

64. *Résoudre le triangle connaissant la base* a, *la hauteur* h *et la différence* d *des angles à la base.*

On a $B = d + C.$

Il vient (fig. 18)

$$BD = h \operatorname{cotg} B, \quad DC = h \operatorname{cotg} C$$

et $\frac{a}{h} = \operatorname{cotg} B + \operatorname{cotg} C.$

Or,
$$\text{cotg B} = \text{cotg}\,(d + \text{C});$$

d'où
$$\frac{a}{h} = \frac{\text{cotg}\,d\ \text{cotg C} - 1}{\text{cotg}\,d + \text{cotg C}} + \text{cotg C} \quad . \quad . \quad . \quad (1),$$

équation qui donne cotg C et par suite C.

En représentant BD par x, DC est égal à $a - x$. Les valeurs de x et de $a - x$ fournissent :

$$\text{cotg B} = \frac{x}{h}, \quad \text{cotg C} = \frac{a - x}{h}.$$

Remplaçant cotg B et cotg C dans (1), on obtient :

$$x = \frac{a \sin d + 2h \cos d \pm \sqrt{4h^2 + a^2 \sin^2 d}}{2 \sin d}.$$

65. *Connaissant les trois angles* A, B, C *et la hauteur* h, *trouver l'aire et le périmètre tant du triangle proposé que de celui qui joint les pieds de ses hauteurs* (fig. 21).

Dans le triangle rectangle ABF, on a :

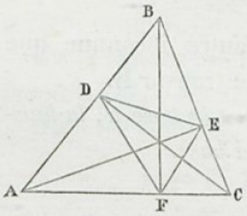
$$\text{AF} = h\ \text{cotg A}.$$

Le triangle rectangle BFC donne :

$$\text{FC} = h\ \text{cotg C},$$

$$b = h(\text{cotg A} + \text{cotg C}) = \frac{h \sin \text{B}}{\sin \text{A} \sin \text{C}}.$$

Fig. 21.



La hauteur h étant donnée, il vient :

$$\text{surf. ABC} = \frac{h^2 \sin \text{B}}{2 \sin \text{A} \sin \text{C}}.$$

On connait les trois angles, ainsi que b ; par conséquent,

$$\frac{\sin \text{A} + \sin \text{B} + \sin \text{C}}{2p} = \frac{\sin \text{B}}{b} = \frac{\sin \text{A} \sin \text{C}}{h};$$

d'où
$$2p = \frac{h \cos \frac{B}{2}}{\sin \frac{A}{2} \sin \frac{C}{2}}.$$

Passons au triangle qui joint les pieds des trois hauteurs.

BCD donne $h' = a \sin B = \frac{h \sin B}{\sin C}$;

de même, $h'' = \frac{h \sin B}{\sin A}$. Il vient : $AF = h \operatorname{cotg} A$.

Triangle ADF fournit :

$$DF = \frac{h \cos A}{\sin C}, \quad DE = \frac{h \sin B \cos B}{\sin C \sin A}, \quad EF = \frac{h \cos C}{\sin A}.$$

Le périmètre de DEF est :

$$2p = \frac{h \cos A}{\sin C} + \frac{h \cos C}{\sin A} + \frac{h \sin B \cos B}{\sin C \sin A},$$

$$2p = h \left[\frac{2 \sin A \cos A + 2 \sin C \cos C + 2 \sin B \cos B}{2 \sin A \sin C}\right],$$

$$2p = \frac{h}{2} \left[\frac{\sin 2A + \sin 2B + \sin 2C}{\sin A \sin C}\right] = 2h \sin B.$$

Connaissant les trois côtés, on déterminera les trois angles. Il sera facile de trouver la hauteur de DEF et, par suite, sa surface S. On trouve :

$$S = h^2 \operatorname{cotg} A \operatorname{cotg} C \cos B \sin B.$$

66. *Résoudre le triangle connaissant la hauteur* h, *le rayon du cercle circonscrit* R *et celui du cercle inscrit* r.

a, b, c étant les trois côtés du triangle cherché, on a :

$$pr = \sqrt{p(p-a)(p-b)(p-c)};$$

d'où
$$p^2r^2 = p(p-a)(p-b)(p-c),$$

le périmètre $2p$ étant égal à $a + b + c$.

Divisant par p^2, on obtient :

$$r^2 = -p^2 + a(2p - a) + 2Rh - 4Rr.$$

En remplaçant p et p^2 par leurs valeurs $\frac{ah}{2r}$ et $\frac{a^2h^2}{4r^2}$, et en substituant $2Rh$ au lieu de bc, il vient :

$$a^2(h - 2r)^2 = 4r^2(2Rh - r^2 - 4Rr);$$

d'où
$$a = \frac{2r}{h - 2r}\sqrt{2Rh - r(r + 4R)}.$$

67. *Résoudre le triangle dans lequel on donne : l'angle* A, *la hauteur* h *menée du sommet de cet angle et l'excès* d *de la somme des côtés de cet angle sur le troisième. Chercher la relation qui doit exister entre les données de la question pour que le triangle soit isoscèle.*

A, B, C étant les trois angles de ce triangle et x, y, z les côtés opposés à ces angles, on a les trois équations :

$$y + z = d + x \quad \ldots\ldots \quad (1),$$

$$yz = \frac{hx}{\sin A} \quad \ldots\ldots \quad (2),$$

$$y^2 + z^2 - 2yz\cos A = x^2 \quad \ldots\ldots \quad (3).$$

En ajoutant les deux dernières, après avoir multiplié l'équation (2) par 2, on obtient :

$$(y + z)^2 = x^2 + 2hx\,\mathrm{cotg}\,\frac{A}{2}$$

et, en ayant égard à l'équation (1),

$$x = \frac{d^2}{2\left(h\,\mathrm{cotg}\,\frac{A}{2} - d\right)},$$

valeur que l'on peut rendre calculable par logarithmes, au moyen d'un angle auxiliaire.

De ces équations, on tire :

$$y+z=\frac{d\left[2h\operatorname{cotg}\frac{A}{2}-d\right]}{2\left[h\operatorname{cotg}\frac{A}{2}-d\right]},$$

$$yz=\frac{hd^2}{2\sin A\left(h\operatorname{cotg}\frac{A}{2}-d\right)}.$$

On aura donc pour les valeurs de y et de z, l'équation

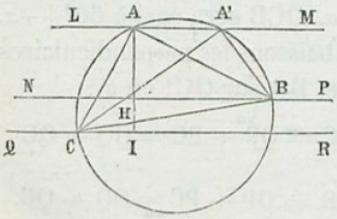
$$u^2-\frac{d\left(2h\operatorname{cotg}\frac{A}{2}-d\right)}{2\left(h\operatorname{cotg}\frac{A}{2}-d\right)}u+\frac{hd^2}{2\sin A\left(h\operatorname{cotg}\frac{A}{2}-d\right)}=0.$$

La condition pour que les racines de cette équation soient égales, c'est-à-dire, pour que le triangle soit isoscèle, est :

$$d^2+4hd\operatorname{tg}\frac{A}{2}=4h^2.$$

68. *Trois parallèles* LM, NP, QR *étant données, chercher les côtés d'un triangle dont les angles sont connus et dont les sommets sont situés sur ces parallèles* (fig. 22).

Fig. 22.



Soit A B C le triangle demandé; représentons par x, y, z, les côtés de ce triangle opposés aux angles A, B, C. Du sommet A, abaissons la perpendiculaire AHI sur NP.

Posons $AH=a$, $AI=b$. La perpendiculaire AHI divise l'angle A en deux parties : $BAH=\alpha$, $CAH=\beta$.

On a dans les triangles rectangles BAH, CAI :

$$a=z\cos\alpha,\quad b=y\cos\beta$$

et $$\cos A = \cos\alpha \cos\beta - \sin\alpha \sin\beta;$$

en remplaçant α et β par leurs valeurs, il vient :

$$\cos A = \frac{ab}{yz} - \sqrt{\left(1 - \frac{a^2}{z^2}\right)\left(1 - \frac{b^2}{y^2}\right)}$$

et, en faisant disparaître le radical :

$$y^2z^2 \sin^2 A = a^2y^2 + b^2z^2 - 2abyz \cos A.$$

On a : $$x : y = \sin A : \sin B,$$
$$x : z = \sin A : \sin C.$$

En substituant dans l'équation précédente, on obtient, après les simplifications :

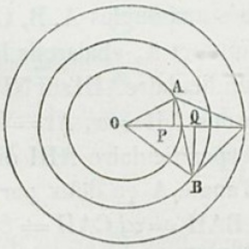
$$x^2 = \frac{a^2}{\sin^2 C} + \frac{b^2}{\sin^2 B} - \frac{2ab \cos A}{\sin B \sin C}.$$

Il est facile de construire le triangle ; à cette fin, par un point A′ de la droite LM, faisons les angles A′BH = B et A′CR = C : les points B et C détermineront la longueur BC = x.

69. *Étant donnés trois cercles concentriques de rayon* R, r, r′, *chercher le côté du triangle équilatéral dont les sommets sont situés sur chaque circonférence.*

Soit ABC le triangle cherché (fig. 23).

Fig. 23.



Menons les rayons OA, OB, OC. Si nous représentons ACO par α, OCB sera égal à $60^0 - \alpha$.

Abaissons les perpendiculaires AP et BQ sur OC ; on a :

$$OC = OP + PC = OQ + QC$$

ou

$$R = OP + PC = OQ + QC.$$

Mais on sait que $\overline{OP}^2 = r'^2 - \overline{AP}^2$ et $AP = x \sin\alpha$;

donc $OP = \sqrt{r'^2 - x^2 \sin^2\alpha}$ et $PC = x \cos\alpha$.

Il vient : $$R = x\cos\alpha + \sqrt{r'^2 - x^2\sin^2\alpha} \quad \ldots \quad (1).$$

On a aussi : $$OQ = \sqrt{r^2 - x^2\sin^2(60^0 - \alpha)}$$

et $$QC = x\cos(60^0 - \alpha);$$

d'où $$R = x\cos(60^0 - \alpha) + \sqrt{r^2 - x^2\sin^2(60^0 - \alpha)} \quad . \quad (2).$$

On obtient : $$x^2 - 2Rx\cos\alpha = r'^2 - R^2 \quad \ldots \quad (1),$$

$$x^2 - 2Rx\cos(60^0 - \alpha) = r^2 - R^2 \quad \ldots \quad (2).$$

En nous rappelant que $\sin 60^\circ = \frac{1}{2}\sqrt{3}$ et $\cos 60^\circ = \frac{1}{2}$, ce système devient :

$$x^2 - 2Rx\cos\alpha = r'^2 - R^2 \quad \ldots \quad (1),$$

$$x^2 - Rx\cos\alpha - \sqrt{3}Rx\sin\alpha = r^2 - R^2 \quad . \quad . \quad (2).$$

De (1), on tire : $$\cos\alpha = \frac{x^2 + R^2 - r'^2}{2Rx} \quad \ldots \quad (4).$$

Cette valeur, remplacée dans (2), donne :

$$\sin\alpha = \frac{x^2 + R^2 + r'^2 - 2r^2}{2\sqrt{3}Rx} \quad \ldots \quad (5).$$

On sait que $\sin^2\alpha + \cos^2\alpha = 1$. Élevant (4) et (5) au carré et additionnant membre à membre, il vient :

$$\frac{(x^2 + R^2 - r'^2)^2}{4R^2x^2} + \frac{(x^2 + R^2 + r'^2 - 2r^2)^2}{12R^2x^2} = 1,$$

équation bi-carrée qui donnera la valeur du côté cherché.

Exercices.

I. *On connaît : 1° le périmètre* 2p; *2° la hauteur* h *et 3° l'angle* B *à la base d'un triangle quelconque* ABC. *Calculer les trois côtés et les deux angles.*

II. *On connaît* : 1° *la médiane* m; 2° *la hauteur* h *partant du même sommet et 3° l'angle* B *à la base d'un triangle quelconque* ABC; *calculer les trois côtés et les deux angles.*

III. *On connaît le rayon* R *du cercle circonscrit, le rayon* r *du cercle inscrit et l'un des angles du triangle; calculer les trois côtés et les deux autres angles du triangle.*

IV. *Connaissant la surface* S *d'un triangle quelconque, un angle et le rayon du cercle inscrit, calculer les côtés et les angles du triangle.*

V. *Calculer les trois côtés du triangle quelconque* ABC *connaissant :* 1° *le périmètre* $2p$; 2° *le produit ou rectangle* K^2 *des deux côtés de l'angle* A ; 3° *la médiane* $AM = m$.

VI. *Trouver l'aire du triangle équilatéral, connaissant, soit les distances de ses sommets à une droite extérieure, soit les projections des côtés sur cette droite.*

VII. *Dans un triangle quelconque on donne les deux hauteurs partant des deux extrémités d'un même côté, et l'angle qu'elles font entre elles. Déterminer les trois côtés et les trois angles.*

VIII. *Dans un triangle quelconque on connaît la hauteur, la bissectrice et la médiane partant d'un même sommet; calculer les trois côtés et les trois angles du triangle.*

IX. *Étant donnés les angles, la surface et le périmètre d'un trapèze, trouver les quatre côtés.*

X. *Une circonférence et deux tangentes étant données, mener une troisième tangente telle que sa partie interceptée, soit par les deux premières, soit par les prolongements de deux diamètres, à angles droits, ait une longueur donnée* c.

XI. *Un point* M *et un cercle de centre* C *étant donnés, inscrire dans ce cercle un triangle dont un côté* AB *passe par* M, *et dont les deux autres côtés sont parallèles à deux droites données de position.*

XII. *Dans un triangle quelconque* ABC, *on donne :* 1° *l'angle* A ; 2° *les deux médianes qui partent des sommets* B *et* C *du triangle. Calculer les trois côtés et les deux angles.*

orbital. The next orbital up in energy ψ_2, is different from those we have met so far. Its symmetry demands that the node be in the middle; but this time the centre of the conjugated system is occupied by an *atom* and not by a *bond*. Having a node in the middle means having a zero coefficient c_2 on C-2, and hence the coefficients on C-l and C-3 in this orbital must be $\pm 1/\sqrt{2}$, if, squared and summed, they are to equal one. The atomic orbitals in ψ_2 are so far apart in space that their repulsive interaction does not, to a first approximation, raise the energy of this molecular orbital relative to that of an isolated p orbital. In consequence, whether filled or not, it does not contribute to the overall bonding. If the sum of the squares of the three orbitals on C-2 is also to equal one, then the coefficients on C-2 in ψ_1 and ψ_3* must also be $\pm 1/\sqrt{2}$. Finally, since symmetry requires that the coefficients on C-1 and C-3 in ψ_1 and ψ_3* have the same absolute magnitude, and the sum of their squares must equal $1-(1/\sqrt{2})^2$, we can deduce the unique set of *c*-values shown in Fig. 1.30. A pattern present in the allyl system because of its symmetry is seen with other symmetrical conjugated systems: the $|c|$ values are reflected across a mirror plane placed horizontally, half way up the set of orbitals, between ψ_1 and ψ_3*, and also across a mirror plane placed vertically, through C-2. It is only necessary therefore to calculate four of the nine numbers in Fig. 1.30, and deduce the rest from the symmetry.

In this picture of the bonding, we get no immediate appreciation of the energies of these orbitals relative to those of ethylene. The nonbonding orbital ψ_2 is clearly on the α level, that of a p orbital on carbon, and ψ_1 is lowered by the extra π bonding and ψ_3* is raised. To assess the energies, there is a simple geometrical device that works for linear conjugated systems. The conjugated system, *including the dummy atoms at the ends of the sine curves*, is inscribed vertically inside a circle of radius 2β, following the convention that one π bond in ethylene defines β. This is shown for ethylene and the allyl system in Fig. 1.31, where the dummy atoms are marked as dots at the top and bottom of the circle. The energies *E* of the π orbitals can then be calculated using Equation 1.10:

$$E = 2\beta \cos\frac{k\pi}{n+1} \qquad 1.10$$

where *k* is the number of the atom along the sequence of *n* atoms. This is simply an expression based on the trigonometry of Fig. 1.31, where, for example, the π orbital of ethylene is placed on the first atom ($k = 1$) of the sequence of two ($n = 2$) reading anticlockwise from the bottom. Thus the energies of the π orbitals in the allyl system are 1.414β below the α level and 1.414β above the α level.

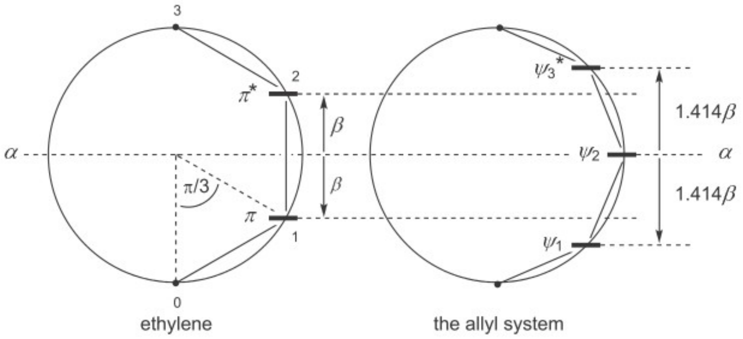

Fig. 1.31 Energies of π molecular orbitals in ethylene and the allyl system

We can gain further insight by building the picture of the π orbitals of the allyl system in another way. Instead of mixing together three p orbitals on carbon, we can combine two of them in a π bond first, as in Fig. 1.26, and then work out the consequences of having a third p orbital held within bonding distance of

$$E = 2\beta \cos \frac{k\pi}{n+1}$$

$$a = \frac{-1+\sqrt{5}}{2} = 0.618033988\ldots.$$

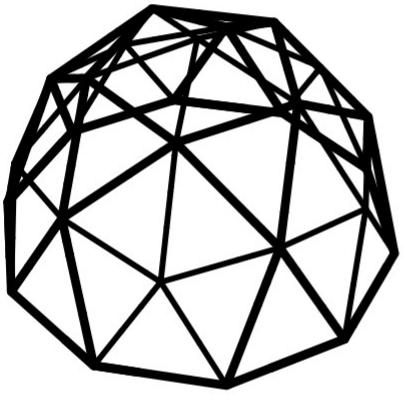

Figure 6.44. Geodesic dome

6.7.18. Figure 6.44 shows a geodesic dome with 5-fold vertices and 6-fold vertices. (A *geodesic* of the sphere is a great circle.) Figure 6.45 shows a bird's-eye view of the dome. The thinner edges emanate from the 5-vertices, while four of the six edges emanating from each 6-vertex are thicker. The five triangles that meet at a 5-vertex are isosceles, while two of the six triangles that meet at a 6-vertex are equilateral. This exercise uses vector algebra and the spherical coordinate system to work out the lengths and angles of the dome. Integration and the change of variable theorem play no role in this exercise.

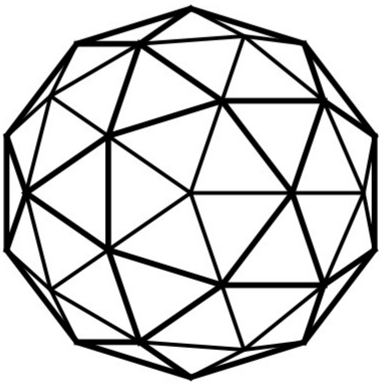

Figure 6.45. Geodesic dome, bird's-eye view

(a) Take all vertices to lie on a sphere of radius 1. The ten thick edges around the equator form a regular 10-gon. Show that consequently the thick edges have length

$$a = 2\sin(\pi/10) = 2\cos(2\pi/5).$$

This famous number from geometry goes back to Euclid. Note that $a = \zeta_5 + \zeta_5^{-1}$ where $\zeta_5 = e^{2\pi i/5} = \cos(2\pi/5) + i\sin(2\pi/5)$ is the fifth root of unity one-fifth of the way counterclockwise around the complex unit circle. Thus $a^2 + a - 1 = \zeta_5^2 + 2 + \zeta_5^3 + \zeta_5 + \zeta_5^4 - 1$, and the right side is 0 by the finite geometric sum formula. That is,

$$a^2 + a - 1 = 0, \quad a > 0,$$

and so the length of the thick edges is

$$a = \frac{-1+\sqrt{5}}{2} = 0.618033988\ldots.$$

This number is a variant of the so-called golden ratio.

(b) The dome has a point at the north pole $(0,0,1)$; then a layer of five points p_0 through p_4 around the north pole at some colatitude φ; then a layer of ten points q_0 through q_9, five at colatitude 2φ and the other five at some second colatitude ϕ; and finally the layer of ten equatorial points r_0 through r_9. The colatitude φ must be such that the triangle with vertices n, q_0, and q_2 is equilateral. These vertices may be taken to be

$$\begin{aligned} n &= (0,0,1), \\ q_0, q_2 &= (\cos(\pi/5)\sin(2\varphi), \mp\sin(\pi/5)\sin(2\varphi), \cos(2\varphi)). \end{aligned}$$

Show that the equilateral condition $|n - q_0|^2 = |q_2 - q_0|^2$ gives the condition $\cos^2(\varphi) = 1/(2-a)$, then $\sin^2(\varphi) = (1-a)/(2-a)$, then $\tan^2(\varphi) = a^2$, so that the colatitude of the five points about the north pole is

$$\varphi = \arctan(a) = 31.7174\ldots^\circ.$$

Use the cross-sectional triangle having vertices $\mathbf{0}$, n, p_0 and the law of cosines to show that the shorter segments have length

$$b = \sqrt{2(1 - 1/\sqrt{2-a})} = 0.546533057\ldots.$$

(Alternatively, one can find φ and b using the triangle with vertices n, p_0, p_1.) For reference in part (e), show that

$$2\varphi = \arctan(2) = 63.4349\ldots^\circ.$$

(c) Show that the angle of an isosceles triangle where its equal sides meet at a 5-vertex is

$$\alpha = 2\arcsin(a/(2b)) = 68.8619\ldots^\circ,$$

and the angles where its unequal sides meet at 6-vertices are

$$\beta = \arccos(a/(2b)) = 55.5690\ldots^\circ\,.$$

(d) Show that the angle where two a-segments meet along a geodesic is $180^\circ - 36^\circ$. Show that the angle where two b-segments meet along a geodesic (this happens at the 6-vertices but not at the 5-vertices) is $180^\circ - \varphi$.

(e) To find the colatitude ϕ of $q_1, q_3, \ldots, q_9$, take q_9 and q_1 to be

$$q_9, q_1 = (\cos(\pi/5)\sin(2\varphi), \mp\sin(\pi/5)\sin(2\varphi), \cos(2\varphi)),$$

and consider the geodesic containing them. Their cross product is normal to the plane of the geodesic. Show that this cross product is

$$q_9 \times q_1 = 2\sin(\pi/5)\sin(2\varphi)(-\cos(2\varphi), 0, \cos(\pi/5)\sin(2\varphi)).$$

Show by illustration that the latitude of this cross product is the colatitude ϕ of q_9 and q_1. Show that $\phi = \arctan(\sqrt{2+a})$. Show further that $(a+1)^2 = 2+a$, so that in fact,

$$\phi = \arctan(a+1) = 58.2825\ldots^\circ\,.$$

6.8 Topological Preliminaries for the Change of Variable Theorem

This section establishes some topological results to prepare for proving the change of variable theorem (Theorem 6.7.1), and then the next section gives the proof. Both sections are technical, and so the reader is invited to skim as feels appropriate. For instance, one might focus on the discussion, the statements, and the figures, but go light on the proofs.

In preparation for proving the change of variable theorem, we review its statement. The statement includes the terms *boundary* and *interior*, which we have considered only informally so far, but we soon will discuss them more carefully. The statement also includes the term *open*, and the reader is reminded that a set is called open if its complement is closed; we soon will review the definition of a closed set. The statement includes the term $\mathcal{C}^1$*-mapping*, meaning a mapping such that all partial derivatives of all of its component functions exist and are continuous. And the statement includes the notation K° for the interior of a set K. The theorem says:

> *Let $K \subset \mathbb{R}^n$ be a compact and connected set having boundary of volume zero. Let A be an open superset of K, and let*
>
> $$\Phi : A \longrightarrow \mathbb{R}^n$$
>
> *be a $\mathcal{C}^1$-mapping such that*

6 (-& .- - -/ ' ! - Kd ' & " ! "#
$ ' % 6 $"
7')%;<6

$$U_{U3} = \frac{2U_{E3}}{\sqrt{2+\sqrt{2+\sqrt{2}}}} \tag{4.61}$$

where U_{Un} and U_{En} refer to the perimeters of circumscribed and inscribed polygons with 2^{n+1} sides. Kabus then made the numerically interesting observation that the perimeters of the circumscribed polygons were always twice as far from the circumference of the circle as those of the inscribed 2^n-sided polygons. He proved

$$\lim_{n\to\infty} \frac{\frac{1}{2}U_{Un} - \pi}{\pi - \frac{1}{2}U_{En}} = 2 \tag{4.62}$$

From the two observations, Kabus then derived the following iterative algorithm for π:

Algorithm (4.63) Kabus (alg 4.63)

```
Initialise:
    $a_0 := \sqrt{\frac{1}{2} + \frac{1}{4}\sqrt{2}}$
Iterate: $(n = 0, 1, 2, \ldots K - 1)$
    $a_{n+1} := \sqrt{\frac{1}{2} + \frac{1}{2}a_n}$
Then:
    $p_K = \frac{2^{K+2}}{3} \frac{\sqrt{2-2a_K}+\sqrt{2-2a_{K+1}}}{\sqrt{2+2a_{K+1}}} \xrightarrow{1} \pi$
```

Each iteration improves the π approximation by 1.2 places, whereas, for example, Archimedes's method only produced 0.6 places each time the number of sides of the polygon was doubled. Adding various cunning improvements in the arithmetic and using a PASCAL program, Kabus arrived in this way at 5000 decimal places of π.

4.4 On continued fractions

Continued fractions are mentioned a number of times in this book and we would therefore like to say a few words about them at this point.

Continued fractions are the "lost sons" of mathematics classroom teaching. They are regarded as too advanced for secondary schools and too elementary for universities, as a result of which they generally fall between the cracks of both syllabuses [18, p. 129]. Their historical roots go back to the 17th century mathematicians Cataldi, Wallis and Huygens, and their theory traces its origins to Leonhard Euler, who presented them in 1748 in his *Introductio in analysin infinitorum* [52, pages 303 ff]. The classic textbook on this interesting topic was written by Oskar Perron [90], and a more recent textbook is that by C. D. Olds [87].

A continued fraction is a fraction whose numerator is an integer and whose denominator is the sum of an integer and a fraction which in turn possesses the same form.

$$b_0 + \cfrac{a_1}{b_1 + \cfrac{a_2}{b_2 + \cfrac{a_3}{b_3 + \ddots \cfrac{a_{n-1}}{b_{n-1} + \cfrac{a_n}{b_n}}}}} \tag{4.64}$$

$$= b_0 + a_1/\,(b_1 + a_2/\,(b_2 + a_3/(b_3 + \cdots + a_n/b_n))) \tag{4.65}$$

This representation, which rapidly grows to occupy a large physical area, is often replaced by

$$b_0 + \frac{a_1|}{|b_1} + \frac{a_2|}{|b_2} + \frac{a_3|}{|b_3} + \cdots + \frac{a_n|}{|b_n} \tag{4.66}$$

A. Pringsheim, 1898

or by

$$b_0 + \frac{a_1}{b_1 +} \frac{a_2}{b_2 +} \frac{a_3}{b_3 +} \cdots \frac{a_n}{b_n} \tag{4.67}$$

L.J. Rogers, 1907

Regular (Perron) or *simple* (Olds) continued fractions [90][87] are ones in which all the numerators $a_i = 1$. They can be written even more concisely like this:

$$[b_0, b_1, b_2, \dots b_n] \tag{4.68}$$

The elements a_i and b_i of a continued fraction are also known, respectively, as "partial numerator" and "partial denominator".

Every real number can be represented uniquely by a simple continued fraction. A number is rational if its continued fraction is finite and irrational if its continued fraction is infinite.

The second theorem immediately proves, for example, that all the numbers contained in the following list are irrational because their continued fractions are infinite. The proof of the irrationality of π which Johann Heinrich Lambert wrote in 1766 is also based on this theorem. Lambert showed that the continued fraction of $\arctan 1 =$

$\pi/4$ is infinite and therefore $\pi/4$ and hence π must be irrational (see page 192).

The transformation of a number from its decimal representation into its simple continued fraction form, and vice versa, is quite simple. It can be performed with any pocket calculator which has an inverse operation $1/x$. The two algorithms look like this:

```
// cf[] : array with the elements of the continued fraction

procedure NumberToCf(number, n, cf[0..n-1])
{
    for k:=0 to n-1
    {
       x      := floor(number)
       cf[k]  := x
       number:= 1/(number-x)
    }
}
```

and the reverse procedure for calculating a number from the elements of its simple continued fraction goes like this:

```
function CfToNumber(n, cf[0..n-1])
{
   number := cf[n-1]

   for k:=n-2 to 0 step -1
   {
      number := 1/number + cf[k]
   }
   return number
}
```

The simple continued fractions of some prominent constants are shown below[3]:

$$\begin{aligned}\phi &= \frac{\sqrt{5}+1}{2} \quad \text{(Golden ratio)} \qquad (4.69)\\ &= 1.61803\,39887\,49894\,84820\,\ldots\\ &= [1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,1,\ldots]\end{aligned}$$

$$\begin{aligned}\sqrt{2} &= 1.41421\,35623\,73095\,04880\,\ldots \qquad (4.70)\\ &= [1,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,2,\ldots]\end{aligned}$$

$$\begin{aligned}\sqrt{3} &= 1.73205\,08075\,68877\,29352\,\ldots \qquad (4.71)\\ &= [1,1,2,1,2,1,2,1,2,1,2,1,2,1,2,1,2,1,2,1,2,1,\ldots]\end{aligned}$$

---

[3] As this book is concerned almost exclusively with numbers that are transcendental and, as a very minimum, are irrational, we are naturally only interested in *infinite* continued fractions.

$$\begin{aligned} e &= 2.71828\,18284\,59045\,23536\,\ldots \qquad (4.72)\\ &= [2,1,2,1,1,4,1,1,6,1,1,8,1,1,10,1,1,12,1,1,14,1,\ldots] \end{aligned}$$

Euler, 1737

$$\begin{aligned} e^2 &= 7.38905\,60989\,30650\,22723\,\ldots \qquad (4.73)\\ &= [7,2,1,1,3,18,5,1,1,6,30,8,1,1,9,42,11,1,1,12,54,\ldots] \end{aligned}$$

Stieltjes, c. 1890 [90]

$$\sqrt{e} = 1.64872\,12707\,00128\,14684\,\ldots \qquad (4.74)$$

Sundman, 1895

$$= [1,1,1,1,5,1,1,9,1,1,13,1,1,17,1,1,21,1,1,25,1,1,\ldots]$$

$$\begin{aligned} \pi &= 3.14159\,26535\,89793\,23846\,\ldots \qquad (4.75)\\ &= [3,7,15,1,292,1,1,1,2,1,3,1,14,2,1,1,2,2,2,2,1,84,\ldots] \end{aligned}$$

$$\begin{aligned} \sqrt{\pi} &= 1.77245\,38509\,05516\,02729\,\ldots \qquad (4.76)\\ &= [1,1,3,2,1,1,6,1,28,13,1,1,2,18,1,1,1,83,1,4,\ldots] \end{aligned}$$

$$\begin{aligned} \pi^e &= 22.45915\,77183\,61045\,47343\,\ldots \qquad (4.77)\\ &= [22,2,5,1,1,1,1,1,3,2,1,1,3,9,15,25,1,1,5,4,1,\ldots] \end{aligned}$$

$$\begin{aligned} \sqrt[3]{2} &= 1.25992\,10498\,94873\,16476\,\ldots \qquad (4.78)\\ &= [1,3,1,5,1,1,4,1,1,8,1,14,1,10,2,1,4,12,2,3,2,1,\ldots] \end{aligned}$$

$$\begin{aligned} \gamma &= \lim_{n\to\infty} \sum_{k=1}^{n} \frac{1}{k} - \ln(n+1) \quad \text{(Euler's constant)} \qquad (4.79)\\ &= 0.57721\,56649\,01532\,86060\,\ldots\\ &= [0,1,1,2,1,2,1,4,3,13,5,1,1,8,1,2,4,1,1,40,1,11,3,\ldots] \end{aligned}$$

Euler, 1734

On closer examination we find there is a recurring pattern in the continued fractions of the first 6 constants, e.g. in $\sqrt{e}$ the pattern $1, 1, 4n+1$, whereas this does not occur in the second five cases beginning with π.

We cannot conclude from this that the simple continued fractions of many or even of the majority of common constants possess a regular pattern. In reality, this applies only to a minority, namely to the so-called quadratic irrationalities, one example of which is the "Golden ratio" ($\phi = 1 + \sqrt{5}/2$), also to a few well-known transcendental numbers, such as the constant e itself and individual algebraic expressions containing e, e^2 or $e^{1/q}$, where q is an integer.

Interestingly, in almost all irrational or transcendental numbers, including π, the geometric mean of their first n continued fraction elements converges towards a fixed limit and this limit is the same in all such numbers. This astonishing discovery was made in 1935 by Alexander Khintchine (1894–1959) [74]:

$$\lim_{n\to\infty} \sqrt[n]{b_1 \cdot b_2 \cdot \ldots \cdot b_n} = 2.68545\,20010\ldots = K_0 \tag{4.80}$$

The limit K_0 is defined as $\prod_{k=1}^{\infty}[1 + \frac{1}{k(k+2)}]^{\log_2 k}$ and became known as the *Khintchine constant*. The number is difficult to calculate, and only a modest 110,000 decimal places are available.

For the number π, the geometric mean of the first $17,001,303$ elements of its simple continued fraction come to 2.686393 [12], which is fairly close to the Khintchine constant. On the other hand, the geometric mean for the number e, the big exception, moves away as n increases, while in the case of another exception, the constant ϕ (Golden ratio), whose continued fraction consists of pure ones, the geometric mean does converge, but towards 1 rather than K_0.

If one looks at the table with the approximations for π on page 54 in this light, one could form the opinion that continued fractions produce a more compact representation of π than the decimal representation. For the table shows, for example, that π can be just as well approximated with 3 continued fraction elements as with 6 decimal digits. However, this is only the case at particular places, and these are precisely the ones at which it is especially beneficial to terminate a continued fraction. Further on in both representations, the advantage of the continued fraction always disappears, and generally the simple continued fraction of an irrational number requires just as many elements as its equally accurate decimal fraction possesses decimal places. The quotient from the number of accurate decimal places of the approximation and the number of continued fraction elements converges towards a fixed limit which is close to 1, as Alexander Khintchine once again proved in 1935. The exact value $1.03064\ldots = \pi^2/(6 \cdot \ln 2 \cdot \ln 10)$ was stated somewhat later, in 1937, by Paul Lévy.

irrationality of $\sqrt[3]{2}$. (The irrationality of $\sqrt[3]{2}$ may be established very simply as in Problem 2 of the previous section.) ∎

The basic idea of this section will be slightly generalized in the next section, where it will yield the solution of the angle trisection problem.

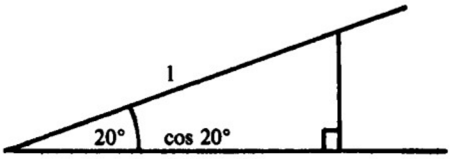
PROBLEMS

1. Can the cube be "tripled"?
2. Can the cube be "quadrupled"?

Section 1.3 Trisecting the Angle

The classical problem involving angle trisection is: **Given an arbitrary angle, is it possible to trisect it?** (As usual, we are restricting ourselves to the use of a compass and an unmarked straightedge.) The answer is "no", but one must be careful to understand what this answer means. There are certainly some particular angles that can be trisected, as, for example, the angle of 90°. (Why?) However, it is not possible to trisect an *arbitrary* angle. To put it another way, there exists at least one angle that *cannot* be trisected. We shall actually produce one such angle, in particular the innocuous-looking angle of 60°.

Since a 60° angle can be constructed, if it could also be trisected, then a 20° angle could be constructed. But then, as illustrated in Figure 5, the number cos 20° would be constructible. It will be shown, however, that the number cos 20° is a root of a cubic equation which has no constructible roots, thus leading to a contradiction.



Mark off a unit length on one side and drop a perpendicular to the other.

Figure 5

From elementary trigonometric formulas, we have

$$\begin{aligned}\cos 3\theta &= \cos(2\theta + \theta)\\ &= \cos 2\theta \cos \theta - \sin 2\theta \sin \theta\\ &= (\cos^2\theta - \sin^2\theta)\cos \theta - (2 \sin \theta \cos \theta)\sin \theta\\ &= \cos^3\theta - 3 \sin^2\theta \cos \theta\\ &= \cos^3\theta - 3(1 - \cos^2\theta)\cos \theta\\ &= 4 \cos^3\theta - 3 \cos \theta.\end{aligned}$$

When $\theta = 20°$, $\cos 3\theta = \frac{1}{2}$, so the number cos 20° must be a root of the cubic equation

$$8u^3 - 6u - 1 = 0.$$

This equation is made a little simpler by the change of variable $x = 2u$, which yields

$$x^3 - 3x - 1 = 0.$$

If cos 20° were constructible, then it would be possible to construct a root of this equation. As the first step in the proof that this is impossible, we make an observation which is very similar to that of Lemma 2:

LEMMA 3. *Let* $\mathbf{F}(\sqrt{k})$ *be a quadratic extension of a field* $\mathbf{F}$. *If the equation* $x^3 - 3x - 1 = 0$ *has a root in* $\mathbf{F}(\sqrt{k})$, *then it has a root in* $\mathbf{F}$ *itself.*

Proof. If the equation has a root in $\mathbf{F}(\sqrt{k})$, we may denote it by $a + b\sqrt{k}$, where a, b, and k are in $\mathbf{F}$. If $b = 0$ we are done, for $a \in \mathbf{F}$ is a root. If $b \neq 0$, it will be shown that $-2a$ is a root, and this is obviously in $\mathbf{F}$.

Substituting the given root into the equation, we obtain:

$$(a + b\sqrt{k})^3 - 3(a + b\sqrt{k}) - 1 = 0$$

$$a^3 + 3a^2b\sqrt{k} + 3ab^2k + b^3k\sqrt{k} - 3a - 3b\sqrt{k} - 1 = 0$$

$$[a^3 + 3ab^2k - 3a - 1] + [3a^2b + b^3k - 3b]\sqrt{k} = 0.$$

But now we can conclude that $[3a^2b + b^3k - 3b] = 0$, for otherwise we could solve for $\sqrt{k}$ as an element of $\mathbf{F}$. But this then also requires that $[a^3 + 3ab^2k - 3a - 1] = 0$. After dividing the first of these two equations by b (which is not 0), we have

$$3a^2 + b^2k - 3 = 0$$

$$a^3 + 3ab^2k - 3a - 1 = 0.$$

Solving the first for b^2k and substituting the result into the second, we obtain

$$a^3 + 3a(3 - 3a^2) - 3a - 1 = 0$$

$$-8a^3 + 6a - 1 = 0$$

$$(-2a)^3 - 3(-2a) - 1 = 0$$

from which we see that $-2a$, which is in $\mathbf{F}$, is a solution of the original equation. ∎

Now the main result is easily accessible.

THEOREM 3. *It is not possible to trisect an arbitrary angle.*

Proof. If it were possible to trisect an arbitrary angle, it would be possible to trisect, say, a 60° angle, which is itself constructible. But, as noted earlier, this would imply the constructibility of cos 20° and hence the constructibility of a root of the cubic equation $x^3 - 3x - 1 = 0$. By Theorem 1, such a root would have to belong to a field $\mathbf{F}_N$ situated in a sequence $\mathbf{Q} = \mathbf{F}_0 \subset \mathbf{F}_1 \subset \mathbf{F}_2 \subset \cdots \subset \mathbf{F}_N$ in which each field is a quadratic extension of the previous one. By a repeated application of Lemma 3, then, there would have to be a *rational* root of $x^3 - 3x - 1 = 0$. But this will now be shown to be impossible.

If a rational number M/N, expressed in lowest terms, were a root of the equation, we would have

$$\frac{M^3}{N^3} - \frac{3M}{N} - 1 = 0,$$

and so

$$M^3 - 3MN^2 - N^3 = 0.$$

Thus we could write both

$$M^3 = N[3MN + N^2]$$

and

$$N^3 = M[M^2 - 3N^2].$$

From the first we conclude that if N had a prime factor p, then p would divide M^3 and hence M. From the second we conclude that if M had a prime factor q, then q would divide N^3 and hence N. Since M and N were assumed to have no factors in common, the only possible values for M and N are ±1, and so the only possible rational roots are ±1. But by inspection, neither of these actually turns out to be a root. ∎

It is important to realize that there is a difference between the questions:

(i) Is it possible to construct the angle θ?

(ii) Given the angle 3θ, is it possible to construct the angle θ?

The second question is the one addressed by the angle trisection problem, and it only reduces to the first question in cases where the angle 3θ is itself constructible. It happened to be convenient to use such a case in the proof of Theorem 3, but the reader should know that there are angles for which the answer to question (i) is "no" but the answer to question (ii) is "yes". To analyze these two different questions, it is useful to convert them into more algebraic terms. Remembering that in the presence of a unit segment we have available an angle if and only if we have available a segment whose length is its cosine, we can rephrase these questions as follows:

(i′) Is $\cos\theta$ constructible?

(ii′) Is $\cos\theta$ constructible if, in addition to a unit segment, we are also given a segment of length $\cos 3\theta$?

In Problem 4, the reader is asked to show the existence of an angle for which these questions have different answers.

PROBLEMS

1. It is obvious that by repeated bisection it is possible to divide an arbitrary angle into 4 equal parts. Show

how this may also be deduced algebraically from the equation relating cos 4θ and cos θ.

2. Discuss the validity of the following proof of Theorem 3: "By the continuity of cos θ, there exists an angle θ_0 such that cos $\theta_0 = (\sqrt[3]{2})/2$. By Theorem 2, cos θ_0 is not constructible. Hence $3\theta_0$ is an angle that cannot be trisected."

*3. Prove that it is not possible, in general, to quintisect an arbitrary angle, i.e., to divide it into five equal parts.

4. Is the difficulty in Problem 2 real or imagined? Show that there are trisectible angles 3θ such that θ is not constructible.

Section 1.4. Squaring the Circle

The third classical construction problem, that of squaring the circle, turns out to be much more difficult than the previous two. The question is: **Given a circle, is it possible to construct a square with the same area as the circle?** If we take as our unit length the radius of the circle, its area is π, and so the construction of the appropriate square amounts to the construction of a segment of length $\sqrt{\pi}$, which would necessitate the constructibility of π itself. It will be shown, however, that π is not constructible, and thus that it is not possible to square the circle. The proof that π is not constructible will consist of two main parts: first, that every constructible number is the root of some polynomial equation with rational coefficients; second, that π cannot be a root of any polynomial equation with rational coefficients. The first part, which is fairly simple, will be covered in this section. The second part, which is much more difficult, will be proved in Section 1.7, the intervening sections being used to introduce some ideas needed there as well as later on.

Section 1.4. Squaring the Circle

The third classical construction problem, that of squaring the circle, turns out to be much more difficult than the previous two. The question is: **Given a circle, is it possible to construct a square with the same area as the circle?** If we take as our unit length the radius of the circle, its area is π, and so the construction of the appropriate square amounts to the construction of a segment of length $\sqrt{\pi}$, which would necessitate the constructibility of π itself. It will be shown, however, that π is not constructible, and thus that it is not possible to square the circle. The proof that π is not constructible will consist of two main parts: first, that every constructible number is the root of some polynomial equation with rational coefficients; second, that π cannot be a root of any polynomial equation with rational coefficients. The first part, which is fairly simple, will be covered in this section. The second part, which is much more difficult, will be proved in Section 1.7, the intervening sections being used to introduce some ideas needed there as well as later on.

We shall make use of the following simple lemma:

LEMMA 4. *Let* $\mathbf{F}(\sqrt{k}\,)$ *be a quadratic extension of a field* $\mathbf{F}$. *If* a *is a root of a polynomial equation of degree* n *with coefficients in* $\mathbf{F}(\sqrt{k}\,)$, *then* a *is a root of a polynomial equation of degree* $2n$ *with coefficients in* $\mathbf{F}$.

Proof. By hypothesis, a is a root of an equation of the form

$$\left(a_n + b_n\sqrt{k}\,\right)x^n + \left(a_{n-1} + b_{n-1}\sqrt{k}\,\right)x^{n-1} + \cdots + \left(a_0 + b_0\sqrt{k}\,\right) = 0,$$

where for all i, a_i and $b_i \in \mathbf{F}$, and furthermore, a_n and b_n are not both zero. Transferring the terms involving $\sqrt{k}$ to the other side of the equation, we obtain

$$a_nx^n + a_{n-1}x^{n-1} + \cdots + a_0 = -\sqrt{k}\left(b_nx^n + b_{n-1}x^{n-1} + \cdots + b_0\right).$$

Upon squaring both sides and collecting all terms together again on the left, we have a polynomial equation of which a is also a root. Its degree is $2n$, because the coefficient of x^{2n}, the highest power present, is $a_n^2 - kb_n^2$, which is not 0 by the assumption that $\sqrt{k} \notin \mathbf{F}$. ∎

Using this lemma, we are now able to prove:

THEOREM 4. *Every constructible number is the root of some polynomial equation with rational coefficients.*

Proof. If the number a is constructible, then by Theorem 1 there is a sequence of fields $\mathbf{Q} = \mathbf{F}_0 \subset \mathbf{F}_1 \subset \cdots \subset \mathbf{F}_N$ such that $a \in \mathbf{F}_N$ and for each j, $0 \leqslant j$

$\leqslant N-1$, $\mathbf{F}_{j+1}$ is a quadratic extension of $\mathbf{F}_j$. Now, a satisfies a polynomial equation of degree 1 with coefficients in $\mathbf{F}_N$, namely, the equation $x - a = 0$. By the repeated application of Lemma 4, a satisfies a polynomial equation of degree 2^i with coefficients in $\mathbf{F}_{N-i}$. Hence for $i = N$, we see that a satisfies a polynomial equation of degree 2^N with coefficients in $\mathbf{Q}$. ∎

In view of Theorem 4, once it has been shown (in Section 1.7) that π is not the root of any polynomial equation with rational coefficients, we shall have a complete proof of the result stated earlier, namely:

THEOREM 5. *It is not possible to "square the circle".*

PROBLEMS

1. The number $\sqrt{2}+\sqrt{3}$, being constructible, has associated with it a sequence of quadratic field extensions $\mathbf{Q} = \mathbf{F}_0 \subset \mathbf{F}_1 \subset \cdots \subset \mathbf{F}_N$ such that $\sqrt{2}+\sqrt{3} \in \mathbf{F}_N$. Determine the smallest such number N. Using this value, what is the degree of the polynomial whose existence is proved in Theorem 4? Following the procedure in the proof of Theorem 4, determine this and any intermediate polynomials.
2. Does there exist a polynomial equation with rational coefficients and of degree less than that determined in Problem 1 such that $\sqrt{2}+\sqrt{3}$ is a root?

Section 1.5. Polynomials and Their Roots

It now becomes essential for us to expand our considerations to the set $\mathbf{C}$ of complex numbers. These

This is how I first got interested in mathematics, and irrational numbers in particular. Getting to "know" the infinite decimal for $\sqrt{2}$ may be too discouraging for some—mathematicians generally prefer a problem that gives them some chance of success—but it is a reminder of how much remains to be understood. And since the infinite decimal is so completely baffling, we are encouraged to look at different approaches to $\sqrt{2}$, in the hope of finding enlightenment elsewhere. Surely $\sqrt{2}$ is a simple irrational number, so there should be a simple way of looking at it.

1.6 The Continued Fraction for $\sqrt{2}$

A more enlightening process than the infinite decimal algorithm would relate $\sqrt{2}$ to a *predictable* infinite sequence of numbers, and such a process actually exists: the famous *Euclidean algorithm.* The algorithm is named after Euclid because its first known appearance is in the *Elements*, Book VII, but there is evidence for its earlier use in the investigation of irrationals.

The object of the Euclidean algorithm is to find a *common measure* of two magnitudes a and b. We say that c is a common measure of a and b if

$$a = mc \quad \text{and} \quad b = nc \quad \text{for some natural numbers } m \text{ and } n.$$

The key to the algorithm is the fact that

$$a - b = (m - n)c,$$

so *any common measure c of a and b is also a measure of their difference.* If a is greater than b, we can therefore replace the problem of finding a common measure of a and b by the "smaller" problem of finding a common measure of $a - b$ and b. This is precisely what the algorithm does. The algorithm seeks a common measure by "continually subtracting the lesser magnitude from the greater" (as Euclid put it).

When a common measure exists the Euclidean algorithm will find it in a finite number of steps. In particular, when a and b are positive natural numbers the algorithm gives what is called the *greatest common divisor* of a and b. This concept is very important in the theory of natural numbers, and we pursue it further in Chapter 7.

Right now, we are interested in the opposite situation, where a and b have no common measure. In this case the algorithm necessarily runs forever, but perhaps in a way that enables to us to understand *why* it runs forever. We are in luck when $a = \sqrt{2}$ and $b = 1$. Here, the Euclidean algorithm runs forever because it becomes *periodic*: it returns to a situation it has been in before. Unlike

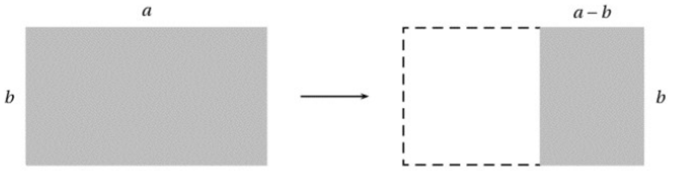

Figure 1.9. Subtracting the lesser from the greater of two magnitudes.

the infinite decimal process for $\sqrt{2}$, the Euclidean algorithm on $\sqrt{2}$ and 1 has infinite behavior of the simplest possible kind.

To show periodic behavior as clearly as possible, I apply the Euclidean algorithm instead to the numbers $a = \sqrt{2}+1$ and $b = 1$, where periodicity kicks in a little earlier. Also, I present the algorithm in a geometric form. Two magnitudes a and b will be represented by the greater and lesser sides of a rectangle, and the lesser b is subtracted from the greater a by cutting off a square of side b (Figure 1.9).

When $a = \sqrt{2}+1$ and $b = 1$ we can subtract b from a twice before getting a magnitude less than b. The result is a rectangle with greater side 1 and lesser side $\sqrt{2}-1$, as shown in Figure 1.10. I claim *this is a repetition of the original situation* because *the new rectangle is the same shape as the old.*

To see why, we calculate the ratio $\frac{\text{long side}}{\text{short side}}$, which represents the shape of the rectangle. For the old rectangle,

$$\frac{\text{long side}}{\text{short side}} = \frac{\sqrt{2}+1}{1} = \sqrt{2}+1.$$

For the new rectangle,

$$\begin{aligned}
\frac{\text{long side}}{\text{short side}} &= \frac{1}{\sqrt{2}-1} \\
&= \frac{1}{\sqrt{2}-1}\,\frac{\sqrt{2}+1}{\sqrt{2}+1} \quad \text{multiplying top and bottom by } \sqrt{2}+1 \\
&= \frac{\sqrt{2}+1}{(\sqrt{2})^2-1^2} \quad \text{because } (\sqrt{2}-1)(\sqrt{2}+1) = (\sqrt{2})^2-1^2, \\
&\qquad \text{by the “difference of two squares” from Section 1.4} \\
&= \frac{\sqrt{2}+1}{2-1} = \sqrt{2}+1.
\end{aligned}$$

Thus the new rectangle has the same shape as the old, so as we continue to run the Euclidean algorithm the same thing will happen over and over: two

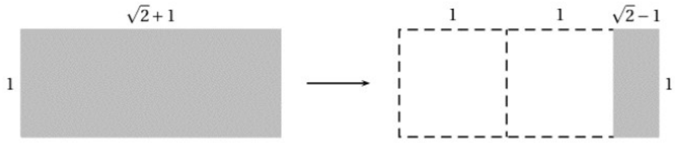

Figure 1.10. Subtracting 1 twice from $\sqrt{2}+1$.

squares will be cut off the new rectangle, producing yet another rectangle of the same shape, and so on. The algorithm will not terminate because it keeps reproducing the same geometric situation.

It is also clear that the Euclidean algorithm will not terminate if it starts with the pair $\sqrt{2}$ and 1. The only change is that just one square is cut off the initial rectangle. After that, rectangles with sides in the ratio $\sqrt{2}+1:1$ recur forever.

Since the Greeks knew that $\sqrt{2}$ is irrational, they knew that the Euclidean algorithm does not terminate when applied to $\sqrt{2}$ and 1. Indeed, the *Elements*, Book X, Proposition 2 actually states nontermination of the algorithm as a criterion for irrationality. What is not so clear is whether the Greeks observed the *periodicity* of the algorithm on $\sqrt{2}$ and 1. Many people believe they did, but the *Elements* does not mention it, and the other likely sources of this information are lost.

One thing is clear. It is a lot easier to display the periodicity of $\sqrt{2}$ using notation for fractions, which the Greeks did not have. Again, it is better to use $\sqrt{2}+1$ for purposes of demonstration, because the periodicity starts earlier. We start by subtracting 1 twice from $\sqrt{2}+1$, as the algorithm requires. This produces the remainder $\sqrt{2}-1$, which equals $\frac{1}{\sqrt{2}+1}$ because $(\sqrt{2}-1)(\sqrt{2}+1)=1$, as found above. Thus

$$\sqrt{2}+1=2+(\sqrt{2}-1)=2+\frac{1}{\sqrt{2}+1}.$$

This says that the $\sqrt{2}+1$ in the bottom of the fraction on the right side equals the *whole* right side. We can therefore replace $\sqrt{2}+1$ by $2+\frac{1}{\sqrt{2}+1}$, and keep on doing this to our hearts' content:

$$\sqrt{2}+1=2+\frac{1}{\sqrt{2}+1}=2+\frac{1}{2+\frac{1}{\sqrt{2}+1}}=2+\frac{1}{2+\frac{1}{2+\frac{1}{\sqrt{2}+1}}}\quad\cdots$$

The logical conclusion of this process is an infinite periodic fraction for $\sqrt{2}+1$, called its *continued fraction*:

$$\sqrt{2}+1=2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\ddots}}}}}$$

Finally, we get the continued fraction for $\sqrt{2}$ by subtracting 1 from both sides:

$$\sqrt{2}=1+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\ddots}}}}}$$

The infinite recurrence of 2s produced by the Euclidean algorithm is reflected by the infinite sequence of 2s in the continued fraction.

Periodicity in Continued Fractions and Decimals

You may be wondering whether it is valid to expel $\sqrt{2}$ from the right side of the equations as we did above, by letting the bottom line of the fraction descend to infinity. As soon as we accept that the continued fraction is meaningful, we can verify that its value is $\sqrt{2}+1$ as follows. Let

$$x=2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\cfrac{1}{2+\ddots}}}}}$$

Then x is a positive number (greater than 2 in fact), and since the term under the 1 on the right side equals the whole right side, we also have

$$x=2+\frac{1}{x}.$$

Multiplying both sides by x, and rearranging, we get the equation

$$x^2-2x-1=0.$$

This quadratic equation has two solutions, $1+\sqrt{2}$ and $1-\sqrt{2}$, but only the first one is positive, hence it is the value of the continued fraction.

A similar argument shows that any periodic continued fraction is the solution of a quadratic equation, which means periodicity is quite rare. In infinite decimals, periodicity is even more special: it occurs only for rational numbers. The reason for this can be seen by taking a random example, such as

$$x = 0.235717171717171\cdots$$

First we shift the decimal point three places (the length of the segment 235 that comes before the periodic part) by multiplying by 1,000:

$$1000x = 235.717171717171\cdots$$

Then we shift by another two places (the length of the "period" 71) by multiplying by 100:

$$100000x = 23571.717171717171\cdots$$

Finally we subtract $1000x$ from $100000x$, to cancel the parts after the decimal point:

$$100000x - 1000x = 23571 - 235, \quad \text{that is,} \quad 99000x = 23336,$$

so x is the rational number $\frac{23336}{99000}$.

1.7 Equal Temperament

Now it is time to return to the music question raised in Section 1.1: can a sum of fifths equal a sum of octaves? The answer is no, because summing m fifths corresponds to multiplying frequency by $(3/2)^m$, while summing n octaves corresponds to multiplying frequency by 2^n. If the two sums of intervals are equal, then

$$\left(\frac{3}{2}\right)^m = 2^n,$$

and therefore, multiplying both sides by 2^m,

$$3^m = 2^m \times 2^n.$$

But this is impossible, because the left side is odd (being a product of odd numbers) and the right side is even (being a product of even numbers). Thus the octave and the fifth have no "common measure" and the Pythagorean attempt to divide the octave into natural steps using rational numbers was doomed from the start—though the Pythagoreans may never have noticed.

If one wants a scale with the sweetest harmonies, given by the octave and the fifth, then it is impossible to include both by dividing the octave into equal steps. An *approximation* to such a scale is possible, since the sum of 12 fifths is close to seven octaves. But (as mentioned in Section 1.1) the difference between 12 fifths and seven octaves is a noticeable fraction of a step, so some compromise is necessary. If the perfect fifth is a note in the scale, then some steps in the scale that are supposed to be equal will not be. If we insist on equal steps, then the fifth note of the scale will be imperfect—its frequency ratio with the first note will not be exactly 3:2.

This problem bedevilled music in both the East and West. In China, music was generally based on a different scale (dividing the octave into five steps instead of seven—corresponding to the black keys on the piano), but the Chinese also tried to build their scale from a cycle of 12 perfect fifths, and ran into the same problem. Amazingly, the compromise solution that builds the scale from 12 equal parts of an octave ("semitones") was proposed in the East and West almost simultaneously: by Zhu Zaiyu in China and by Simon Stevin in Holland. Their discoveries are generally given the dates 1584 and 1585, respectively, but neither is known exactly, so it seems fair to consider the discoveries independent. (An additional fact, which makes coincidence almost unbelievable, is that the 1580s were also the decade when Jesuit missionaries arrived in China, bringing western mathematics to the region for the first time.)

Both Zhu and Stevin realized that adding 12 equal semitones to form an octave amounts to doing 12 multiplications, by the same number, to achieve multiplication by 2. Therefore, one semitone corresponds to multiplication by the 12th root of 2, or $2^{1/12}$ as Stevin wrote it. In both eastern and western scales the crucial note is seven semitones above the first, hence at a frequency ratio of

$$\left(2^{1/12}\right)^7 = 2^{7/12} = 1.49831\cdots$$

This is certainly close to the perfect fifth ratio of 1.5, though some people can hear the difference. The advantage of this imperfect fifth, however, is that 12 of them make exactly seven octaves, and a cycle of 12 fifths hits all notes of the new scale exactly.

The system of equal semitones, or *equal temperament*, obviously has great simplicity and mathematical beauty. However, it was not immediately popular with musicians. In western music it did not become widespread until the nineteenth century. Bach's *Well-Tempered Clavier* of 1722 is often thought to be an advertisement for equal temperament, but more likely it was intended to show off an older system. There are many systems of "just temperament" that retain perfect fifths while coming closer to equal semitones than the Pythagorean scale.

For a modern mathematician, of course, equal temperament is interesting because the basic ratio $2^{1/12}$ is *irrational*. It must be, because its sixth power is the irrational number $\sqrt{2}$, while powers of rational numbers are rational. Thus *equal temperament rejects all integer ratios in music except the ratio 2:1 for the octave.* For a long time, the Chinese do not seem to have been aware of irrational numbers. According to Joseph Needham's *Science and Civilisation in China* [40, vol. III, p. 90]:

> The Chinese mathematicians ... seem to have been neither attracted nor perplexed by irrationals, if indeed they appreciated their separate existence.

Zhu Zaiyu may be an exception to this characterization. In 1604, he wrote a *New Explanation of the Theory of Calculation* in which he derived values of the roots of 2 needed for equal temperament. He was so attracted to $\sqrt{2}$ that he used nine abacuses to compute it to 25-digit accuracy!

As we know from Section 1.3, Stevin appreciated the existence of irrationals, and aggressively asserted their equal rights with rational numbers. In his *Theory of the Art of Singing* he seized the fresh opportunity to mock the unbelievers in irrational numbers. He even claimed that the equal-tempered fifth must *sound* sweet because $2^{7/12}$ is such a wonderful number!

> Now someone might wonder, according to the ancient view, how the sweet sound of the fifth could consist in so unspeakable, irrational, and inappropriate a number. To this we might give a detailed answer. However, ... it is not our intention to teach those with the inexpressible irrationality and inappropriateness of such a misunderstanding the expressibility, rationality, appropriateness, and natural wonderful perfection of these numbers ... .[1]

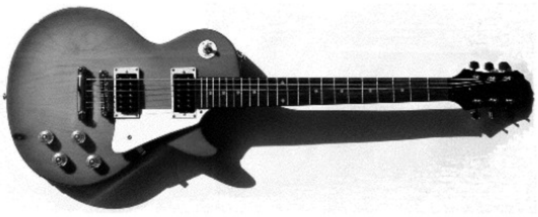

Figure 1.11. Frets on a guitar.

---

[1] Translation by Adriaan Fokker in *The Principal Works of Simon Stevin*, vol. V, p. 441. (Modified by the author with the assistance of Hendrik Lenstra.)

This is Pythagoreanism reborn! “All is number” again, but the meaning of “number” has been expanded to include irrationals.

In conclusion, we should mention that both Zhu and Stevin saw musical ratios the way Pythagoras did—as ratios of string lengths—because they were writing a few decades before Beeckman discovered that pitch corresponds to frequency of vibration. Thus the most direct realization of their idea today is seen in the placement of frets on an instrument such as a guitar (see Figure 1.11). Sliding the finger from one fret to the next changes the length of the vibrating string by a factor of $2^{1/12}$.

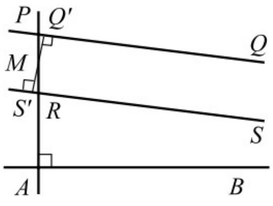
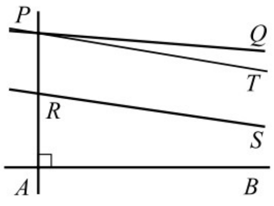
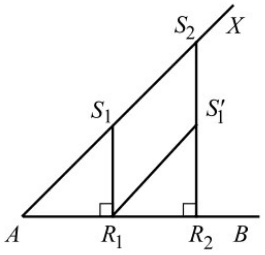
Suppose $\Pi(AP) > \Pi(AR)$, then there is a line through P, say $\overrightarrow{PT}$ with $\angle RPT \cong \angle ARS$. Then $\angle APT < \angle APQ$ and $\overrightarrow{PT}$ meets $\overleftrightarrow{AB}$, and hence $\overleftrightarrow{RS}$. By the Alternate Interior Angles Theorem (Proposition I.27), however, $\overleftrightarrow{PT}$ does not meet $\overleftrightarrow{RS}$.





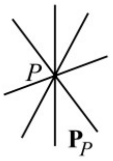


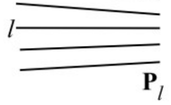
(3) In fact, any acute angle is the angle of parallelism for some length. To see this, fix the angle $\angle BAX$. Suppose R_1S_1 is perpendicular to $\overleftrightarrow{AB}$ at R_1 and S_1 lies on $\overrightarrow{AX}$. The triangle $\triangle AR_1S_1$ has some angle defect, say $\delta > 0$. Mark R_2 along $\overleftrightarrow{AB}$ with $R_1R_2 \cong AR_1$. If the perpendicular to $\overleftrightarrow{AB}$ from R_2 meets $\overrightarrow{AX}$ at S_2, then $R_2S_2 > R_1S_1$ and we can construct the point S_1' along R_2S_2 such that $R_2S_1' \cong R_1S_1$. It follows that $\triangle AR_2S_2$ contains two copies of $\triangle AR_1S_1$ and so the angle defect of $\triangle AR_2S_2$ is at least 2δ (see Exercise 3.2). If every perpendicular to $\overleftrightarrow{AB}$ within $\angle BAX$ meets $\overrightarrow{AX}$, then we can iterate this procedure to construct a triangle with angle defect greater than $n\delta$ for any n and so greater than two right angles, which is impossible. Hence, some perpendicular to $\overleftrightarrow{AB}$ does not meet AX and $\angle BAX$ is the angle of parallelism for some length.

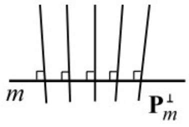
The hyperbolic plane

Without the millstone of proving Postulate V around their necks, Gauss, J. Bolyai, and Lobachevskiĭ developed the properties of the plane with the new definition of parallelism and **HAA**. Auxiliary constructions and curves led to new tools and results, especially when developed in space.

We introduce properties and objects that do not depend on the choice of **HAA** or **HRA**. We call such a property or object **absolute**. The following collections of lines are absolute. A **pencil of lines** is a set of lines satisfying one of three properties: There is the pencil of all lines through a given point P, denoted $\mathbf{P}_P$; the pencil of all lines parallel to a given line l, denoted $\mathbf{P}_l$; and the pencil of all lines perpendicular to a given line, m, denoted $\mathbf{P}_m^{\perp}$.





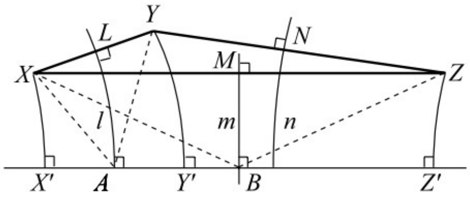


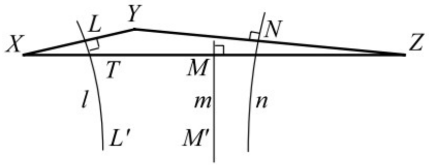
The pencil of lines $\mathbf{P}_l$ parallel to a given line l can be thought of as a limit of pencils of lines $\mathbf{P}_X$ through a point X, as X travels along l to “infinity.” Notice that every point in the plane lies on a unique line in the pencils of parallels or perpendiculars, and every point other than the given point P lies on a unique line in $\mathbf{P}_P$.

A choice of three distinct points determines each sort of pencil of lines.

Theorem 4.4. *Given distinct points X, Y, and Z, the lines l, m, and n that are the perpendicular bisectors of the segments XY, YZ, and XZ, respectively, lie in a pencil of lines.*

Proof (Shirikov 1964): Consider the triangle $\triangle XYZ$. If l and m meet, then they meet at the center of a circle circumscribed around the triangle. Furthermore, the line n passes through the same point of intersection. We leave it to the reader to prove this.

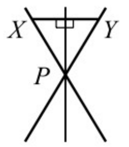


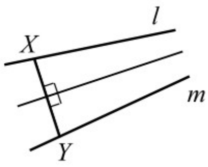


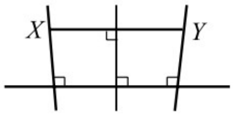
Suppose that l and m have a common perpendicular $\overleftrightarrow{AB}$. Let $L = l \cap XY$, $M = m \cap XZ$, and $N = n \cap YZ$, the midpoints of the segments XY, XZ, and YZ. Construct segments XX', YY', and ZZ' perpendicular to $\overleftrightarrow{AB}$ through X, Y, and Z, respectively. Join X to B and Z to B. Then by Side–Angle–Side, $\triangle BMZ \cong \triangle BMX$. It follows from $\angle XBM \cong \angle ZBM$ that $\angle XBX' \cong \angle ZBZ'$. By Angle–Angle–Side we find $\triangle XBX' \cong \triangle ZBZ'$ and so $XX' \cong ZZ'$. By a similar construction joining X to A and Y to A we find $XX' \cong YY'$. Thus $Y'YZZ'$ is a Saccheri quadrilateral and the line n perpendicular to YZ through the midpoint of YZ meets the side $\overleftrightarrow{Y'Z'} = \overleftrightarrow{AB}$ in a right angle. Thus l, m, and n lie in $\mathbf{P}^{\perp}_{\overleftrightarrow{AB}}$, the pencil of lines perpendicular to $\overleftrightarrow{AB}$.

Finally, if l and m are parallel, then n cannot meet either l or m nor will n share a common perpendicular with l or m. It remains to show that l, m, and n are parallel in the same direction. By Pasch’s Axiom, a line entering a triangle along a side must exit through another side. The midpoint on the longest side separates the other lines from each other and so all the lines pass through the longest side. Let $l = \overleftrightarrow{LL'}$ meet XZ at T. Since $\angle LTZ$ is exterior to the right triangle $\triangle TLX$, this angle is obtuse by the Exterior Angle Theorem. Therefore the supplement $\angle L'TZ$ is acute. Since l is parallel to m and m is perpendicular to XZ, $\angle L'TZ = \Pi(TM)$ and so l and m are parallel away from XZ in the direction of L' and M'. The analogous argument shows n parallel to m in the same direction. Thus l, m, and n are elements of $\mathbf{P}_l$. ■

Definition 4.5 (Gauss 1831). *Given a pencil of lines* **P**, *two points X and Y are said* **to correspond with respect to P** *if the line in the pencil that passes through* *the midpoint of segment XY is perpendicular to XY. When the pencil of lines is the set of lines parallel to a given line, the set of all points corresponding to a given point X is called a* **horocycle** *through X (*Parazykel *in Gauss).*







Points that correspond are related by a reflection of the plane across a line in the pencil. For a pencil of lines through a given point, a direct consequence of the proof of Euclid's Proposition I.6 (the converse of *Pons Asinorum*) is that the set of points corresponding to a given point forms a circle. From this point of view, a horocycle may be thought of as a "circle with center at infinity." The set of points corresponding to a given point with respect to $\mathbf{P}_m^{\perp}$ is the curve of points equidistant to the line m. The properties of the Saccheri quadrilateral may be used to explore the properties of this curve.

We leave the proof of the following proposition to the reader.

Proposition 4.6. *A horocycle is a line if and only if* **HRA** *holds.*

Thus, a new feature of the plane with **HAA** is the set of horocycles in the plane. An immediate consequence of Theorem 4.4 is the independence of the choice of the point X in the definition of a horocycle through X.

Corollary 4.7. *If Y and Z lie on the horocycle through X determined by $\mathbf{P}_l$, then X and Y lie on the horocycle through Z determined by $\mathbf{P}_l$.*

The points on a horocycle can be characterized by the angle of parallelism: If X and Y are on the horocycle, the perpendicular bisector m of the segment XY lies in the pencil of parallel lines that determine the horocycle. The corresponding angles at X and Y have measure $\Pi(XM) = \Pi(YM)$, where M is the midpoint of XY.

If m meets the horocycle at a point Q, then the tangent to the horocycle at Q is perpendicular to m as can be seen by letting the chord XY shrink to Q. Thus, as in the case of radii to a circle, the lines in the pencil $\mathbf{P}_l$ meet the horocycle at right angles.

We say that two horocycles are **concentric** if they are determined by the same pencil of parallel lines. Segments of horocycles have lengths that are, as usual, limits of polygonal approximations.

Lemma 4.8.

(1) *To equal chords there correspond equal arcs of the horocycle. To the longer chord there corresponds a longer arc.*

(2) *Segments of lines in the pencil bounded by two concentric horocycles are congruent.*
(3) *The arcs of concentric horocycles bounded by two lines in the pencil decrease in the direction of parallelism.*

PROOF:

(1) Suppose X, Y and X', Y' lie on a horocycle determined by $\mathbf{P}_l$ and that $XY \cong X'Y'$. Denote the arc along a horocycle between points X, and Y by $\overset{\frown}{XY}$. The goal is to show that the horocycle segment $\overset{\frown}{XY}$ is congruent to $\overset{\frown}{X'Y'}$. Let M be the midpoint of XY and m the line in $\mathbf{P}_l$ through M which is perpendicular to XY and suppose m meets the horocycle at Q. By construction $\triangle XMQ \cong \triangle YMQ$ and $XQ \cong YQ$. The angle $\angle XQM$ is congruent to $\Pi(XQ/2)$ because X and Q correspond.

Let M' be the midpoint of $X'Y'$ and m' the line in $\mathbf{P}_l$ through M' perpendicular to $X'Y'$. On m' let Q' be away from the direction of parallelism with $M'Q' \cong MQ$. The triangles $\triangle XMQ$ and $\triangle X'M'Q'$ are congruent so $XQ \cong X'Q'$ and $\angle X'Q'M' \cong \Pi(XQ/2) \cong \Pi(X'Q'/2)$ and so the line through the midpoint of $X'Q'$ perpendicular to $X'Q'$ lies in $\mathbf{P}_l$. Thus Q' corresponds to X' and Q' lies on the horocycle. The arc $\overset{\frown}{XY}$ is approximated by the line segments XQ and QY and $\overset{\frown}{X'Y'}$ by the congruent $X'Q'$ and $Q'Y'$. To complete the proof, take the midpoints of the approximating segments and make the comparisons. Iterated halving gives the arcs in the limit.

(2) Suppose $\overleftrightarrow{XA}$ and $\overleftrightarrow{YB}$ are in $\mathbf{P}_l$ and X and Y lie on one horocycle and A and B on a concentric horocycle determined by $\mathbf{P}_l$. We want to show that $XA \cong YB$. Let m be the line through the midpoint M of XY and perpendicular to XY. Suppose m meets AB at a point N. Join X to N and Y to N to form triangles $\triangle XMN$ and $\triangle YMN$. These triangles are congruent by Side–Angle–Side and so $XN \cong YN$. It follows that:

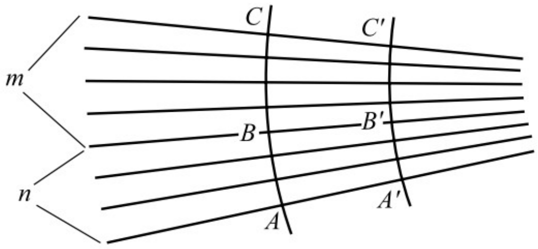
$$\angle NXA \cong \Pi(XM) - \angle MXN \cong \Pi(YM) - \angle NYB \cong \angle NYB.$$

It is also the case that $\angle NAX \cong \pi - \Pi(AB/2) \cong \angle NBY$. By the congruence criterion Angle–Angle–Side, triangles $\triangle NAX$ and $\triangle NBY$ are congruent and so $XA \cong YB$. It also follows that m is the perpendicular bisector of AB.

(3) This statement follows from the approximations in part 1 and the fact that the angle of parallelism decreases with increasing length (Property 2 of $\Pi(x)$). ■

With these ideas we arrive at the following result.

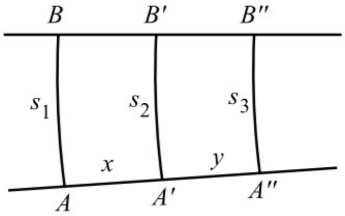
Theorem 4.9. *The ratio of the lengths of concentric arcs of two horocycles intercepted between two lines in the pencil is expressible in terms of an exponential function of the distance between these arcs.*



PROOF: We first show that the ratio depends only on the distance. Denote the length of an arc along the horocycle between points A, B by $l(\overset{\frown}{AB})$. First suppose $l(\overset{\frown}{BC}) = (m/n)l(\overset{\frown}{AB})$. Then the congruent segments along the parallels AA', BB', and CC' induce equal subdivisions of $\overset{\frown}{A'B'}$ and $\overset{\frown}{B'C'}$. We then have $l(\overset{\frown}{B'C'}) = (m/n)l(\overset{\frown}{A'B'})$, and so:

$$\frac{l(\overset{\frown}{AB})}{l(\overset{\frown}{A'B'})} = \frac{(m/n)l(\overset{\frown}{BC})}{(m/n)l(\overset{\frown}{B'C'})} = \frac{l(\overset{\frown}{BC})}{l(\overset{\frown}{B'C'})};$$

therefore, the ratio $l(\overset{\frown}{AB})/l(\overset{\frown}{A'B'})$ depends only on the length of AA'. If $l(\overset{\frown}{AB})$ and $l(\overset{\frown}{BC})$ are related by an irrational number, a limiting process obtains the desired ratio.



Suppose $s_1 = l(\overset{\frown}{AB})$, $s_2 = l(\overset{\frown}{A'B'})$, and $s_3 = l(\overset{\frown}{A''B''})$. We can write $s_1/s_2 = f(x)$ and $s_2/s_3 = f(y)$, where x and y denote the lengths of the line segments AA' and $A'A''$, respectively. It follows that $s_1/s_3 = f(x+y)$ and we obtain the equation:

$$f(x+y) = f(x)\cdot f(y).$$

Assuming the differentiability of $f(x)$ for the moment we get

$$f'(x) = \lim_{\Delta x\to 0}\frac{f(x+\Delta x)-f(x)}{\Delta x} = f(x)\cdot\lim_{\Delta x\to 0}\frac{f(\Delta x)-1}{\Delta x}.$$

By the definition of $f(x)$, as Δx goes to 0, $f(\Delta x)$ goes to 1, and we write, for some value of k,

$$\lim_{\Delta x\to 0}\frac{f(\Delta x)-1}{\Delta x} = \frac{1}{k}.$$

Then $f'(x) = (1/k)f(x)$ and so $f(x) = e^{x/k}$ or $l(\widehat{AB}) = l(\widehat{A'B'})e^{l(AA')/k}$. ∎

The value $1/k$ is chosen to anticipate the more general development in Chapter 12 where it shows up again. Theorem 4.9 offers us a first step into the analytic properties of the plane under **HAA**. The factor of the exponential function will lead us to the *hyperbolic trigonometric functions*, the elementary properties of which we review next.

In the study of the integral giving the area under a semicircle, $\int \sqrt{a^2 - x^2}\,dx$, the familiar trigonometric functions $\sin(x)$, $\cos(x)$, and $\tan(x)$ play a role as parametrizing functions. Analogously, the functions $\sinh(x)$, $\cosh(x)$, and $\tanh(x)$ play the same roles in the study of the integral giving the area under a hyperbola, $\int \sqrt{x^2 - a^2}\,dx$. In 1768, Lambert produced a comprehensive study of the hyperbolic trigonometric functions containing the work of Euler and the Bernoullis (Lambert 1768). Similar developments were made by V. Riccati (1701–75) with Saladini for studying the solutions to cubics.

To define the hyperbolic trigonometric functions, formally introduce a complex variable into the Taylor series for e^x to get:

$$\begin{aligned} e^{iy} &= 1 + iy - \frac{y^2}{2} - \frac{iy^3}{3} + \frac{y^4}{4} - \cdots \\ &= \left(1 - \frac{y^2}{2} + \frac{y^4}{4} - \cdots\right) + i\left(y - \frac{y^3}{3} + \frac{y^5}{5} - \cdots\right) \\ &= \cos y + i \sin y. \end{aligned}$$

It follows from these formulas that:

$$\cos y = \frac{e^{iy} + e^{-iy}}{2}, \quad \sin y = \frac{e^{iy} - e^{-iy}}{2i} \quad \text{and} \quad \tan y = \frac{\sin y}{\cos y} = \frac{1}{i}\frac{e^{iy} - e^{-iy}}{e^{iy} + e^{-iy}}.$$

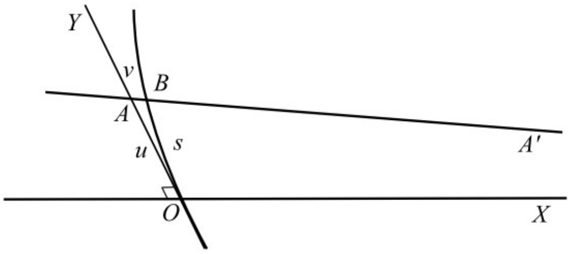
By analogy with these formulas, we define the real-valued functions:

$$\cosh x = \frac{e^x + e^{-x}}{2}, \quad \sinh x = \frac{e^x - e^{-x}}{2}, \quad \text{and} \quad \tanh x = \frac{\sinh x}{\cosh x} = \frac{e^x - e^{-x}}{e^x + e^{-x}}.$$

From the power series, notice that $\cos(iy) = \cosh y$, and $\sin(iy) = i \sinh(y)$. The fundamental relation for the hyperbolic trigonometric functions is given by:

$$\cosh^2 x - \sinh^2 x = 1.$$

The convergence theorems that support our formal manipulations are classical and can be found in any good complex analysis book, for example, Ahlfors (1979).

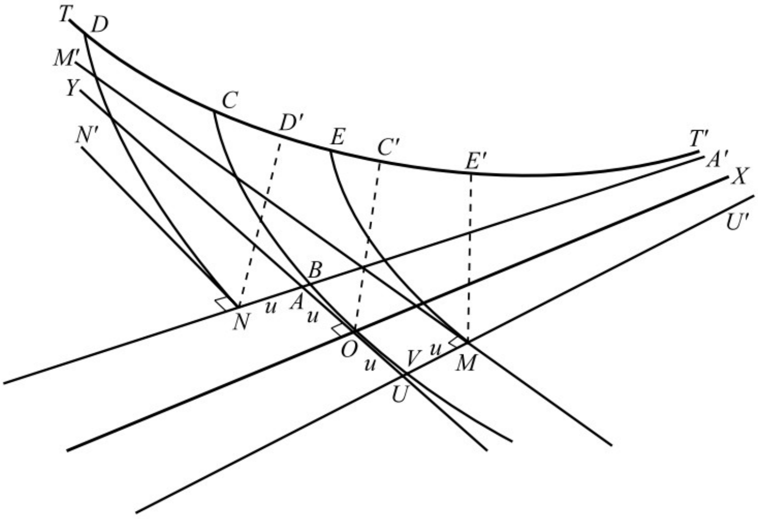


Under **HAA**, a horocycle differs from a straight line. We next seek to measure how much it differs. Fix some line segment RR_1 as a unit length with which we can assign a positive real number length to all other line segments. Let $\overleftrightarrow{OX} = l$ denote a line and consider the horocycle through O determined by the pencil of parallels $\mathbf{P}_l$ in the direction $\overrightarrow{OX}$. Let $\overleftrightarrow{OY}$ denote the line perpendicular to l through O. If we measure a length u along OY to a point A, then there is a line $\overleftrightarrow{AA'}$ in $\mathbf{P}_l$ with A' toward X and a point B on the line $\overleftrightarrow{AA'}$ and on the horocycle through O. Denote the length of AB by v. We apply Theorem 4.9 to relate u and v.

Lemma 4.10. *In the notation of the previous paragraph,* $e^{v/k} = \cosh(u/k)$.

Proof: In order to apply Theorem 4.9, we need a family of strategically chosen concentric horocycles. To construct them we first obtain a reference line: Among the properties of the angle of parallelism, it was shown that any acute angle is $\Pi(x)$ for some x. Let OC' denote a segment of length x_0 for which $\Pi(x_0) = \pi/4$. Then there is a line $\overleftrightarrow{TT'}$ that is parallel to the perpendicular lines $\overleftrightarrow{OX}$ and $\overleftrightarrow{OY}$. Also $\overleftrightarrow{TT'}$ is in $\mathbf{P}_l$. The horocycle through O determined by $\mathbf{P}_l$ meets $\overleftrightarrow{TT'}$ at a point C. Denote the length of $\overset{\frown}{OC}$ by σ.

Consider the diagram in which we use reflections across lines to construct various comparable angles and figures.



Let $\overleftrightarrow{NN'}$ be perpendicular to $\overleftrightarrow{AA'}$ and parallel to $\overrightarrow{OY}$, that is, choose N with $\angle NAY = \Pi(AN)$. Since $\angle OAA' = \Pi(OA) = \Pi(u)$ and $\angle NAY = \angle OAA'$ we have $AN \cong OA$. Similarly let U be on $\overrightarrow{YO}$ with $OU \cong OA$, $U \neq A$, and $\overleftrightarrow{UU'}$ the parallel to $\overrightarrow{OX}$ through U in the direction of X. Let UM have length u and construct $\overleftrightarrow{MM'}$ perpendicular to $\overleftrightarrow{UU'}$ with $\overleftrightarrow{MM'}$ parallel to $\overrightarrow{OY}$. The segments AN and UM determine concentric horocycles $\overset{\frown}{ND}$, $\overset{\frown}{OC}$, and $\overset{\frown}{ME}$. The perpendiculars to $\overleftrightarrow{TT'}$ from N, O, and M, determine points D', C', and E', respectively. By the construction we see that $\overleftrightarrow{TT'}$ is parallel to $\overleftrightarrow{AA'}$ and $\overleftrightarrow{NN'}$ and so $\angle D'NA' \cong \angle D'NN' \cong \Pi(x_0) = \pi/4$. Similarly, $ND' \cong OC' \cong ME'$ are all of length x_0. It follows from Lemma 4.8 that $\overset{\frown}{ND} \cong \overset{\frown}{OC} \cong \overset{\frown}{ME}$. Their common length is σ.

We can apply the formula in Theorem 4.9, that is, the ratio of the lengths of concentric arcs of two horocycles is given by $l(\overset{\frown}{ZW}) = l(\overset{\frown}{Z'W'})e^{-t/k}$, where t is the distance between the arcs. If B denotes the point along $\overleftrightarrow{AA'}$ where $\overset{\frown}{OC}$ crosses, then let V denote the point corresponding to B along $\overleftrightarrow{UU'}$. Then $l(BN) = u + v$. Let $s = l(\overset{\frown}{OB})$, the length between O and B along the horocycle; we then have:

$$l(\overset{\frown}{ND}) = l(\overset{\frown}{OC}) = \sigma = (\sigma - s)e^{(u+v)/k} \quad \text{or} \quad \frac{\sigma - s}{\sigma} = e^{-(u+v)/k}.$$

Horocycle arcs $\overset{\frown}{VC}$ and $\overset{\frown}{ME}$ are concentric and $l(VM) = u - v$. Since $l(\overset{\frown}{VC}) = \sigma + s$ and $l(\overset{\frown}{ME}) = \sigma$, then we also have $\sigma + s = \sigma e^{(u-v)/k}$, or $(\sigma + s)/\sigma = e^{(u-v)/k}$. Thus,

$$2 = \frac{\sigma + s}{\sigma} + \frac{\sigma - s}{\sigma} = e^{(u-v)/k} + e^{-(u+v)/k}.$$

Multiplying through by $e^{v/k}$ gives $e^{v/k} = \dfrac{e^{u/k} + e^{-u/k}}{2} = \cosh(u/k)$. This proves the lemma. ■

Corollary 4.11. $s = \sigma \tanh(u/k)$.

PROOF: By the proof of Lemma 4.10 we see that:

$$2\frac{s}{\sigma} = \frac{\sigma + s}{\sigma} - \frac{\sigma - s}{\sigma} = e^{(u-v)/k} - e^{-(u+v)/k} = (e^{u/k} - e^{-u/k})e^{-v/k}.$$

Therefore,

$$\frac{s}{\sigma}\cosh(u/k) = \frac{s}{\sigma}e^{v/k} = \frac{e^{u/k} - e^{-u/k}}{2} = \sinh(u/k),$$

and so $s = \sigma \tanh(u/k)$. ■

These analytical relations will play a key role in building non-Euclidean trigonometry. To develop further tools we introduce three dimensions.

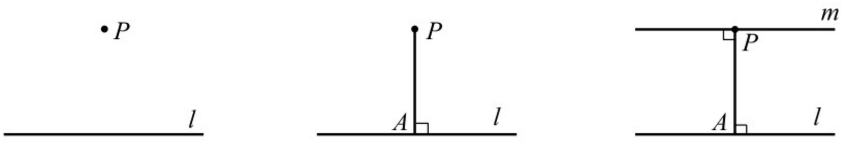
Digression: Neutral space

In Chapter 1 we saw that the trigonometric formulas for triangles on the sphere could be proved by using the fact that the sphere is embedded in three dimensional space. We adopt this approach more generally by considering three dimensional space, where we find points, lines, and planes for which Hilbert's Axioms of Incidence hold, together with the Postulates I–IV of Euclid (Book XI of *The Elements*). We call such a space *neutral space*.

Without using Postulate V, define *parallel lines* in space to be two lines ℓ_1, ℓ_2 that are coplanar, and, in a chosen direction on that plane, satisfy Definition 4.1.

In order to develop the geometry of neutral space we need to explore certain relations between pairs of lines, lines and planes, and pairs of planes. According to the assumptions of an incidence geometry (Definition 2.1), if we are given three noncollinear points, P, Q, and R, or a line l and a point P not on l or two intersecting lines l and m, then each group uniquely determines a plane. We denote this relation by $T = \text{Plane}(P,Q,R)$ or $T = \text{Plane}(P,l)$ or $T = \text{Plane}(l,m)$.

Our goal in this digression is to prove Theorem 4.25, an analogue of Playfair's Axiom but in a higher dimension. For Playfair's Axiom we are given a point P not on a line m, from which we obtain a unique line m' through P with m' parallel to m. One dimension higher, the role of the point is played by a line l, which is parallel to a plane T from which we obtain a unique plane T' containing l and parallel to T. To prove this assertion we generalize a special case of Euclid's proof of Playfair's Axiom, Proposition I.31: First construct the unique perpendicular PA through P to the given line l (Proposition I.12), then construct the unique perpendicular m to PA through P. The line m is parallel to l under the assumption of Postulate V.



What is remarkable about neutral space is that the same construction, appropriately construed, leads to the analogous result for a line l parallel to a given plane T.

In order to make these constructions in space, we begin by exploring parallelism of lines. Our presentation is inspired by the relevant sections of the book by Borsuk and Smielew (1960).

Lemma 4.12. *Suppose l_1 and l_2 are two lines parallel in space and T_1 and T_2 are two planes with l_1 on T_1, l_2 on T_2, and $T_1 \neq T_2$. If m is the line of intersection of T_1 and T_2, and $l_1 \neq m \neq l_2$, then m is parallel to l_1 and to l_2.*

decorre do problema da quadratura 2D e do valor infinitesimal do π (Pi).
Valor este irracional e transcendental
(o pi não é uma solução de uma equação polinomial com coeficientes racionais). Portanto, o pi transcende a classe dos números algébricos.

The Transcendence of π

Return:

Na Fig. 01 observamos a discrepância decorrente do π.

Fazendo uma simulação na qual iremos fazer uma distorção do space-time (2D) criaremos um valor para converter 2D que se enquadre na quadratura do círculo.

Este valor é **MUS**. ($\pi\!\!\!\pi$)

π $\pi\!\!\!\pi$

This is typical when one knows the R^i_{kl}'s and R^i_{jlm}'s but not the ω^k and ω^r_s. Sometimes, one refers to the $d\omega^i - \omega^j \wedge \omega^i_j$ and the $d\omega^j_i - \omega^k_i \wedge \omega^j_k$ themselves as the torsion and the curvature. Since computations with the explicit form that ω^j and ω^i_j take in the bundle would be laborious in general, one actually computes in sections of the bundle, a concept which we are about to introduce. The Ω^i and Ω^i_j may be viewed as differential form components of a $(1,0)-$tensor and $(1,1)-$tensor respectively. But this is only just one way of looking at curvature and torsion. Impatient readers can refer to sections 5.9 and 8.13 for their Lie algebra valuedness.

Let us return to affine space. The equations of structure of affine space are then written as

$$\Omega^i = 0, \qquad \Omega^i_j = 0. \tag{3.8}$$

One then says that affine spaces are particular cases of differentiable manifolds endowed with affine connections whose torsion and curvature are zero.

An interesting exercise at this point with the equations of affine space is the following. Substitute Eqs. (2.7) in (3.5). Use $A^j_i B^k_j = \delta^k_i$ and reach two trivially looking identities, $0 = 0$. In generalized spaces, they will take interesting forms. We shall then use this trivial identity to simplify calculations.

5.4 Curvilinear coordinates: holonomic bases

A section of the affine frame bundle is a continuous map $S : Af^n \to F^n$ such that $\mathbf{P} \circ S$ is the identity. In simpler terms, it is a map that picks one and only one point from each fiber. Since those points are frames, the section is a frame field, which we shall assume to be not only continuous but also differentiable to whichever order may be needed. The concept is equally applicable to the bundles of generalizations of affine and Euclidean spaces.

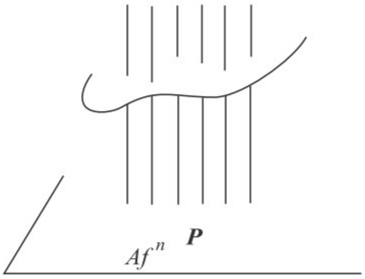

Figure 4: Section of F^n

As we shall see in the next paragraph, sections emerge naturally when one introduces in the base manifold (i.e. affine space in this chapter) curvilinear coordinates through an invertible transformation: $x^i = x^i(A^1 \ldots A^n)$, $i = 1 \ldots n$. Needless to say that we may define new curvilinear coordinates in terms of other curvilinear coordinates rather than directly from the A^i. The x^i are no longer rectilinear if the equations of the transformation are not linear. Inexperienced readers should be aware of the inconsistency in terminology from one area of mathematics to another. One should use the term affine equations to refer to what are usually called linear equations. Linear transformation yields the special linear equations whose independent terms are all zero.

Curvilinear coordinate systems define point-dependent bases of vectors $\mathbf{e}_i$ by means of

$$\mathbf{e}_i \equiv \frac{\partial \mathbf{P}}{\partial x^i}. \tag{4.1}$$

We use the same term $\mathbf{e}_i$ as before since these frame fields are sections of the bundle of frames. One says that the $\mathbf{e}_i$ of (4.1) are pull-backs (to sections) of the $\mathbf{e}_i$ of (2.3). Curvilinear coordinates are not components of $\mathbf{P}$ or some other vector upon some basis $\{\mathbf{b}_i\}$ and, in fact, one first defines those coordinates and then a basis field associated with them.

The basis vectors $\mathbf{e}_i$ and $\mathbf{a}_j$ are related by:

$$\mathbf{e}_i = \frac{\partial \mathbf{P}}{\partial A^j}\frac{\partial A^j}{\partial x^i} = \frac{\partial A^j}{\partial x^i}\mathbf{a}_j. \tag{4.2}$$

The partial derivatives are not constants but functions of the coordinates, unless we were dealing with a transformation between two rectilinear coordinate systems. To be precise, we are dealing here with composite functions, since the A^i are themselves functions that assign numbers to the points of the manifold (Refer to point (c) of section 6 of chapter 1). Because of its importance, we repeat that, when dealing with coordinates, we use the same symbol for coordinate functions and for the value that those functions take. Whether we are considering the ones or the others will be obvious from the context. The nature of the coordinates as functions on the manifold started with the definition of $\mathbf{P}$ as a projection map on Af^n. It follows that rectilinear coordinates are also functions on Af^n. Curvilinear coordinates being functions of the rectilinear coordinates, they also are (composite) functions on Af^n.

The $(\mathbf{e}_i)$ vary from one point to another. Each coordinate system determines a vector basis at each point of the region of affine space that it covers (No basis is determined at the origin of the system of polar coordinates, since this system does not assign a unique pair of numbers to it; the definition (4.2) fails in any case). We are thus dealing here with fields of bases, not just one basis as was the case with $(\mathbf{a}_i)$. But $(\mathbf{a}_i)$ can now be viewed as a constant basis field. This becomes obvious when we obtain a system of rectilinear coordinates from another one in the same way as for curvilinear coordinates.

The vector basis fields generated in the preceding way by the system of curvilinear coordinates is referred to as holonomic or coordinate basis field. In that change from rectilinear to rectilinear, the new basis field $(\mathbf{b}_i)$ appears as a particular case of curvilinear basis field that happens to be the same everywhere in terms of the $(\mathbf{a}_i)$, and thus equal to itself from one point to another. The argument can be reversed, meaning that we could have started the whole argument with the basis ($\mathbf{b}_i$) and have obtained the basis ($\mathbf{a}_i$) as a constant frame field also denoted ($\mathbf{a}_i$).

Non-holonomic basis fields will be introduced in the next section. We leave for then the push-forward (a concept that amounts here to a recovery) of the invariant forms in the bundle from the dx^k and ω_i^j just considered.

The use of a particular coordinate system does not force us to use corresponding holonomic basis fields (unlike in the most common version of the tensor calculus, version where bases are not explicitly used).

From the definition (4.1) of $\mathbf{e}_i$, we have:

$$d\mathbf{P} = dx^i \mathbf{e}_i. \tag{4.3}$$

Along each coordinate line, all the dx^i's but one are zero. Equation (4.3) then shows that the vector is tangent to the coordinate line x^i. In a similar way to the obtaining of Eq. (4.2), we would get

$$\mathbf{a}_i = \frac{\partial \mathbf{P}}{\partial x^j}\frac{\partial x^j}{\partial A^i} = \frac{\partial x^j}{\partial A^i}\mathbf{e}_j. \tag{4.4}$$

This shows that the vectors $(\mathbf{e}_j)_P$ constitute a basis since any vector can be expressed as a linear combination of the $\mathbf{e}_i$'s through the $\mathbf{a}_i$'s (and the number of vectors $\mathbf{e}_j$ is the same as the dimension of the vector space).

Let us practice some of these ideas using polar coordinates in the plane

$$x = \rho\ \cos\phi, \qquad y = \rho\ \sin\phi. \tag{4.5}$$

We use (4.2) with (x, y) and (ρ, ϕ) replacing the A^i's and x^i's respectively. We thus have

$$\mathbf{e}_\rho = \cos\phi \mathbf{a}_1 + \sin\phi \mathbf{a}_2 \qquad \mathbf{e}_\phi = -\rho\sin\phi \mathbf{a}_1 + \rho\cos\phi \mathbf{a}_2 \tag{4.6}$$

where we have used $\mathbf{a}_1$ and $\mathbf{a}_2$ for $\mathbf{i}$ and $\mathbf{j}$. Notice that, with this definition of $\mathbf{e}_j$, $d\mathbf{P}$ is not given by the familiar $d\mathbf{P} = d\rho\mathbf{e}_\rho + \rho d\phi\mathbf{e}_\phi$, which corresponds to orthonormal bases, but rather by

$$d\mathbf{P} = d\rho\mathbf{e}_\rho + d\phi\mathbf{e}_\phi, \tag{4.7}$$

in accordance with Eq. (4.3). The concept of orthonormal bases does not even enter here since a dot product or a metric has not been defined. Thus, although ρ and ϕ have metric connotation, we ignore it here and consider those functions of (x, y) as any other functions without such connotation.

From (4.6), we read $A_1^1 = \cos\ \phi$, $A_1^2 = \sin\phi$, $A_2^1 = -\rho\sin\ \phi$, $A_2^2 = \rho\cos\phi$ for the vector basis (on the section) that is above the point (ρ,ϕ) of Af^2.

Exercise. Obtain $\mathbf{e}_i$ in terms of $\boldsymbol{a}_j$, and vice versa, for the spherical coordinates:

$$r = \sqrt{x^2 + y^2 + z^2}, \quad \phi = \arctan\frac{y}{x}, \quad \theta = \arctan\frac{\sqrt{x^2 + y^2}}{z}. \tag{4.8}$$

It is not convenient to invert the change of basis by inverting the matrix that gives this change if the inverse coordinate transformation is remembered. Thus, in this case, we would proceed in the same way but starting from the transformations

$$x = r\sin\theta\cos\phi, \quad y = r\sin\theta\sin\phi, \quad z = r\cos d\theta. \tag{4.9}$$

Notice that we do not need to draw figures to relate different vector bases, which may not be easy to do for unusual coordinate systems.

We next summarize much of what has been done in this section. We arbitrarily chose a point of affine space and introduced an arbitrary basis $(\mathbf{a}_i)$. Rectilinear coordinates (A^i) were obtained as components of $\mathbf{P}$ relative to that basis. This was followed by the introduction of curvilinear coordinates as functions of the rectilinear ones. We then generated basis fields associated with the coordinate system. We completed the process by finally viewing the rectilinear coordinates as the particular cases of curvilinear coordinates that generate constant vector basis fields $\{\mathbf{a}_i\}$.

The use of sections —thus of a specific vector basis at each point of affine space— has the implication that the ω_i^j's are now linear combinations

$$\omega_i^j = \Gamma_{ik}^j dx^k \tag{4.10}$$

of the differentials of the coordinates in affine space. We thus have

$$d\mathbf{P} = dx^i \mathbf{e}_i \tag{4.11a}$$

$$d\mathbf{e}_i = \omega_i^j \mathbf{e}_j = \Gamma_{ik}^j \mathbf{e}_j dx^k. \tag{4.11b}$$

Consistently with concepts already advanced, these equations pertain to quantities (on the left) that are said to be pull-backs to sections of quantities in the bundle.

One can show that the pull-backs of exterior derivatives and exterior products are the exterior derivatives and exterior products of the pull-backs of the quantities being exterior differentiated and exterior multiplied. We leave for section 6 the pull-back of the equations of structure to sections of the bundle, whether holonomic sections like those we have just seen, or anholonomic ones, about to be considered.

Finally, the basis fields of two different coordinate patches can be related in a way similar to (4.4). Let (x^i) and (x'^i) be two sets of coordinates. We shall denote by $(\mathbf{e}'^i)$ the basis field for the coordinate patch (x'^i). A change of coordinate vector basis field is then given by

$$\mathbf{e}_i = \frac{\partial \mathbf{P}}{\partial x'^j}\frac{\partial x'^j}{\partial x^i} = \frac{\partial x'^j}{\partial x^i}\mathbf{e}'_j \tag{4.12a}$$

$$\mathbf{e}'_i = \frac{\partial \mathbf{P}}{\partial x^j}\frac{\partial x^j}{\partial x'^i} = \frac{\partial x^j}{\partial x'^i}\mathbf{e}_j. \tag{4.12b}$$

Figure 1.6 (*a*) The three mutually perpendicular surfaces of the circular cylindrical coordinate system. (*b*) The three unit vectors of the circular cylindrical coordinate system. (*c*) The differential volume unit in the circular cylindrical coordinate system; $d\rho$, $\rho d\phi$, and dz are all elements of length.

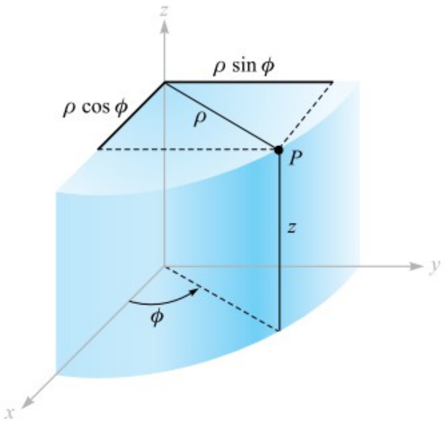

Figure 1.7 The relationship between the rectangular variables x, y, z and the cylindrical coordinate variables ρ, ϕ, z. There is no change in the variable z between the two systems.

The variables of the rectangular and cylindrical coordinate systems are easily related to each other. Referring to Figure 1.7, we see that

$$\begin{aligned} x &= \rho \cos \phi \\ y &= \rho \sin \phi \\ z &= z \end{aligned} \tag{10}$$

From the other viewpoint, we may express the cylindrical variables in terms of x, y, and z:

$$\begin{aligned} \rho &= \sqrt{x^2 + y^2} \quad (\rho \geq 0) \\ \phi &= \tan^{-1} \frac{y}{x} \\ z &= z \end{aligned} \tag{11}$$

$$
\begin{aligned}
\theta &= \frac{\partial L}{\partial \dot{t}} = \dot{t} + 2r^2\dot{\phi},\\
\eta &= \frac{\partial L}{\partial \dot{\phi}} = r^2\dot{\phi} + 2\dot{t}r^2 + 4r^4\dot{\phi},\\
\rho &= \frac{\partial L}{\partial \dot{r}} = \dot{r}.
\end{aligned}
$$

9.4.1.1 The Euler–Lagrange system

The momenta are

$$\begin{aligned}\theta &= \frac{\partial L}{\partial \dot t} = \dot t + 2r^2\dot\phi,\\ \eta &= \frac{\partial L}{\partial \dot\phi} = r^2\dot\phi + 2\dot t r^2 + 4r^4\dot\phi,\\ \rho &= \frac{\partial L}{\partial \dot r} = \dot r.\end{aligned}$$

As the Lagrangian L does not depend on t and ϕ, the Euler–Lagrange equations yield

$$\theta = \text{constant}, \qquad \eta = \text{constant}.$$

The momentum η can be written in terms of θ as

$$\eta = r^2(\dot\phi + 2\dot t + 4r^2\dot\phi)s = r^2(\dot\phi + 2\theta).$$

The Euler–Lagrange equation $\dot\rho = \dfrac{\partial L}{\partial r}$ becomes

$$\begin{aligned}\ddot r &= r\dot\phi^2 + 4\dot t r\dot\phi + 8r^3\dot\phi^2\\ &= r\dot\phi^2 + 4r\dot\phi(\dot t + 2r^2\dot\phi)\\ &= r\dot\phi^2 + 4r\dot\phi\theta\\ &= r\dot\phi(\dot\phi + 4\theta).\end{aligned}$$

Hence the Euler–Lagrange system is

$$\begin{cases}\ddot r & = r\dot\phi(\dot\phi + 4\theta),\\ r^2(\dot\phi + 2\theta) & = \eta,\\ \dot t + 2r^2\dot\phi & = \theta\\ \theta & = \text{constant},\\ \eta & = \text{constant}.\end{cases} \tag{9.4.17}$$

It suffices to study only the geodesics from the origin, because of the Heisenberg translation. In this case $r(0) = 0$ and hence $\eta = 0$. It follows that $\dot{\phi} = -2\theta$ and the system (9.4.17) becomes

$$\begin{cases} \ddot{r} &= -4\theta^2 r, \\ \dot{\phi} &= -2\theta, \\ \dot{t} &= \theta - 2r^2\dot{\phi} = \theta(1+4r^2), \\ \theta &= \text{constant} \end{cases} \tag{9.4.18}$$

with the boundary conditions

$$r(0) = 0, \quad \phi(0) = \phi_0, \qquad t(0) = t_0 = 0, \tag{9.4.19}$$

$$r(\tau) = \mathbf{r}, \quad \phi(\tau) = \Phi, \qquad t(\tau) = \mathbf{t}. \tag{9.4.20}$$

We shall show in the following that the system (9.4.18) has solutions if and only if some compatibility of the above boundary conditions holds. The solutions are

$$r(s) = \frac{\sin(2\theta s)}{\sin(2\theta\tau)}\mathbf{r}, \tag{9.4.21}$$

$$\phi(s) = -2\theta s + \phi_0. \tag{9.4.22}$$

The boundary condition $\phi(\tau) = \Phi$ yields

$$\theta = \frac{1}{2\tau}(\phi_0 - \Phi). \tag{9.4.23}$$

Integrating in (9.4.21) yields

$$\begin{aligned} t(s) &= \theta \int_0^s (1 + 4r^2(u))\,du = \theta\Big(s + 4\int_0^s r^2\Big) \\ &= \theta\Big(s + \frac{4\mathbf{r}^2}{\sin^2(2\theta\tau)}\int_0^s \sin^2(2\theta u)\,du\Big) \\ &= \theta\Big[s + \frac{4\mathbf{r}^2}{2\theta\sin^2(2\theta\tau)}\Big(\frac{1}{2}(2\theta s) - \frac{1}{4}\sin(4\theta s)\Big)\Big] \\ &= \theta s + \frac{\mathbf{r}^2}{\sin^2(2\theta\tau)}\Big(2\theta s - \frac{1}{2}\sin(4\theta s)\Big). \end{aligned} \tag{9.4.24}$$

The boundary condition $t(\tau) = \mathbf{t}$ yields

$$\begin{aligned} \mathbf{t} &= \theta\tau + \frac{\mathbf{r}^2}{\sin^2(2\theta\tau)}\Big(2\theta\tau - \sin(2\theta\tau)\cos(2\theta\tau)\Big) \\ &= \theta\tau + \mathbf{r}^2\Big(\frac{2\theta\tau}{\sin^2(2\theta\tau)} - \cot(2\theta\tau)\Big). \end{aligned} \tag{9.4.25}$$

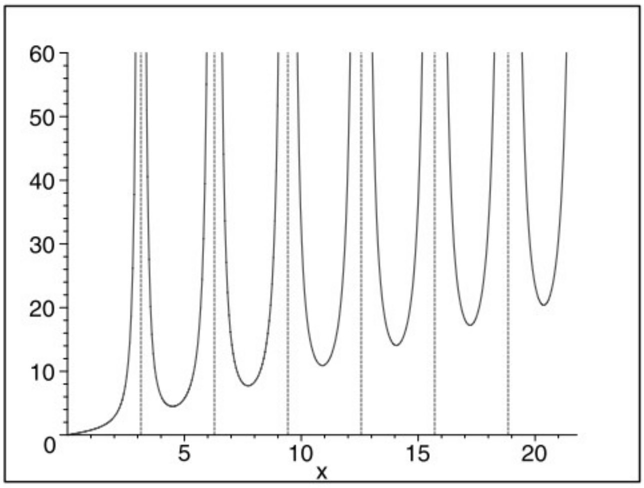

Figure 9.3: The graph of $\mu(x)$.

Let

$$\mu(x) = \frac{x}{\sin^2 x} - \cot x. \tag{9.4.26}$$

The graph of μ for $x > 0$ is sketched in Figure 9.3. It suffices to study only the case $\theta > 0$. The case $\theta < 0$ can be obtained from the previous one changing $t \to -t$ and $\phi \to -\phi$. This follows from the relation $\theta = \dot{t} + 2r^2\dot{\phi}$. Then (9.4.25) becomes

$$\mathbf{t} = \theta\tau + \mathbf{r}^2\mu(2\theta\tau). \tag{9.4.27}$$

In order to understand the exact number of geodesics, which join the origin with any given point, we need the following lemma, see Beals, Gaveau and Greiner [37].

Lemma 9.20 *μ is a monotone increasing diffeomorphism of the interval $(-\pi, \pi)$ onto $\mathbb{R}$. On each interval $(m\pi, (m+1)\pi)$, $m = 1, 2, \ldots$, μ has a unique critical point x_m. On this interval μ decreases strictly from $+\infty$ to $\mu(x_m)$ and then increases strictly from $\mu(x_m)$ to $+\infty$. Moreover*

$$\mu(x_m) + \pi < \mu(x_{m+1}), \quad m = 1, 2, \ldots, \tag{9.4.28}$$

$$0 < \Big(m + \frac{1}{2}\Big)\pi - x_m < \frac{1}{m\pi}. \tag{9.4.29}$$

Proof. As μ is an odd function, it suffices to show that it is a monotone increasing diffeomorphism of the interval $(0, \pi)$ onto $(0, +\infty)$. We note that $\sin x - x\cos x$ vanishes at $x = 0$ and it is increasing in $(0, \pi)$. Then

$$\frac{1}{2}\mu'(x) = \frac{\sin x - x\cos x}{\sin^3 x} = \begin{cases} = 1/3, & x = 0, \\ > 1/3, & x \in (0, \pi). \end{cases}$$

The first identity holds as an application of the l'Hospital rule:

$$\lim_{x\to 0}\frac{\sin x - x\cos x}{\sin^3 x} = \lim_{x\to 0}\frac{\cos x - \cos x + x\sin x}{3\sin^2 x}$$
$$= \frac{1}{3}\lim_{x\to 0}\frac{x}{\sin x} = \frac{1}{3}.$$

The second inequality holds because

$$\frac{1}{2}\mu''(x) = \frac{x + 2x\cos^2 x - 3\cos x\sin x}{\sin^4 x} > 0.$$

The numerator vanishes at $x = 0$, and its derivative is

$$4\sin x(\sin x - x\cos x) > 0, \quad x \in (0, \pi).$$

Therefore μ is a diffeomorphism of the interval $(0, \pi)$ onto $(0, \infty)$. In the interval $(m\pi, (m+1)\pi)$ μ approaches $+\infty$ at the endpoints. In order to find the critical points, we set

$$\frac{1}{2}\mu'(x) = \frac{\sin x - x\cos x}{\sin^3 x} = \frac{1 - x\cot x}{\sin^4 x} = 0.$$

Hence the critical point x_m is the solution of the equation $x = \tan x$ on the interval $(m\pi, (m+1)\pi)$. Note that

$$\begin{aligned}\mu(x+\pi) &= \frac{x+\pi}{\sin^2(x+\pi)} - \cot(x+\pi)\\ &= \frac{x}{\sin^2(x+\pi)} - \cot(x+\pi) + \frac{\pi}{\sin^2 x}\\ &= \mu(x) + \frac{\pi}{\sin^2 x},\end{aligned}$$

so the successive minimum values increase by more than π. From Figure 9.4 we have

$$m\pi < x_m < m\pi + \frac{\pi}{2} = (m + \frac{1}{2})\pi. \tag{9.4.30}$$

Using $x_m = \tan x_m$ yields

$$\cot x_m = \frac{1}{x_m} < \frac{1}{m\pi}. \tag{9.4.31}$$

Let $f(x) = \cot x$. As $f'(x) = -\frac{1}{\sin^2 x} < -1$, there is a ξ between x and y such that

$$f(x) - f(y) = f'(\xi)(x - y) < -(x - y).$$

Hence $x - y < f(y) - f(x)$. Choosing $x = m\pi + \frac{\pi}{2}$, $y = x_m$ and using

$$f(m\pi + \frac{\pi}{2}) = \frac{\cos(m\pi + \frac{\pi}{2})}{\sin(m\pi + \frac{\pi}{2})} = 0,$$

and (9.4.31) yields

$$0 < (m + \frac{1}{2})\pi - x_m < \cot x_m < \frac{1}{m\pi}.$$

■

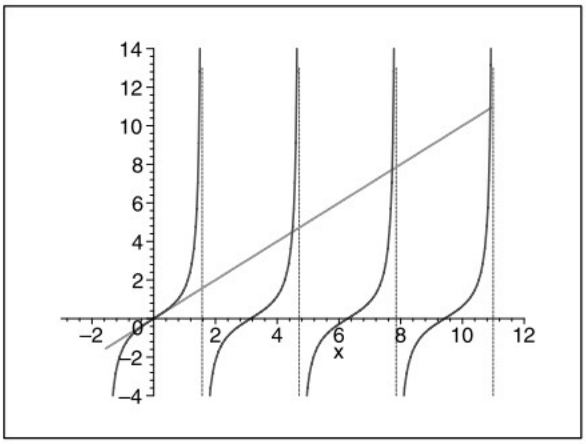

Figure 9.4: Critical points of μ are solutions of $\tan x = x$.

The number of geodesics that join the origin with an arbitrary given point is given in the following theorems.

Theorem 9.21. *(i) Given a point* $P(\mathbf{x}, \mathbf{t})$, $\mathbf{r} = |\mathbf{x}| \neq 0$, $\mathbf{t} > 0$, *there are finitely many geodesics between the origin and* P. *Let* $0 < \zeta_1 < \cdots < \zeta_N$ *be the solutions of*

$$\mathbf{t} - \frac{1}{2}\zeta = \mathbf{r}^2\mu(\zeta). \tag{9.4.32}$$

Then, with $\theta_m = \dfrac{\zeta_m}{2\tau}$, *the geodesic equations are*

$$\begin{aligned} r_m(s) &= \frac{\sin(2\theta_m s)}{\sin(2\theta_m \tau)}\mathbf{r}, \\ \phi_m(s) &= -2\theta_m s + \phi_0, \\ t_m(s) &= \theta_m s + \frac{\mathbf{r}^2}{\sin^2(2\theta_m \tau)}\Big(2\theta_m \tau - \frac{1}{2}\sin(4\theta_m s)\Big), \quad m = 1, 2, \dots N. \end{aligned}$$

(ii) The compatibility condition for the boundary conditions is

$$\zeta_m = \phi_0 - \Phi, \quad m = 1, 2, \dots, N. \tag{9.4.33}$$

Given the point $P(\mathbf{x}, \mathbf{t})$, *let* $\Phi = \arctan(|\mathbf{x}|)$ *be the final argument. Then the initial arguments of the geodesics joining the origin and* P *are*

$$\phi_{0,m} = \zeta_m - \Phi, \quad m = 1, 2, \dots, N. \tag{9.4.34}$$

Proof. (i) It is obvious that equation (9.4.32) has finitely many solutions, see Figure 9.3. For each solution of (9.4.27), substitute θ in the equations (9.4.21), (9.4.22) and (9.4.24).
(ii) It follows from (i) and condition (9.4.23). See Figure 9.5. ■

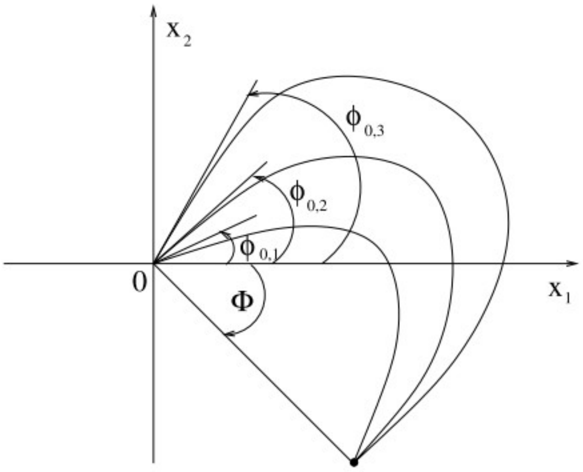

Figure 9.5: The projections of the geodesics on an x-plane start with different arguments.

Remark 9.22 *A similar theorem works for the case* $\mathbf{t} < 0$.

It is well known that locally, there is only one geodesic joining the origin and the point P. The size and the shape of the neighborhood is given by the following result.

Theorem 9.23. *Given a point* $P(\mathbf{x}, \mathbf{t})$*, with* $|\mathbf{t}| < \big(\frac{1}{2} + |\mathbf{x}|^2\big)\pi$ *and* $|\mathbf{x}| \neq 0$*, there is a unique geodesic joining the origin and the point* P.

Proof. We shall discuss the following cases: $0 < \mathbf{t} < \big(\frac{1}{2} + |\mathbf{x}|^2\big)\pi$, $\mathbf{t} = 0$ and $-\big(\frac{1}{2} + |\mathbf{x}|^2\big)\pi < \mathbf{t} < 0$. The third case can be treated in a similar way as the first case.
Case $0 < \mathbf{t} < \big(\frac{1}{2} + |\mathbf{x}|^2\big)\pi$.
We shall show that equation (9.4.32) has only one solution $\zeta > 0$. Consider the function $\varphi(\zeta) = \dfrac{1}{|\mathbf{x}|^2}(\mathbf{t} - \dfrac{1}{2}\zeta)$. We shall show that the solutions of the equation $\varphi(\zeta) = \mu(\zeta)$ are only in the interval $(0, \pi)$. It suffices to show that

$$\varphi(\zeta) < \mu(\zeta), \qquad \text{for} \quad \pi < \zeta. \tag{9.4.35}$$

Let $x_1 \in (\pi, 2\pi)$ be the first critical point of μ. Using Lemma 9.20, the monotonicity of μ and convexity of μ yields

$$\varphi(\zeta) < \varphi(\pi) = \frac{1}{|\mathbf{x}|^2}(\mathbf{t} - \frac{1}{2}\pi) < \pi < \mu(x_1) = \min_{\pi<\zeta} \mu(\zeta),$$

which yields (9.4.35). Then there are no solutions on $(\pi, +\infty)$. As φ is decreasing and μ is increasing on $(0, \pi)$, there is only one solution for the equation $\varphi(\zeta) = \mu(\zeta)$, see Figure 9.6

Case $\mathbf{t} = 0$.
If $\mathbf{t} = 0$, then $-\dfrac{1}{2}\zeta = |\mathbf{x}|\mu(\zeta)$ yields only the solution $\zeta = 0$. Then $\theta = \dfrac{\zeta}{2\tau} = 0$. Theorem 9.21 yields $\phi_0 = \Phi$, $t(s) = 0$. $r(s)$ satisfies $\ddot{r} = 0$, with solution $r(s)|\mathbf{x}|s$. There is a unique solution, which is a straight line from the origin to P, in the x-plane. ■

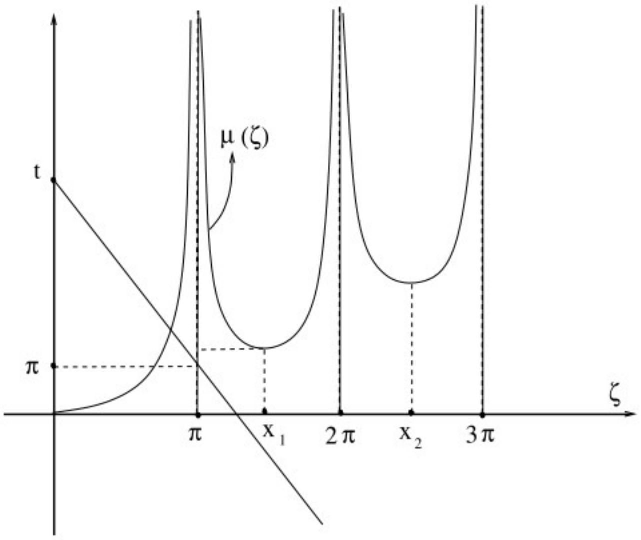

Figure 9.6: The case when $\phi(\zeta) = \mu(\zeta)$ has a unique solution.

Corollary 9.24 *Given a point $P(\mathbf{x}, 0)$, $|\mathbf{x}| \neq 0$, there is a unique geodesic between the origin and P. The geodesic is given by the equations $r(s) = |\mathbf{x}|s$, $\phi(s) = \Phi$, and $t(s) = 0$, i.e., it is a straight segment in the x-plane.*

In Theorems 9.21 and 9.23 we assumed $|\mathbf{x}| \neq 0$. In the following we shall cover the case when $|x| = 0$.

Theorem 9.25. *Given a point $P(0, \mathbf{t})$ on the t-axis, there is a unique geodesic between the origin and the point P.*

Proof. If $|\mathbf{x}| = \mathbf{r} = 0$, from (9.4.21) we get $r(s) = 0$. Using (9.4.24) yields $t(s) = \theta s$, with $\theta = \mathbf{t}/\tau$. The geodesic is along the t-axis. ■

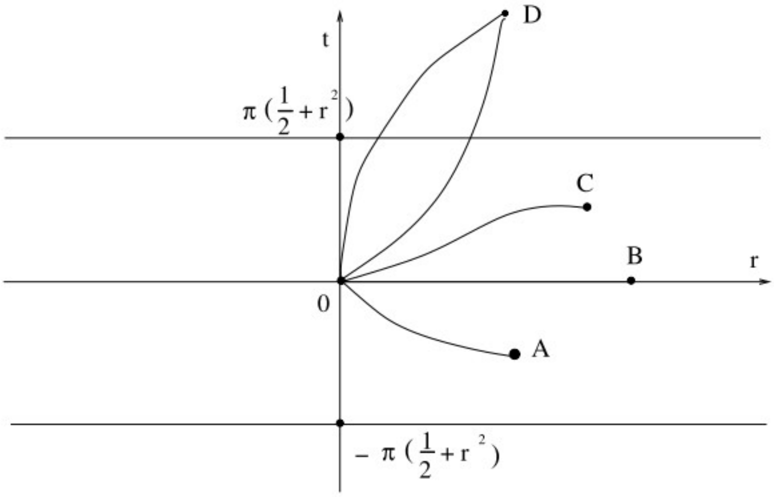

Figure 9.7: There is a unique geodesic in the strip $|\mathbf{t}| < \pi(\frac{1}{2} + \mathbf{r}^2)$ between O and (x, t).

Remark 9.26 *Theorem* 9.23 *works also in the case* $|\mathbf{x}| = 0$.

9.4.2 The classical action

In a strip like in Theorem 9.23 the geodesic is unique. Let θ denote the unique solution. The Lagrangian along the geodesic is

$$\begin{aligned}
L &= \frac{1}{2}(\dot r^2 + r^2\dot\phi^2 + \dot t^2) + 2(r^2\dot\phi + \dot t)r^2\dot\phi \\
&= \frac{1}{2}(\dot r^2 + r^2\dot\phi^2 + \dot t^2) + 2(\theta - r^2\dot\phi)r^2\dot\phi \\
&= \frac{1}{2}(\dot r^2 + r^2\dot\phi^2 + \dot t^2) + 2\theta r^2\dot\phi - 2r^4\dot\phi^2 \\
&= \frac{1}{2}\dot r^2 + \frac{1}{2}r^2\dot\phi^2 + \frac{1}{2}(\theta - 2r^2\dot\phi)^2 + 2\theta r^2\dot\phi - 2r^4\dot\phi^2 \\
&= \frac{1}{2}\dot r^2 + \frac{1}{2}r^2\, 4\theta^2 + \frac{1}{2}\theta^2 \\
&= \frac{1}{2}\dot r^2 + \frac{1}{2}\theta^2(1 + 4r^2) \\
&= \frac{1}{2}\dot r^2 + \frac{1}{2}\theta\dot t.
\end{aligned}$$

The classical action is obtained by integrating the Lagrangian along the geodesic

$$\begin{aligned}
S(\tau) = S(\mathbf{x}, \mathbf{y}, \tau) &= \int_0^\tau L\, ds = \int_0^\tau \left(\frac{1}{2}\dot r^2 + \frac{1}{2}\theta\dot t\right) ds \\
&= \frac{1}{2}\int_0^\tau \dot r^2(s)\, ds + \frac{1}{2}\theta\big(t(\tau) - t(0)\big). \qquad (9.4.36)
\end{aligned}$$

Integrating the first term yields

$$\begin{aligned}\int_0^\tau \dot{r}(s)^2\,ds &= \frac{4\theta^2\mathbf{r}^2}{\sin^2(2\theta\tau)}\int_0^\tau \cos^2(2\theta s)\,ds = \frac{2\theta\mathbf{r}^2}{\sin^2(2\theta\tau)}\int_0^{2\theta\tau}\cos^2 v\,dv\\
&= \frac{2\theta\mathbf{r}^2}{\sin^2(2\theta\tau)}\Big[\theta\tau + \frac{1}{4}\sin(4\theta\tau)\Big]\\
&= \frac{\theta\mathbf{r}^2}{\sin^2(2\theta\tau)}\Big(2\theta\tau + \sin(2\theta\tau)\cos(2\theta\tau)\Big)\\
&= \theta\mathbf{r}^2\Big[\frac{2\theta\tau}{\sin^2(2\theta\tau)} + \cot(2\theta\tau)\Big] = \theta\mathbf{r}^2\widetilde{\mu}(2\theta\tau),\end{aligned} \tag{9.4.37}$$

where

$$\widetilde{\mu}(x) = \frac{x}{\sin^2 x} + \cot x \tag{9.4.38}$$

Proposition 9.27 *The classical action starting at the origin is*

$$\begin{aligned}S(\mathbf{x},\mathbf{t},\tau) &= \theta^2|\mathbf{x}|^2\Big(\frac{1}{2} + \frac{2|\mathbf{x}|^2}{\sin^2(2\theta\tau)}\Big)\\
&= \theta\mathbf{t} - \frac{1}{2}\theta^2\tau + \theta|\mathbf{x}|^2\cot(2\theta\tau).\end{aligned}$$

Proof. Using $t(0) = 0$, substituting (9.4.37) in equation (9.4.36) yields

$$\begin{aligned}S(\mathbf{x},\mathbf{t},\tau) &= \frac{1}{2}\theta\mathbf{r}^2\widetilde{\mu}(2\theta\tau) + \frac{1}{2}\theta\mathbf{t}\\
&= \frac{1}{2}\theta\mathbf{r}^2\widetilde{\mu}(2\theta\tau) + \frac{1}{2}\theta\big(\theta\tau + \mathbf{r}^2\mu(2\theta\tau)\big)\\
&= \frac{1}{2}\theta\mathbf{r}^2\widetilde{\mu}(2\theta\tau) + \frac{1}{2}\theta^2\tau + \frac{1}{2}\theta\mathbf{r}^2\mu(2\theta\tau)\\
&= \frac{1}{2}\theta\mathbf{r}^2\big[\widetilde{\mu}(2\theta\tau) + \mu(2\theta\tau)\big] + \frac{1}{2}\theta^2\tau\\
&= \theta\mathbf{r}^2\frac{2\theta\tau}{\sin^2(2\theta\tau)} + \frac{1}{2}\theta^2\tau\\
&= \theta^2\mathbf{r}\Big(\frac{1}{2} + \frac{2\mathbf{r}^2}{\sin^2(2\theta\tau)}\Big).\end{aligned}$$

For the second identity, using $\mu(x) = \widetilde{\mu}(x) + 2\cot(x)$, we have

$$\begin{aligned}S(\mathbf{x},\mathbf{t},\tau) &= \frac{1}{2}\theta\mathbf{r}^2\Big(\mu(2\theta\tau) + 2\cot(2\theta\tau)\Big) + \frac{1}{2}\theta\mathbf{t}\\
&= \frac{1}{2}\theta\mathbf{r}^2\mu(2\theta\tau) + \theta\mathbf{r}^2\cot(2\theta\tau) + \frac{1}{2}\theta\mathbf{t}\end{aligned}$$

$$
\begin{aligned}
&= \frac{1}{2}\theta(\mathbf{t} - \theta\tau) + \theta\mathbf{r}^2\cot(2\theta\tau) + \frac{1}{2}\theta\mathbf{t} \\
&= \frac{1}{2}\theta\mathbf{t} - \frac{1}{2}\theta^2\tau + \theta\mathbf{r}^2\cot(2\theta\tau) + \frac{1}{2}\theta\mathbf{t} \\
&= \theta\mathbf{t} - \frac{1}{2}\theta^2\tau + \theta\mathbf{r}^2\cot(2\theta\tau).
\end{aligned}
$$

Replacing $\mathbf{r}$ by $|\mathbf{x}|$ we obtain the desired formulas. ■

9.4.3 The complex action

The space $(\mathbb{R}^3, h)$ with h given by (9.4.15) is *not a radially symmetric space*. The reason is the fact that the momentum $\theta = \theta(\mathbf{x}, \mathbf{t}, \tau)$, which appears in the classical action given by Proposition 9.27, is a solution of the equation $\mathbf{t} = \theta\tau + |\mathbf{x}|^2\mu(2\theta\tau)$, and hence depends on the boundary conditions $\mathbf{t}$ and $\mathbf{x}$ in a complicated manner. Therefore we do not expect $\Delta_{Cas}S(\mathbf{x}, \mathbf{t}, \tau)$ to be a function that depends just on τ.

However, we can fix the situation. In the next chapter, when computing the heat kernels, we need an action function, which satisfies the Hamilton–Jacobi equation. We define the *complex action* for our problem to be the function obtained by substituting $\theta = -i$ in the classical action. Let $S_{\mathbb{C}}$ denote the complex action. Using the properties $\sin(-ix) = -i\sinh(x)$ and $\cos(-ix) = i\cosh(x)$ yields

$$
S_{\mathbb{C}} = -i\mathbf{t} + \frac{1}{2}\tau + (\mathbf{x}_1^2 + \mathbf{x}_2^2)\coth(2\tau). \tag{9.4.39}
$$

Proposition 9.28 *The complex action* (9.4.39) *satisfies the Hamilton–Jacobi equation*

$$
\frac{\partial S_{\mathbb{C}}}{\partial\tau} + \frac{1}{2}\Big(X_1 S_{\mathbb{C}}\Big)^2 + \frac{1}{2}\Big(X_2 S_{\mathbb{C}}\Big)^2 + \frac{1}{2}\Big(T S_{\mathbb{C}}\Big)^2 = 0. \tag{9.4.40}
$$

Proof. A computation provides

$$
\begin{aligned}
\partial_t S_{\mathbb{C}} &= -i, \\
\partial_{x_1} S_{\mathbb{C}} &= 2\mathbf{x}_1\coth(2\tau), \\
\partial_{x_2} S_{\mathbb{C}} &= 2\mathbf{x}_2\coth(2\tau).
\end{aligned}
$$

$$
\begin{aligned}
2H(\nabla S_{\mathbb{C}}) := {} & \big(X_1 S_{\mathbb{C}}\big)^2 + \big(X_2 S_{\mathbb{C}}\big)^2 + \big(T S_{\mathbb{C}}\big)^2 \\
= {} & \big(\partial_{x_1} S_{\mathbb{C}} + 2\mathbf{x}_2\partial_t S_{\mathbb{C}}\big)^2 + \big(\partial_{x_2} S_{\mathbb{C}} - 2\mathbf{x}_1\partial_t S_{\mathbb{C}}\big)^2 + \big(\partial_t S_{\mathbb{C}}\big)^2 \\
= {} & \big(2\mathbf{x}_1\coth(2\tau) - 2i\mathbf{x}_2\big)^2 + \big(2\mathbf{x}_2\coth(2\tau) + 2i\mathbf{x}_1\big)^2 + (-i)^2 \\
= {} & 4\mathbf{x}_1^2\coth^2(2\tau) - 4\mathbf{x}_2^2 - 8i\mathbf{x}_1\mathbf{x}_2\coth(2\tau) \\
& +4\mathbf{x}_2^2\coth^2(2\tau) - 4\mathbf{x}_1^2 + 8i\mathbf{x}_1\mathbf{x}_2\coth(2\tau) - 1 \\
= {} & 4|\mathbf{x}|^2\coth^2(2\tau) - 4|\mathbf{x}|^2 - 1.
\end{aligned} \tag{9.4.41}
$$

The local geometry of a general Riemannian manifold differs from the flat geometry of the Euclidean space $\mathbb{R}^n$: for example, the internal angles of a geodesic triangle in the 2-sphere S^2 (with the standard metric) always add up to **more** than π. A measure of this difference is provided by the notion of **curvature**, introduced by Gauss in his 1827 paper "General investigations of curved surfaces", and generalized to arbitrary Riemannian manifolds by Riemann himself (in 1854). It can appear under many guises: the rate of deviation of geodesics, the degree of non-commutativity of covariant derivatives along different vector fields, the difference between the sum of the internal angles of a geodesic triangle and π, or the angle by which a vector is rotated when parallel-transported along a closed curve.

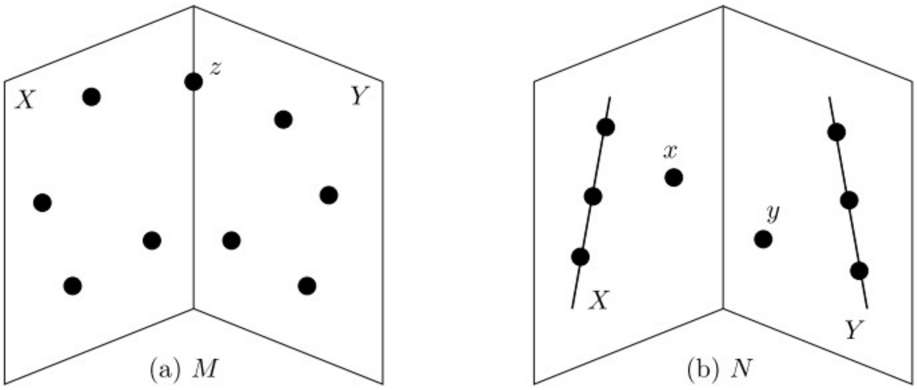
Lemma 8.2.11 *Let X and Y be disjoint subsets of the ground set of a matroid M. Then*

$$\sqcap_M(X,Y) + \sqcap_{M^*}(X,Y) = \lambda(X) + \lambda(Y) - \lambda(X \cup Y).$$



(a) M (b) N

FIG. 8.3. $z \in \mathrm{cl}_M(X) \cap \mathrm{cl}_M(Y)$ and $y \in \mathrm{cl}^*{}_N(X) \cap \mathrm{cl}^*{}_N(Y \cup x)$.

Proof The result follows easily by substitution using the facts that X and Y are disjoint and $\lambda(Z) = r_M(Z) + r_{M^*}(Z) - |Z|$. □

In a matroid M, a set X or a pair $(X, E - X)$ is *exactly k-separating* if $\lambda_M(X) = k - 1$. Similarly, a k-separation (X, Y) is *exact* if $\lambda_M(X) = k - 1$.

Example 8.2.12 Consider the rank-4 matroid M for which a geometric representation is shown in Figure 8.3(a). Let z be as labelled, let X be the set of four points on the left-hand plane other than z, and let Y be the corresponding set of four points on the right-hand plane. It is not difficult to verify that M has no 1- or 2-separations and that $(X, Y \cup z)$ and $(X \cup z, Y)$ are exact 3-separations. Thus the element z can be moved from one side of the 3-separation to the other. We observe that $z \in \mathrm{cl}(X) \cap \mathrm{cl}(Y)$.

Next let N be the rank-4 matroid shown in Figure 8.3(b), where X and Y are 3-point lines as indicated. Then N has no 1- or 2-separations and has each of $(X, Y \cup \{x, y\}), (X \cup x, Y \cup y)$, and $(X \cup \{x, y\}, Y)$ as an exact 3-separation. Moreover, although it is perhaps less obvious from the figure, $(X \cup y, Y \cup x)$ is also an exact 3-separation. In this case, we have, for example, that $y \in \mathrm{cl}^*(X) \cap \mathrm{cl}^*(Y \cup x)$, where we recall that $e \in \mathrm{cl}^*(S) - S$ if and only if e is a coloop of $M \backslash S$. □

The phenomenon that was just exemplified can be generalized.

Hence $\langle \varphi_i, \varphi_j \rangle = 0$ for all $i \neq j$. Thus, $(\varphi_i)_{i=1}^M$ is an orthonormal system which is complete by (ii), and (iii) is proved.

(iv) If $(\varphi_i)_{i=1}^M$ is a frame, by (ii), it is also a spanning set for $\mathscr{H}^N$. Towards a contradiction, assume that $(\varphi_i)_{i=1}^M$ is linearly dependent. Then there exist some $i_0 \in \{1, \dots, M\}$ and values λ_i, $i \in I := \{1, \dots, M\} \setminus \{i_0\}$ such that

$$\varphi_{i_0} = \sum_{i \in I} \lambda_i \varphi_i .$$

This implies that $(\varphi_i)_{i \in I}$ is also a frame, thus contradicting exactness of the frame. □

Before presenting some insightful basic results in frame theory, we first discuss some examples of frames to develop an intuitive understanding.

1.3.2 Examples

By Lemma 1.2 (iii), orthonormal bases are unit norm Parseval frames (and vice versa). However, applications typically require *redundant* Parseval frames. One basic way to approach this construction problem is to build redundant Parseval frames using orthonormal bases, and we will present several examples in the sequel. Since the associated proofs are straightforward, we leave them to the interested reader.

Example 1.1 Let $(e_i)_{i=1}^N$ be an orthonormal basis for $\mathscr{H}^N$.

(1) The system

$$(e_1, 0, e_2, 0, \dots, e_N, 0)$$

is a Parseval frame for $\mathscr{H}^N$. This example indicates that a Parseval frame can indeed contain zero vectors.

(2) The system

$$\left(e_1, \frac{e_2}{\sqrt{2}}, \frac{e_2}{\sqrt{2}}, \frac{e_3}{\sqrt{3}}, \frac{e_3}{\sqrt{3}}, \frac{e_3}{\sqrt{3}}, \dots, \frac{e_N}{\sqrt{N}}, \dots, \frac{e_N}{\sqrt{N}} \right)$$

is a Parseval frame for $\mathscr{H}^N$. This example indicates two important issues. First, a Parseval frame can have multiple copies of a single vector. Second, the norms of vectors of an (infinite) Parseval frame can converge to zero.

We next consider a series of examples of non-Parseval frames.

Example 1.2 Let $(e_i)_{i=1}^N$ be an orthonormal basis for $\mathscr{H}^N$.

(1) The system

$$(e_1, e_1, \dots, e_1, e_2, e_3, \dots, e_N)$$

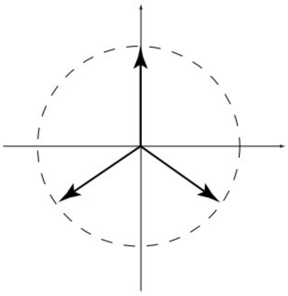

Fig. 1.1 Mercedes-Benz frame

with the vector e_1 appearing $N+1$ times, is a frame for $\mathscr{H}^N$ with frame bounds 1 and $N+1$.

(2) The system

$$(e_1, e_1, e_2, e_2, e_3, e_3, \ldots, e_N)$$

is a 2-tight frame for $\mathscr{H}^N$.

(3) The union of L orthonormal bases of $\mathscr{H}^N$ is a unit norm L-tight frame for $\mathscr{H}^N$, generalizing (2).

A particularly interesting example is the smallest truly redundant Parseval frame for $\mathbb{R}^2$, which is typically coined the *Mercedes-Benz frame*. The reason for this naming becomes evident in Fig. 1.1.

Example 1.3 The *Mercedes-Benz frame* for $\mathbb{R}^2$ is the equal norm tight frame for $\mathbb{R}^2$ given by:

$$\left(\sqrt{\tfrac{2}{3}}\begin{pmatrix}0\\1\end{pmatrix}, \sqrt{\tfrac{2}{3}}\begin{pmatrix}\frac{\sqrt{3}}{2}\\-\frac{1}{2}\end{pmatrix}, \sqrt{\tfrac{2}{3}}\begin{pmatrix}-\frac{\sqrt{3}}{2}\\-\frac{1}{2}\end{pmatrix}\right)$$

Note that this frame is also equiangular.

For more information on the theoretical aspects of equiangular frames we refer to [60, 91, 120, 139]. A selection of their applications is reconstruction without phase [5, 6], erasure-resilient transmission [15, 102], and coding [136]. We also refer to the Chaps. 4, 5 in this book for more details on equiangular frames.

Another standard class of examples can be derived from the *discrete Fourier transform* (*DFT*) *matrix*.

Example 1.4 Given $M \in \mathbb{N}$, we let $\omega = \exp(\frac{2\pi i}{M})$. Then the DFT matrix in $\mathbb{C}^{M\times M}$ is defined by

$$D_M = \frac{1}{\sqrt{M}}\left(\omega^{jk}\right)_{j,k=0}^{M-1}.$$

This matrix is a unitary operator on $\mathbb{C}^M$. Later (see Corollary 1.11) it will be seen that the selection of any N rows from D_M yields a Parseval frame for $\mathbb{C}^N$ by taking the associated M column vectors.

There also exist particularly interesting classes of frames such as Gabor frames utilized primarily for audio processing. Among the results on various aspects of Gabor frames are uncertainty considerations [113], linear independence [119], group-related properties [89], optimality analysis [127], and applications [67, 74, 75, 87, 88]. Chapter 6 provides a survey on this class of frames. Another example is the class of group frames, for which various constructions [24, 101, 147], classifications [64], and intriguing symmetry properties [146, 148] have been studied. A comprehensive presentation can be found in Chap. 5.

1.4 Frames and Operators

For the rest of this introduction we set $\ell_2^M := \ell_2(\{1, \dots, M\})$. Note that this space in fact coincides with $\mathbb{R}^M$ or $\mathbb{C}^M$, endowed with the standard inner product and the associated Euclidean norm.

The analysis, synthesis, and frame operators determine the operation of a frame when analyzing and reconstructing a signal. The Gramian operator is perhaps not that well known, yet it crucially illuminates the behavior of a frame $(\varphi_i)_{i=1}^M$ embedded as an N-dimensional subspace in the high-dimensional space ℓ_2^M.

1.4.1 Analysis and Synthesis Operators

Two of the main operators associated with a frame are the analysis and synthesis operators. The analysis operator—as the name suggests—analyzes a signal in terms of the frame by computing its frame coefficients. We start by formalizing this notion.

Definition 1.15 Let $(\varphi_i)_{i=1}^M$ be a family of vectors in $\mathscr{H}^N$. Then the associated *analysis operator* $T : \mathscr{H}^N \to \ell_2^M$ is defined by

$$Tx := \big(\langle x, \varphi_i \rangle\big)_{i=1}^M, \quad x \in \mathscr{H}^N.$$

In the following lemma we derive two basic properties of the analysis operator.

Lemma 1.3 *Let $(\varphi_i)_{i=1}^M$ be a sequence of vectors in $\mathscr{H}^N$ with associated analysis operator T.*

(i) *We have*

$$\|Tx\|^2 = \sum_{i=1}^M \big|\langle x, \varphi_i \rangle\big|^2 \quad \textit{for all } x \in \mathscr{H}^N.$$

Hence, $(\varphi_i)_{i=1}^M$ is a frame for $\mathscr{H}^N$ if and only if T is injective.

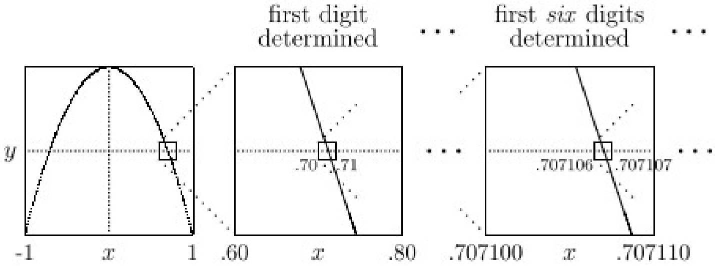
A geometric approach

Exercise 9 on page 40 considered the problem of finding the roots of $f(x) = 1 - 2x^2$. A bit of algebra confirms that $\sqrt{2}/2$ is a root—i.e., $f(\sqrt{2}/2) = 0$. The question is: what is the *numerical value* of $\sqrt{2}/2$?

We'll answer this question by constructing a sequence of approximations that add digits, one at a time, to an estimate for $\sqrt{2}/2$. Since the root lies at the point where the graph of f crosses the x-axis, we just magnify the graph at this point over and over again, "trapping" the point between x values that can be made arbitrarily close together.



The graph of $y = 1 - 2x^2$ under successive magnifications

If we make each stage a ten-fold magnification over the previous one, then, as we zoom in on the next smaller interval that contains the root, one more digit in our estimate will be stabilized. The first six stages are described in the table below. They tell us $\sqrt{2}/2 = .707106\ldots$ to six decimal places accuracy.

Since this method of finding roots requires only that we be able to plot successive magnifications of the graph of f on a computer screen, the method can be applied to any function that can be entered into a computer.

The positive root of $1 - 2x^2$

In the limit process we take $\Delta x \to 0$ because Δx is the width of the field of view. Since five digits of $\Delta y/\Delta x$ have stabilized, we can write

$$f'(27) = -.27235\ldots.$$

To find $f'(x)$ at some other point x, proceed the same way. Magnify the graph at that point repeatedly, until the value of the slope stabilizes. The method is very powerful. In the exercises you will have an opportunity to use it with other functions.

By using a microscope of arbitrarily high power, we have obtained further insights about rates and slopes. In fact, with these insights we can now state definitively what we mean by the slope of a curved graph and the rate of change of a function.

Definition. The **slope** of a graph at a point is the *limit* of the slopes seen in a microscope at that point, as the field of view shrinks to zero.

Definition. The **rate of change** of a function at a point is the slope of its graph at that point. Thus the rate of change is also a limit.

To calculate the value of the slope of the graph of $f(x)$ when $x = a$, we have to carry out a limit process. We can break down the process into these four steps:

1. Magnify the graph at the point $(a, f(a))$ until it appears straight.
2. Calculate the slope of the magnified segment.
3. Repeat steps 1 and 2 with successively higher magnifications.
4. Take the limit of the succession of slopes produced in step 3.

Local Linearity

A microscope gives a local view

The crucial property of a microscope is that it allows us to look at a graph **locally**, that is, in a small neighborhood of a particular point. The two functions we have been studying in this section have curved graphs—like most functions. But *locally*, their graphs are straight—or nearly so. This is

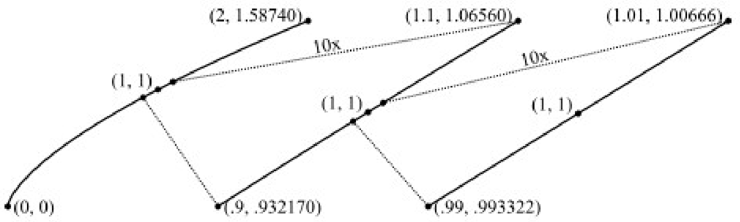
Copyright 1994, 2008 Five Colleges, Inc.
DVI file created at 11:39, 1 February 2008

a remarkable property, and we give it a name. We say these functions are **locally linear**. In other words, a locally linear function looks like a linear function, locally.

The graph of a linear function has a definite slope at every point, and so does a *locally* linear function. For a linear function, the slope is easy to calculate, and it has the same value at every point. For a locally linear function, the slope is harder to calculate; it involves a limit process. The slope also varies from point to point.

How common is local linearity? All the standard functions you already deal with are locally linear almost everywhere. To see why we use the qualifying phrase "almost everywhere," look at what happens when we view the graph of $y = f(x) = x^{2/3}$ with a microscope. At any point other than the origin, the graph is locally linear. For instance, if we view this graph over the interval from 0 to 2 and then zoom in on the point $(1, 1)$ by two successive powers of 10, here's what we see:

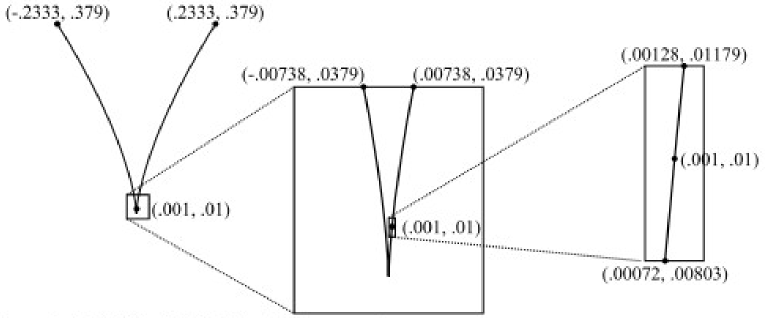
All the standard functions are locally linear at almost all points



As the field of view shrinks, the graph looks more and more like a straight line. Using the highest magnification given, we estimate the slope of the graph—and hence the rate of change of the function—to be

$$f'(1) \approx \frac{\Delta y}{\Delta x} = \frac{1.006656 - .993322}{1.01 - .99} = \frac{.013334}{.02} = .6667.$$

Similarly, if we zoom in on the point $(.001, .01)$ we get:

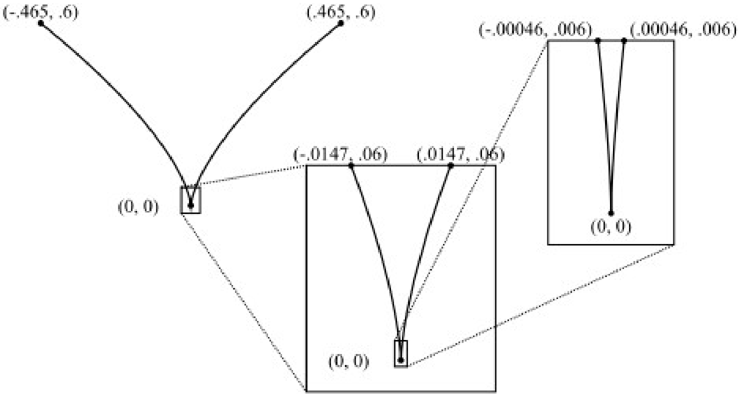


Copyright 1994, 2008 Five Colleges, Inc.
DVI file created at 11:39, 1 February 2008

In the last window the graph looks like a line of slope

$$f'(.001) \approx \frac{.0118 - .0082}{.00128181 - .00074254} = \frac{.0036}{.00053937} = 6.674.$$

At the origin, though, something quite different happens:



The graph simply looks more and more sharply pointed the closer we zoom in to the origin—it never looks like a straight line. However, the origin turns out to be the only point where the graph does not eventually look like a straight line.

Fractals are locally *non*-linear objects

In spite of these examples, it is important to realize that local linearity is a very special property. There are some functions that fail to be locally linear anywhere! Such functions are called **fractals**. No matter how much you magnify the graph of a fractal at any point, it continues to look non-linear—bent and "pointy" in various ways. In recent years fractals have been used in problems where the more common (locally linear) functions are inadequate. For instance, they describe irregular shapes like coastlines and clouds, and they model the way molecules are knocked about in a fluid (this is called *Brownian motion*). However, calculus does not deal with such functions. On the contrary,

Calculus studies functions that are locally linear almost everywhere.

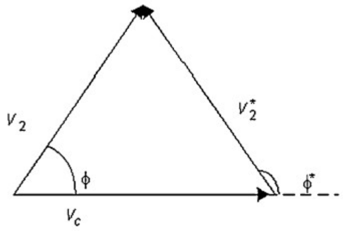

Fig. 1.5 Velocity triangle for the recoil particle

1.2.6 Limits on the Scattering Angle θ

Case (i) $m_2 > m_1$, or $\gamma < 1$; i.e. $v_1^* > v_c$.

In Fig. 1.6, the circle is drawn with O as the centre and radius $OP = v_1^*$. A is a point within the circle such that $AO = v_c$, and the line AOB represents the incident direction. As before, the lab velocity of m_1 is v_1 which is obtained by compounding v_1^* and v_c vectorially. The lab angle $\theta =$ angle PAO and the CM angle $\theta^* =$ angle POB. As the point P moves counterclockwise on the circumference, θ^* increases and so does θ. When P approaches P', $\theta^* = \theta = \pi$. Thus, θ increases monotonically from 0 to π, and in this case there is no restriction on the scattering angle in the LS. In other words, m_1 can be scattered in completely backward direction.

Case (ii) $m_2 = m_1$, or $\gamma = 1$; i.e. $v_1^* = v_c$.

Here A lies on the circumference of the circle (Fig. 1.7). As θ^* increases, θ also increases. But when P approaches A, PA becomes tangential at A and so $\theta \rightarrow \frac{\pi}{2}$. θ varies from 0 to π. Thus, in this case $m_1$can be scattered up to a maximum angle of $\pi/2$ but not beyond. In other words, backward scattering in the LS is not permissible.

Case (iii) $m_2 < m_1$, or $\gamma > 1$, i.e. $v_1^* < v_c$.

Here A lies outside the circle (Fig. 1.8). There are two positions P and P^l for which the same scattering angle θ is obtained for two different values of θ^*. As P moves back on the circumference, θ increases. The maximum angle θ_m is reached when AP becomes tangent to the circle (Fig. 1.9). In that case

$$\sin\theta_m = \frac{OP}{AO} = \frac{v_1^*}{v_c} = \frac{m_2}{m_1} \quad \text{or}$$

$$\theta_m = \sin^{-1}(m_2/m_1)$$

Thus, there is a limitation on the scattering angle when $m_2 < m_1$. θ first increases from 0 to a maximum value $\sin^{-1}(1/\gamma)$ which is less than $\pi/2$, as θ^* increases from 0 to $\cos^{-1}(-1/\gamma)$. θ then decreases to 0 as θ^* further increases to π. At a given angle θ between 0 and $\sin^{-1}(1/\gamma)$, there will be two groups of particles associated with different velocities corresponding to the two values of θ^*.

Fig. 1.6 Limits on the scattering angle for $m_2 > m_1$, θ max $= \pi$

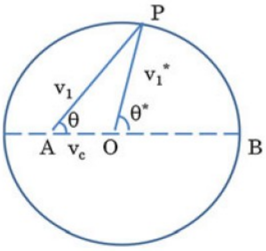

Fig. 1.7 Limits on the scattering angle θ for $m_1 = m_2$, θ max $= \pi/2$

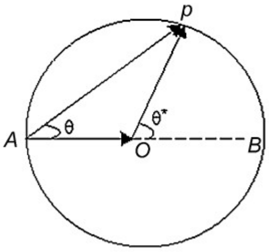

Fig. 1.8 Limits on the scattering angle θ. For $m_2 < m_1$, $\theta(\max) = \sin^{-1}(\frac{m_2}{m_1})$

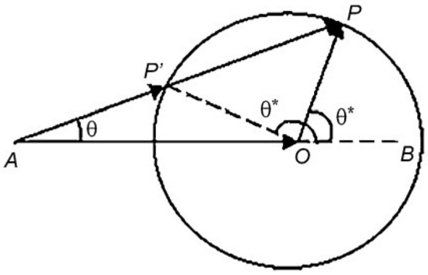

Fig. 1.9 $\theta_{\max}$ is reached when AP is a tangent to the circle

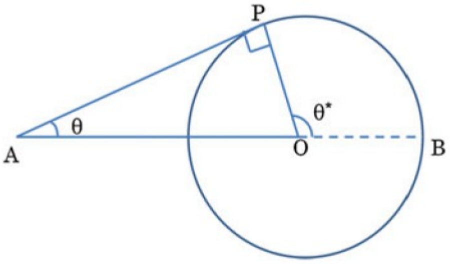

1.2.7 Limits on the Recoil Angle ϕ

Since $v_2^* = v_c$ (always), $\phi = \frac{1}{2}\phi^*$ by (1.15). Since the maximum angle of ϕ^* is π, the maximum angle ϕ_m is $\frac{1}{2}\pi$. In other words, the target particle cannot recoil in the backward hemisphere.

Fig. 1.10 Azimuth angle β is measured with respect to the positive axis in the xy plane $\perp$ to the direction of incidence

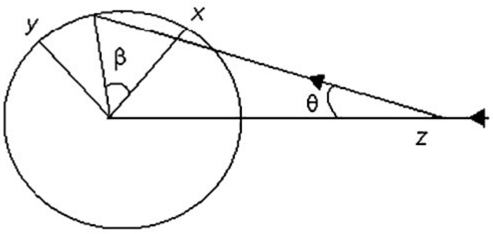

Fig. 1.11 Element of solid angle $d\Omega = ds/r^2$

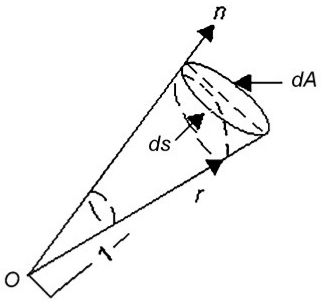

1.2.8 *Scattering in Three Dimensions*

Since scattering is described under central forces, a particle which is incident on a target particle and initially moves in a certain plane would be necessarily confined to this plane after the scattering because of the conservation of angular momentum. Thus, a single scattering event is completely described in two dimensions. However, in practice one is concerned with a flux of particles incident say along the z-axis on a target material. Since various particles proceed in different planes, the scattering on the whole will be in three dimensions. In order to fix the orientation of the plane of scattering, we need to introduce the azimuth angle β which is measured with respect to the positive x-axis in the xy plane, Fig. 1.10. We must also consider the element of solid angle into which the particles are scattered. This is illustrated in Fig. 1.11.

Let dA denote an element of surface area and connect all points on the boundary of dA to O so as to form a cone. Let ds be the area of that portion of a sphere with O as the centre and radius r which is cut out by this cone. The solid angle subtended by dA at O is defined as $d\Omega = ds/r^2$ and is numerically equal to the area cut out by a sphere with centre O and unit radius. From Fig. 1.12, it is seen that $ds = r^2 \sin\theta d\theta d\beta$ so that $d\Omega = \sin\theta d\theta d\beta = 2\pi \sin\theta d\theta$, where we have integrated over $d\beta$. When the scattering is independent of the azimuth angle then the area subtended at O is due to the entire circular strip, $ds = 2\pi r^2 \sin\theta d\theta$ as in Fig. 1.13, so that the element of solid angle $d\Omega = 2\pi \sin\theta d\theta$. Observe that the maximum solid angle is 4π since it is given by the entire surface area of a sphere $(4\pi r^2)$ divided by r^2.

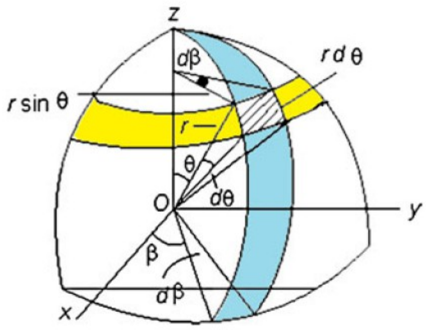

Fig. 1.12 Elements of solid angle for a general case

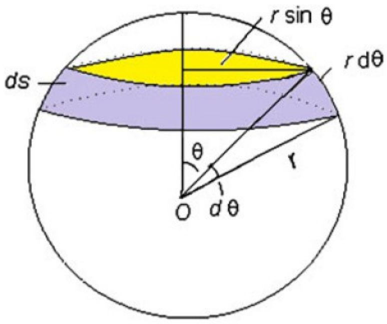

Fig. 1.13 Element of solid angle for an azimuthal symmetry

1.2.9 Scattering Cross-Section

In order to describe the angular distribution of particles scattered by target particles which are initially stationary, the concept of cross-section is introduced. Let a uniform parallel flux of N_0 particles be incident per unit area normal to the direction per unit time on a group of n scattering centres. Let N particles be scattered per unit time into a small solid angle $d\Omega$ centred towards a direction which has polar angle θ and azimuth angle β with respect to the incident direction as polar axis. N will be proportional to N_0, n and $d\Omega$ provided the flux is small enough to ensure that the incident particles do not interfere with one another, that there is no appreciable decrease in the number of scattering centres on account of their being knocked out due to collisions and that the incident particles are far enough apart so that each collision is made only by one of them.

The number of incident particles that emerge per unit time in $d\Omega$ can be written as:

$$N = nN_0\sigma(\theta,\beta)d\Omega \tag{1.16}$$

where the proportionality factor $\sigma(\theta,\beta)$ is called the differential scattering cross-section. The quantity $\sigma(\theta,\beta)$ is a measure of the probability of scattering in a given direction (θ,β), per unit solid angle from the given nucleus.

care, a navigator might compute a distance that would leave us hundreds of miles short of our destination!

The mathematical face of this ambiguity appears immediately when we use the Law of Sines to find $\measuredangle A$: $\sin A = \sin a \sin B / \sin b = 0.9985$, so $A = 86.84^\circ$ or $180^\circ - 86.84^\circ = 93.16^\circ$. We can tell from our diagram that we want the smaller angle 86.84°, but if the ambiguity had passed without notice, we might have run out of fuel at X, with no land in sight.

We now know a, b, A, and B; but finding c and C proves surprisingly awkward. The Law of Sines doesn't help since there is no way to apply it without leaving two unknowns in the equation. It is possible to use the Law of Cosines (rearranging the letters in the diagram appropriately), but only by changing $\sin c$ into $\sqrt{1-\cos^2 c}$, eventually requiring us to solve a quadratic equation for $\cos c$. A cleaner approach would be nice. Fortunately, there are several possibilities.

Delambre's and Napier's Analogies

It's surprisingly common, and rather eerie, when mathematical discoveries are made almost simultaneously by two or more people working on their own. The invention of calculus by Isaac Newton and Gottfried Wilhelm Leibniz is the most famous episode of this kind, followed by the birth of non-Euclidean geometry in the works of János Bolyai, Nicolai Lobachevsky, and Carl Friedrich Gauss in the early 19th century. Bolyai's father wrote to Gauss of his son's breakthrough, only to receive the disheartening reply from an impressed Gauss that he had done it all already, but had not bothered to publish it.

This incident was not the first of Gauss's experiences with simultaneous discovery. The theorems we are about to describe were known first as *Gauss's formulas*, appearing in his 1809 *Theoria motus corporum coelestium*, a monumental two-volume treatise on the motions of celestial bodies. But this time it was Gauss who had been scooped, by mere months; and not once, but twice. In the previous year German scientist Karl Brandon Mollweide had published the same results in Leipzig, and he in turn referred to their appearance in a book by Antonio Cagnoli. However, in a rare case when a name actually changed when a prior discovery was verified, the theorems are now known as *Delambre's analogies* after the astronomer Jean-Baptiste Joseph Delambre, who came up briefly in chapter 5 for maligning Napier's Rules. Delambre likely would prefer to be remembered for his contributions to celestial mechanics, his work on determining the length of the meter, and his books on the history of astronomy. But his discovery and publication of the analogies in 1807 in the long-running French astronomical journal *Connaissance des Temps* (oddly the volume was dated 1809, leading to some of the confusion) grant him a measure of additional fame by crossing the finish line only months before his unwitting rivals.

> →Delambre's analogies are usually demonstrated disappointingly through algebraic manipulation of various known identities. It is not easy to approach them geometrically, but at least one textbook (Isaac Todhunter's classic) gives it a go. The argument, based on Delambre's original demonstration, begins with ΔABC in figure 6.6. We begin by bisecting $\overset{\frown}{AB}$ at M and drawing a perpendicular upward. Next bisect $\measuredangle BCP$ to form $\overset{\frown}{CV}$. Drop arcs perpendicular to $\overset{\frown}{CP}$ and $\overset{\frown}{CB}$, defining P and Q respectively. Finally, join $\overset{\frown}{AV}$ and $\overset{\frown}{BV}$. We show first that ΔAVP and ΔBVQ are equal, by matching three elements of the triangles. They both contain a right angle; since $\overset{\frown}{MV}$ is perpendicular to $\overset{\frown}{AB}$ we know that $\overset{\frown}{AV} = \overset{\frown}{BV}$; finally, since $\measuredangle BCP$ was bisected by $\overset{\frown}{CV}$ we know that $\overset{\frown}{PV} = \overset{\frown}{QV}$. So the two triangles are equal.*
>
> This fact allows us to label the angles at A and B as we have done in the diagram. The angles at the base of the original triangle are $\measuredangle A = y + x$ and $\measuredangle B = y - x$; a little algebra yields $x = (A - B)/2$ and $y = (A + B)/2$. We are in a similar algebraic situation with respect to sides a and b of the original triangle: $a = \overset{\frown}{BQ} + \overset{\frown}{CQ}$ and $b = \overset{\frown}{AP} - \overset{\frown}{CP}$, but $\overset{\frown}{BQ} = \overset{\frown}{AP}$ (since triangles AVP and BVQ are equal) and $\overset{\frown}{CQ} = \overset{\frown}{CP}$, so $\overset{\frown}{BQ} = (a + b)/2$ and $\overset{\frown}{CQ} = (a - b)/2$. Turning to the angles at the top of the diagram, we know that $\measuredangle AVB = \measuredangle PVQ$ since both are composed of $\measuredangle AVQ$ and equal angles. Cutting these angles in half, we have $\measuredangle AVM = \measuredangle PVC$.

---

* As my students gleefully pointed out, there is an error in the argument here. The two triangles are asserted to be equal by side-side-angle equivalence, but side-side-angle is the ambiguous case. The fact that the angle is right seems to allow the argument to escape unscathed from the ambiguity, but this turns out not to be quite true on the sphere. I leave it to my eagle-eyed students and readers to explore the flaw and discover how to patch it.

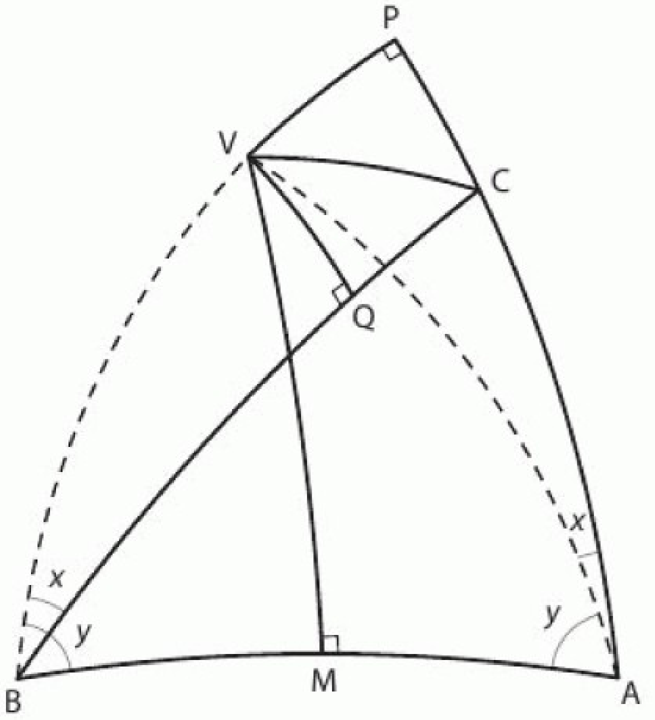

Figure 6.6. The proof of Delambre's first analogy.

We're in the home stretch of the proof. Consider the two right-angled triangles ΔAVM and ΔPVC, with equal angles at V. Apply Geber's Theorem to both and bring the results together:

$$\sin\measuredangle VAM \cos\widehat{AM} = \cos\measuredangle AVM = \sin\measuredangle PCV \cos\widehat{CP}.$$

Substituting each of the angles for their values from the elements of the original triangle and rearranging the terms, we finally arrive at *Delambre's first analogy*: →

$$\frac{\sin\frac{1}{2}(A+B)}{\cos\frac{1}{2}C} = \frac{\cos\frac{1}{2}(a-b)}{\cos\frac{1}{2}c}.$$

Admittedly this argument, as clever as it is, is not much of an advertisement for geometric over algebraic proofs. We shall explore an algebraic derivation in the exercises. Delambre's other three analogies,

$$\frac{\sin\frac{1}{2}(A-B)}{\cos\frac{1}{2}C} = \frac{\sin\frac{1}{2}(a-b)}{\sin\frac{1}{2}c},$$

$$\frac{\cos\frac{1}{2}(A+B)}{\sin\frac{1}{2}C} = \frac{\cos\frac{1}{2}(a+b)}{\cos\frac{1}{2}c}, \text{ and}$$

$$\frac{\cos\frac{1}{2}(A-B)}{\sin\frac{1}{2}C} = \frac{\sin\frac{1}{2}(a+b)}{\sin\frac{1}{2}c},$$

may be demonstrated similarly.

The word "analogy" might seem strange here. We use it in what is now an obsolete mathematical sense that goes back to the original Greek meaning of the word: a ratio, or an equality between ratios. Even today, one might think of a ratio as a comparison, or an "analogy," between two quantities.

It has taken some work to secure these identities, apparently for the purpose of dealing with oblique triangles when a, b, A, and B are known. But each of these identities refers to *all six* of the triangle's elements, and so can be used only if five elements are known, not four! In fact, in most textbooks Delambre's identities are used only as a tool to check the correctness of completed solutions to triangles. Has our effort gone to waste?

Thankfully not. We are on the verge of another set of analogies, named after John Napier (although Napier's friend and successor Henry Briggs actually contributed two of the four). Several terms appear more than once in Delambre's analogies; this suggests that we might combine the analogies by eliminating the common terms. For instance, the first and third of Delambre's analogies both contain $\cos\frac{1}{2}c$, so if we divide one by the other, we get

$$\frac{\tan\frac{1}{2}(A+B)}{\cot\frac{1}{2}C} = \frac{\cos\frac{1}{2}(a-b)}{\cos\frac{1}{2}(a+b)}.$$

We arrive at three other identities in a similar fashion:

$$\frac{\tan\frac{1}{2}(A-B)}{\cot\frac{1}{2}C} = \frac{\sin\frac{1}{2}(a-b)}{\sin\frac{1}{2}(a+b)},$$

$$\frac{\tan\frac{1}{2}(a+b)}{\tan\frac{1}{2}c} = \frac{\cos\frac{1}{2}(A-B)}{\cos\frac{1}{2}(A+B)}, \text{ and}$$

$$\frac{\tan\frac{1}{2}(a-b)}{\tan\frac{1}{2}c} = \frac{\sin\frac{1}{2}(A-B)}{\sin\frac{1}{2}(A+B)}.$$

Napier's analogies each contain only five triangle elements, not six. So for our ambiguous triangle, once we know a, b, A, and B, any one of these four identities will give us either c or C. For instance, for our Honolulu to Tokyo trip, we substitute into Napier's third analogy to get

$$\frac{\tan\frac{1}{2}(68.69^\circ + 54.3^\circ)}{\tan\frac{1}{2}c} = \frac{\cos\frac{1}{2}(86.84^\circ - 60.5^\circ)}{\cos\frac{1}{2}(86.84^\circ + 60.5^\circ)},$$

from which we have $\tan\frac{1}{2}c = 0.5317$, and so $c = 28^\circ$, equal to 1680 nautical miles or 1933 statute miles. And if we're really interested, we can calculate the last unknown C using almost any of the identities we've seen in this chapter.

There is plenty more to spherical trigonometry than we've seen so far, but this concludes the basic theory needed for solving triangles. In the remaining three chapters we'll see some special topics and applications.

Exercises

1. Solve the following triangles:
   (a) $a = 135^\circ$, $b = 120^\circ$, $c = 45^\circ$
   (b) $A = 68.72^\circ$, $B = 104.35^\circ$, $C = 47.62^\circ$
   (c) $b = 48.62^\circ$, $c = 78.85^\circ$, $C = 128.77^\circ$.
   [Brink 1942, 26 # 1 and 4, 43 # 3]
2. Find the perimeter of a spherical triangle with angles 69°, 84°, 100°, upon a sphere whose radius is 10 inches. [Rothrock 1911, 136]
3. Find the length of the shortest air route between Cape Town (33.93° S, 18.47° E) and Dakar (14.67° N, 17.42° W). What is the bearing of this journey as the plane leaves Cape Town?
4. A ship sailing on a great circle from Ceylon to Madagascar crosses the meridian of 79° east longitude bearing S 50° W. After sailing 2060 nautical miles farther, it crosses the meridian of 52° east longitude. Find its latitude and the bearing of its course at this point and its latitude at the first point. [Brink 1942, 41]
5. Charles A. Lindbergh flew his plane *The Spirit of St. Louis* on the great circle route from New York (40.75° N, 73.97° W) to Paris (48.83° N, 2.33° E). He left New York at 7:52 AM (Eastern Standard Time) on May 20, 1927, and arrived at Paris the next day at 5:24 PM (Eastern Standard Time). What was his average speed for the flight? [Rosenbach/Whitman/Moskovitz 1937, 332]
6. We are at the southwest corner of an open field. We walk across the field to the northeast corner, departing with a heading 49° east of north and traveling exactly one nautical mile to the northeast corner. At the end of our journey, our heading is now 49.01° east of north. What is our terrestrial latitude? (*Warning:* use as many digits of precision as your calculator allows.)
7. Given the latitudes and longitudes of two places on the earth's surface, show how to find the shortest distance between them. [Anderegg/Roe 1896, 107]

8. From Napier's third analogy,

$$\frac{\cos\frac{1}{2}(A-B)}{\cos\frac{1}{2}(A+B)}=\frac{\tan\frac{1}{2}(a+b)}{\tan\frac{1}{2}c},$$

show that in any spherical triangle, one-half the sum of two angles is in the same quadrant as one-half the sum of the opposite sides, that is, $\frac{1}{2}(a+b)$ and $\frac{1}{2}(A+B)$ are in the same quadrant. [Kells/Kern/Bland 1942, 81 # 4]
9. We are going to develop an alternate solution to an oblique spherical triangle in the side-side-angle (SSA) case using right-angled triangles. Say we are given sides a, b, and the angle A. Drop a perpendicular from C to a point D on side c. (Note: there are two different possible configurations. You may just solve the case where the perpendicular falls on the side.) Solve the right-angled triangles and show how this will give the solution to the original triangle. [Casey 1889, 60]

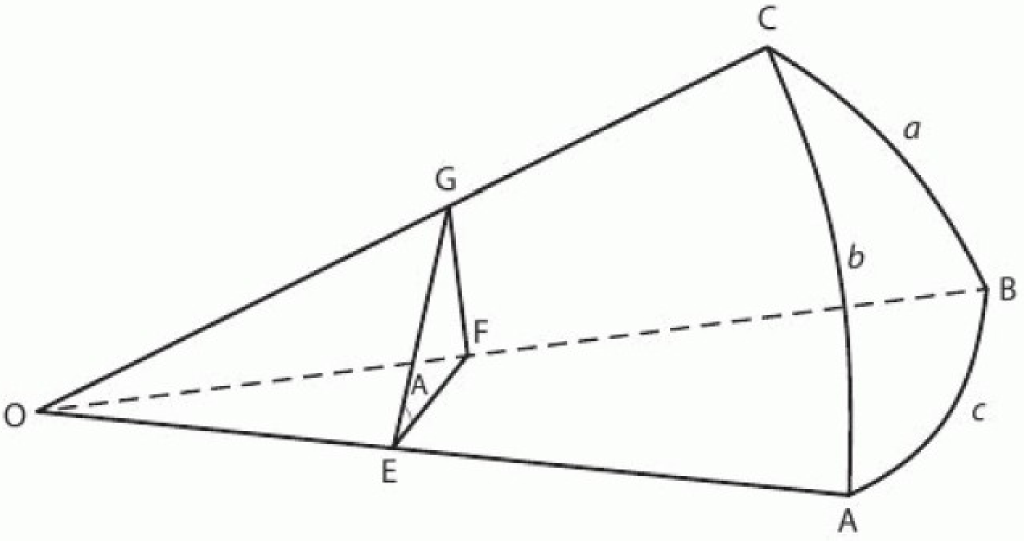

Figure E-6.10.

10. Develop an alternate proof of the Law of Cosines using figure E-6.10, where $\measuredangle OEF$ and $\measuredangle OEG$ are right angles by construction (but $\measuredangle EFG$ is not necessarily a right angle). *Hint:* Apply the planar Law of Cosines to triangles OGF and GFE to solve for their common side and combine the two statements. Simplify the new statement using the Pythagorean theorem on OFE and OEG. Then solve for $\cos a$. [Moritz 1913, 38–39 # 5]
11. Derive the Law of Sines algebraically from the Law of Cosines. (*Hint:* Solve for $\cos A$ in the equation $\cos a = \cos b \cos c + \sin b \sin c \cos A$, form $\sin^2 A$, and reduce the numerator to a form involving cosines only. Then show that $\sin^2 A/\sin^2 a$ is symmetrical in a, b, c.) [Kells/Kern/Bland 1942, 73 # 4]

12. When the polar duality theorem is applied to one of Delambre's analogies, another of Delambre's analogies results. Which pair? What happens if you apply the polar duality theorem to the other two analogies?
13. Napier's analogies were sometimes used as a method of solving geographical problems. Suppose that we know the latitudes of Edmonton (53.6° N) and Vancouver (49.3° N), as well as their difference in longitude (9.6°). The Law of Cosines is the obvious choice here, but instead use Napier's analogies to determine the headings of a great circle path between the cities, and then use some other identity to determine the distance.
14. Here we shall construct an algebraic proof of Napier's first analogy. First, notice from the Law of Sines that $\frac{\sin A}{\sin a} = \frac{\sin B}{\sin b} = \frac{\sin A + \sin B}{\sin a + \sin b}$. Call this ratio m.
(a) Use the Law of Cosines for Angles, twice (once expressed for $\cos A$, once for $\cos B$) to derive the expression

$$(\cos A + \cos B)(1 + \cos C) = m \sin C \sin(a + b).$$

(b) Divide the Law of Sines expression above by your result from (a), to get

$$\frac{\sin A + \sin B}{\cos A + \cos B} = \frac{\sin a + \sin b}{\sin(a+b)} \cdot \frac{1+\cos C}{\sin C}.$$

(c) Transform each of the terms in your expression from (b) using the following identities from plane trigonometry:

$$\sin x + \sin y = 2 \sin \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$$

$$\cos x + \cos y = 2 \cos \tfrac{1}{2}(x + y) \cos \tfrac{1}{2}(x - y)$$

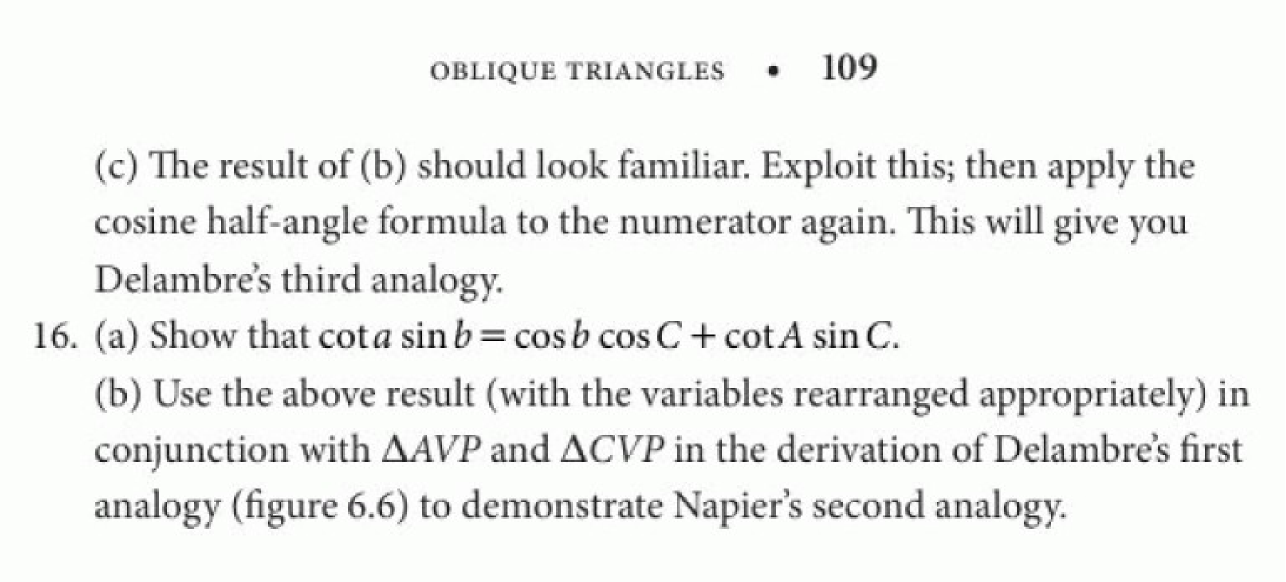
$$\sin 2x = 2 \sin x \cos x$$

$$1 + \cos x = 2 \cos^2 (x/2).$$

(d) Simplify. [Clough-Smith 1978, 76]
15. Although it is possible to derive Delambre's analogies algebraically on their own, it is easier to derive them algebraically from Napier's analogies.
(a) Square Napier's first analogy; solve for the tangent-squared term, and add one to both sides. This should leave you with

$$\sec^2 \tfrac{1}{2}(A + B) = \frac{\cos^2 \tfrac{1}{2}(a-b) \cos^2 \tfrac{1}{2}C + \cos^2 \tfrac{1}{2}(a+b) \sin^2 \frac{1}{2}C}{\cos^2 \tfrac{1}{2}(a+b) \sin^2 \frac{1}{2}C}.$$

(b) Apply the cosine half-angle formula $\cos^2 \frac{\theta}{2} = \frac{1}{2}(1 + \cos\theta)$ to two of the terms in the numerator. Then continue to simplify the numerator, until you arrive at $\frac{1}{2}(1 + \cos a \cos b + \sin a \sin b \cos C)$.



OBLIQUE TRIANGLES • 109

(c) The result of (b) should look familiar. Exploit this; then apply the cosine half-angle formula to the numerator again. This will give you Delambre's third analogy.

16. (a) Show that $\cot a \sin b = \cos b \cos C + \cot A \sin C$.

(b) Use the above result (with the variables rearranged appropriately) in conjunction with ΔAVP and ΔCVP in the derivation of Delambre's first analogy (figure 6.6) to demonstrate Napier's second analogy.

3.3 CENTRAL CONSERVATIVE FORCES

*A force **F** is said to be central if is directed towards or away from a fixed point*. In this course we shall mainly deal with central forces acting according to the law of inverse squares:

$$F=-\frac{C}{r^2}. \tag{3.17}$$

The electrostatic and gravitational forces, acting between two immobile particles has such form. If one of the particles is positioned at the origin of the co-ordinate system and the other at a distance r, these central forces are always directed along the radius-vector **r**:

$$\mathbf{F}=-\frac{C}{r^2}\mathbf{r}^0=-\frac{C}{r^2}\frac{\mathbf{r}}{r}. \tag{3.18}$$

For the gravitational force between two particles of masses m_1 and m_2, we have $C=G_0m_1m_2$, where $G_0=6,67.10^{-11}\ \text{N.m}^2/\text{kg}^2$ is the gravitational constant, and for the electrostatic force between two charges $\mathbf{q_1}$ and $\mathbf{q_2}$, $C=\mathbf{q_1}\mathbf{q_2}/4\pi\varepsilon_0$, where ε_0 is the permittivity of the vacuum. These forces are conservative and can be expressed through the potential energy

$$\mathbf{F}=-\frac{\partial U(r)}{\partial \mathbf{r}},\quad U(r)=-\frac{C}{r}. \tag{3.19}$$

We have chosen the arbitrary constant of U so that $U(\infty)=0$. It is preferable to deal with the scalar $U(r)$ than with the vector $\mathbf{F}(\mathbf{r})$.

We shall note that $C>0$ corresponds to attractive forces (a gravitational force or an electrostatic one between charges of opposite signs) and $C<0$ corresponds to repulsive forces (an electrostatic force between charges of equal signs). In atomic physics another central force plays a basic role – the nuclear force. From experiments on scattering of elementary particles, it is known that the nuclear force acts on a small distance between two nucleons (protons or neutrons) with a potential energy

$$U(r)=-\frac{C\exp(-r/r_0)}{r}. \tag{3.20}$$

Here $r_0 \approx 2.10^{-15}$ m, $C \approx 10^{-27}$ J.m. It is easy to see evaluate that at $r \le r_0$ the nuclear force between two protons dominates the Coulomb force of their repulsion. We shall note that (3.20) is an approximation.

Since central forces are always collinear to the radius-vector **r**, their torque is zero

$$\mathbf{N} = \mathbf{r} \times \mathbf{F} = 0. \tag{3.21}$$

According to (2.39) this means that the angular momentum is constant

$$\mathbf{L} = \mathbf{r} \times \tilde{m}\dot{\mathbf{r}} = \text{const}, \tag{3.22}$$

where $\tilde{m}$ is the reduced mass of the particles interacting with the force (3.18). This is the law of conservation of angular momentum and it contains two statements: that its direction is constant and that its magnitude is constant. The angular momentum is perpendicular to the plane of motion - the vector **L** is along the normal to the plane of **r** and $\dot{\mathbf{r}}$. Hence the statement that the direction of **L** is constant implies that **r** and $\dot{\mathbf{r}}$ must always lie in a fixed plane, which is perpendicular to **L**. From here it is evident that the orbit of the particle lies entirely in one plane. The description of such motion requires only two variables, which may be taken as the polar co-ordinates r and φ. Then the Lagrangian function can be written as

$$\mathscr{L} = \frac{\tilde{m}}{2}\left(\dot{\mathbf{r}}^2 + \mathbf{r}^2\dot{\varphi}^2\right) - U(r). \tag{3.23}$$

The co-ordinate φ is a cyclic co-ordinate (see Section 2.1) and the generalized momentum $P_\varphi = \partial\mathscr{L}/\partial\dot{\varphi}$ is a constant of the motion:

$$P_\varphi = \tilde{m}r^2\dot{\varphi} = \text{const}. \tag{3.24}$$

We shall verify that this quantity is equal to the angular momentum. The velocity $\dot{\mathbf{r}}$ (3.22) has components in the directions of the unit vectors $\mathbf{r}^0$ and $\boldsymbol{\varphi}^0$. Indeed, as it is shown in Fig. 3-5 the displacement $d\mathbf{r}$ of the particle, due to the increments of the elements dr and $d\varphi$, can be represented as

$$d\mathbf{r} = dr\mathbf{r}^0 + rd\varphi\,\boldsymbol{\varphi}^0 \tag{3.25}$$

and dividing by dt, we obtain

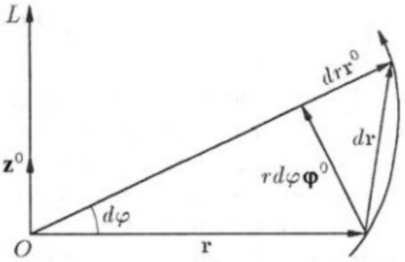

Figure 3-5. The motion of a particle of a reduced mass $\tilde{m}$ in a central field with a centre O is performed in a plane, normal to **L** and is described with the polar co-ordinates r and φ ($\mathbf{r}^0$ and $\boldsymbol{\varphi}^0$ are corresponding unit vectors). At the elementary change of the co-ordinates with dr and $d\varphi$ the particle displaces with $d\mathbf{r}$.

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \dot{r}\mathbf{r}^0 + r\dot{\varphi}\,\boldsymbol{\varphi}^0. \tag{3.26}$$

The substitution of (3.26) into the expression for **L** (3.22) yields

$$\mathbf{L} = \mathbf{r}\times\tilde{m}\mathbf{v} = r\,\mathbf{r}^0\times\tilde{m}\left(\dot{r}\,\mathbf{r}^0 + r\dot{\varphi}\boldsymbol{\varphi}^0\right) = 0 + \tilde{m}r^2\dot{\varphi}\left(\mathbf{r}^0\times\boldsymbol{\varphi}^0\right) = \tilde{m}r^2\dot{\varphi}\mathbf{z}^0. \tag{3.27}$$

The magnitude of **L** is $L = L_z = \tilde{m}r^2\dot{\varphi}.$ We proved that under the motion in central-force field the generalized momentum P_φ has a meaning of angular momentum:

$$L = L_z = P_\varphi = \tilde{m}r^2\dot{\varphi}. \tag{3.28}$$

The law of conservation of angular momentum has an interesting geometrical interpretation. When the angle φ changes by an amount $d\varphi$ the position vector **r** sweeps out an area dS (Fig. 3-5):

$$dS = r^2 d\varphi/2. \tag{3.29}$$

The rate of change of this area, which is called an area velocity or a sector velocity, is

$$\frac{dS}{dt} = \frac{1}{2}r^2\dot{\varphi} = \frac{L}{2\tilde{m}} = \text{const.} \tag{3.30}$$

*For equal intervals of time the radius-vector sweeps equal surfa*ce. This law is known as *second Kepler's law* of the motion of the planets. As we saw, it is valid for any central force, not only for a gravitational one.

The forces acting according to the inverse-square law are central and conservative ones. Besides the law of angular-momentum conservation, the law of the conservation of energy is also valid:

$$E = \frac{\tilde{m}}{2}\left(\dot{r}^2 + r^2\dot{\varphi}^2\right) + U\left(r\right). \tag{3.31}$$

We have found two constants of motion (3.28) and (3.31), which express the laws of conservation of angular momentum and energy. (These constants of motion are very often called first integrals of the motion, as they contain first derivatives of the co-ordinates.) Important information can be obtained directly from these equations, without solving them to determine r and φ as functions of time. Eliminating $\dot{\varphi}$ in (3.31) with the help of (3.28), we obtain an equation for r and $\dot{r}$ only:

$$E = \frac{1}{2}\tilde{m}\dot{r}^2 + \frac{L^2}{2\tilde{m}r^2} + U(r). \tag{3.32}$$

Often this is called a radial equation, underlying that it indicates the energy balance only under the change of the distance r to the centre. Comparing this equation with (3.3), we see that it has the same form as the equation of energy for one-dimensional motion with "potential energy" $\tilde{U}(r)$:

$$\tilde{U}\left(r\right) = \frac{L^2}{2\tilde{m}r^2} + U(r). \tag{3.33}$$

This energy is called effective potential energy.

It is easy to explain the physical meaning of the additional term $L^2/2\tilde{m}r^2$ in $\tilde{U}\left(r\right)$. Taking the value of L from (3.28), it can be represented as $\tilde{m}r^2\dot{\varphi}/2$. This term is different from zero only for motion along φ, i.e. rotation. This is the reason to call the additional energy $L^2/2\tilde{m}r^2$ a centrifugal energy. Despite that in (3.32) the motion is represented as one-dimensional (radial), the motion along φ, i.e. the rotation, is present non-explicitly in the term $\propto L^2$. The angular momentum is a constant, but it exists as a consequence of the motion along φ, i.e., of the fact that $\dot{\varphi} \neq 0$. The effective potential energy can be used for qualitative analysis, just as $U(x)$ can be used in a one-dimensional motion. When

$$\tilde{U}(r)=\frac{L^2}{2\tilde{m}r^2}+U(r)\le E\ . \tag{3.34}$$

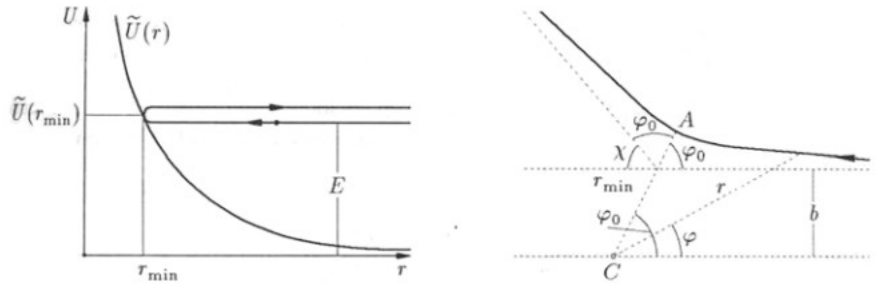
and $\tilde{U}(r')=\tilde{U}(r")=E$ the motion is finite and is bounded in the region $r'\le r\le r"$. Both solutions of the equation determine the minimal and maximal distance from the centre, and the orbit lies between them. Under the conditions (3.34) and $\tilde{U}(r')=E$, the motion is semi-infinite in the region $r\ge r'$ with the turning point r'. If $\tilde{U}(r)$ has a minimum and E is equal to $\tilde{U}_{\min}$, then $\dot{r}$ is always zero (see (3.32)) and r is fixed at the position of the minimum. In this case the particle moves along a circle around the centre.

3.4* ORBITS OF THE MOTION

In order to determine the character of motion we have to know the form of the function $\tilde{U}(r)$ in (3.33). The centrifugal energy is always positive. In the case of a repulsive force, the function of the potential $U(r)=-C/r$ $(\mathrm{C}<0)$ is positive for any r. Then the effective potential energy $\tilde{U}(r)$ decreases monotonically from $+\infty$ at $r=0$ to 0 at $r=\infty$ (Fig. 3-6). There is no minimum and the circular motion is not possible. For any (positive) value of E there is a minimal distance $r=r_{\min}$ (the distance of closest approach) which is the only solution of the equation $\tilde{U}(r)=E$, but there is no maximal distance. If the radial velocity is such that the particle approaches the centre, it will move with an orbit in which the value radius-vector r will decreased to $r_{\min}$ and after that it will increases to infinity. It is known (and later on will be proved) that such an orbit is a hyperbola (Fig. 3-6b). If the force is attractive $(C>0)$ the effective potential energy takes the form

$$\tilde{U}(r)=\frac{L^2}{2\tilde{m}r^2}+U(r)=\frac{L^2}{2\tilde{m}r^2}-\frac{C}{r}. \tag{3.35}$$

From the summation of the potential and centrifugal energy we obtain the curve $\tilde{U}(r)$, which possesses a minimum (Fig. 3-7). Equating the derivative $d\tilde{U}(r)/dr$ to zero, we determine r_0, at which $\tilde{U}(r)$ is minimal



a b

Figure 3-6. Repulsive central conservative force:

a) the effective potential energy is monotonically decreasing function;

b) the orbit of the particle is hyperbola; *b* is the impact factor; the angle χ, determining the deflection from the initial particle direction, is a scattering angle, $r_{\min}$ is the minimal distance of the centre to the orbit, which is symmetrical with respect to the line defining $r_{\min}$.

$$\frac{d\tilde{U}(r)}{dr} = -\frac{L^2}{2\tilde{m}r^3} + \frac{C}{r^2} = 0, \quad r_0 = \frac{L^2}{C\tilde{m}}, \quad \tilde{U}_{\min} = -\frac{C^2\tilde{m}}{2L^2} = \frac{U(r_0)}{2}. \qquad (3.36)$$

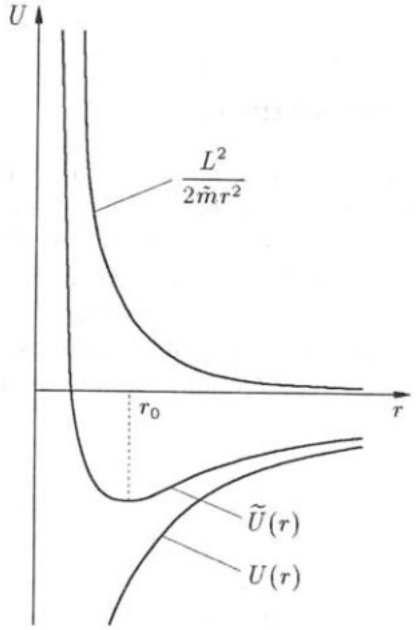


Figure 3-7. The effective potential energy $U(r)$ is a sum of the potential energy $U(r)$ and the centrifugal energy $L^2/2\tilde{m}r^2$, and it possesses a minimum $\tilde{U}_{\min} = U(r_0)/2$ at $r = r_0$.

The form of the curve $\tilde{U}(r)$ allows the determination of the character of the motion. We shall note that the curve is symmetrical with respect to the force centre *O* (Fig. 3-8a).

Figure 3-8. a) View of the effective potential energy $\tilde{U}(r)$ for bodies with equal reduced masses and angular moment **L**, but different energies *E*. The corresponding orbits are: $E > 0$ - a hyperbola, E=0 - a parabola, E<0 - an ellipse, $E=\tilde{U}_{\min}$ - a circle. All orbits go through the points D'' and D'''.

At $E > 0$ the motion is unbounded and the minimal distance to the centre *O* is $r_{\min} = r_A$. The orbit is a hyperbola.

At $E = 0$ the motion is unbounded and the minimal distance to the centre *O* is $r_{\min} = r_B$. The orbit is a parabola.

At $E < 0$ the motion is finite and holds in the region $r_{\min} \le r \le r_{\max}$, where $r_{\min} = r_C$ and $r_{\max} = r_{C'}$. The orbit is an ellipse.

At $E=\tilde{U}_{\min}$ the motion is finite with a constant minimal distance $r=r_0$. The orbit is a circle.

And now, let us show that the orbits are indeed such. In order to find the equation of the orbit, we have to eliminate the time from the constants of motion (3.28) and (3.32), and obtain the equation which relates r and φ. From (3.32) at $U(r)=-C/r$ we readily find

$$\dot{r}\equiv\frac{dr}{dt}=\sqrt{\frac{2}{\tilde{m}}\left(E+\frac{C}{r}-\frac{L^2}{2\tilde{m}r^2}\right)}. \tag{3.37}$$

We rewrite (3.28) as $dt=d\varphi\tilde{m}r^2/L$. Substituting it into the last equation, we get

$$\varphi=\int\frac{L/r^2}{\sqrt{2\tilde{m}\left(E+\frac{C}{r}\right)-\frac{L^2}{r^2}}}dr+\text{const.} \tag{3.38}$$

This equation relates r and φ, i.e., it is the equation of the orbit. We rewrite it in the form

$$\varphi=\int\frac{L/r^2}{\sqrt{2\tilde{m}E+\left(\frac{C\tilde{m}}{L}\right)^2-\left(-\frac{C\tilde{m}}{L}+\frac{L}{r}\right)^2}}dr+\text{const.} \tag{3.39}$$

and use the substitutions

$$2\tilde{m}E+\left(\frac{C\tilde{m}}{L}\right)^2=a^2,\quad \left(-\frac{C\tilde{m}}{L}+\frac{L}{r}\right)=u,\quad \frac{-Ldr}{r^2}=du. \tag{3.40}$$

This yields

$$\varphi=-\int\frac{du}{\sqrt{a^2-u^2}}=\arccos\frac{u}{a}+\text{const.} \tag{3.41}$$

Returning to the initial variable r we represent the relation between r and φ in the following form

$$\varphi = \arccos\frac{-\frac{C\tilde{m}}{L}+\frac{L}{r}}{\sqrt{2\tilde{m}E+\left(\frac{C\tilde{m}}{L}\right)^2}} = \arccos\frac{-1+\frac{L^2}{C\tilde{m}}\frac{1}{r}}{\sqrt{1+\left(\frac{2El^2}{C^2\tilde{m}}\right)^2}} = \arccos\frac{-1+\frac{p}{r}}{e}, \quad (3.42)$$

where we substituted $L^2/C\tilde{m} = r_0 \equiv p$ (see (3.36)) and $\sqrt{1+2L^2E/C_2\tilde{m}} = e$. We set the initial angle $\varphi_0 = 0$ (it determines the orientation of the orbit). The final form of the equation of the orbit is

$$p/r = 1 + e\cos\varphi. \quad (3.43)$$

This is the conventional representation of a conic section with the focus in the centre of the field; the quantity p is called the parameter of the orbit and *e* is called eccentricity. The parameter determines the size of the conic section and the eccentricity - its form. Depending on the values of *e* we obtain the four types of orbits:

$e > 1$ - a hyperbola,
$e = 1$ - a parabola,
$0 < e < 1$ - an ellipse,
$e = 0$ - a circle.

Taking into account (3.36) we can write for the eccentricity

$$e = \sqrt{1-\frac{E}{\tilde{U}_{\min}}} = \sqrt{1+\frac{E}{\left|\tilde{U}_{\min}\right|}}, \quad (3.44)$$

from where it is evident that the conditions for *e*, which determine different types of orbits precisely coincide with the conditions for *E* in Fig. 3-8.

We shall note that the obtained orbits are the orbits of a body moving around another immobile body. In order to find the real orbits around the centre of mass (Fig. 3-9), we have to return to the equations (3.10).

The radius-vector value of the reduced mass changes as (see (3.43))

$$r = \frac{p}{1+e\cos\varphi}. \quad (3.45)$$

According to (3.10), $\mathbf{r}_1$ has the same direction and its magnitude is

$$r_1 = \frac{p\,m_2}{m_1+m_2}\frac{1}{1+e\cos\varphi} = \frac{p_1}{1+e\cos\varphi}\,. \tag{3.46}$$

The particle moves along an ellipse and the direction of its radius-vector $\mathbf{r}_1$ coincides with the direction of **r.**

In any moment the vector $\mathbf{r}_2$ is opposite to **r** (3.10). Therefore, when **r** is oriented at an angle φ, the vector $\mathbf{r}_2$ is oriented at an angle $\varphi_2 = \pi + \varphi$. Then from (3.10) and (3.45) we get

$$r_2 = \frac{m_2}{m_1+m_2}\frac{1}{1+e\cos(\pi+\varphi)} = \frac{p_2}{1-e\cos\varphi}\,. \tag{3.47}$$

The orbit is also an ellipse and m_2 moves so that both particles are on the line passing through the centre of mass at any moment (Fig. 3-9).

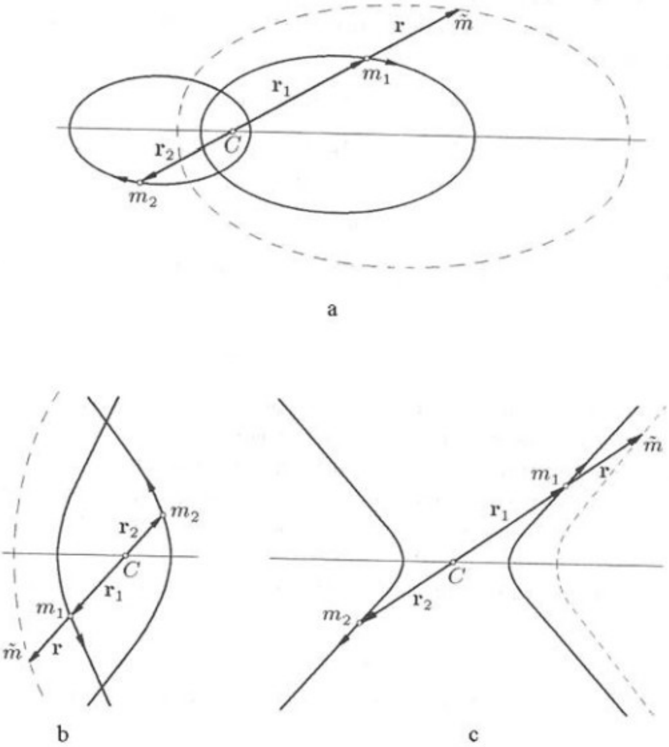

Figure 3-9. The orbits of particles with masses $\tilde{m}, m_1$ and m_2 $(m_1 : m_2 = 2:3)$ in CM-frame with an origin at the point *C*: a) ellipses (if $m_1 << m_2$, the ellipses are contained in one another!); b) hyperbolas (an attractive force); c) hyperbolas (a repulsive force). $\mathbf{r}_1$ and $\mathbf{r}_2$ are radius-vectors of the particles m_1 and m_2, **r** is a radius-vector of the reduced mass $\tilde{m}$.

D. Squeezed states

Squeezed states are important for precision measurements because they have the potential to get precision better than that set by the uncertainty principle. They are defined as quantum states which have **imbalanced** uncertainties between two conjugate variables, such as P and X in a harmonic oscillator. They must, of course, satisfy the uncertainty principle $\Delta P\,\Delta X \geq \hbar/2$. But if the signal is encoded in the X variable, one gains in signal-to-noise ratio (SNR) by having a smaller ΔX (if one is limited by quantum noise), while the increased uncertainty in P does not affect the measurement.

A **balanced** distribution of uncertainties means that the quantities ΔP and ΔX remain constant in time. In a harmonic oscillator this occurs when

$$\Delta P = \omega \Delta X$$

If the oscillator is prepared with a different distribution, then ΔP and ΔX will **oscillate**. For example, if ΔP is small and ΔX is big, the potential will cause the portions of the wavepacket at large X to accelerate so that ΔP will increase dramatically during the next quarter period. If one thinks *classically* of an ensemble of oscillators prepared at the bottom of the potential with a statistical distribution having a narrow ΔX and large ΔP, it is clear that they will rapidly spread due to their high initial velocity distribution. A quarter period later they will all have stopped, so ΔP will be a minimum; however, ΔX will be a maximum. This out-of-phase oscillation of uncertainties for conjugate variables is a hallmark of squeezed states; **note that it occurs at** 2ω.

1. Hyperbolic transform of the HO Hamiltonian

We now present a mathematical treatment of squeezing in a harmonic oscillator. The basic idea is to make a hyperbolic rotation of the operators a and $a^\dagger$ to b and $b^\dagger$, a transformation which distorts the $\widehat{X}\widehat{Y}$ phase space while preserving the commutator. A new Hamiltonian with the same form as the old one is obtained, which has number states which are called **generalized number** states. Investigation of the generalized vacuum* will show that this new state has squeezed uncertainties in the old quadrature variables, $\widehat{X}$ and $\widehat{Y}$.

The transformation to the generalized raising and lowering operators is

$$b \equiv a \cosh r - a^\dagger e^{2i\theta} \sinh r$$
$$b^\dagger \equiv a^\dagger \cosh r - a e^{-2i\theta} \sinh r$$

---

*The ground state is often called the vacuum state even for non-electromagnetic harmonic oscillators.

where r is the distortion parameter, stretching by a factor e^r along an axis at angle θ to the $\widehat{X}$ axis, and shrinking by a factor of e^{-r} perpendicular to this axis, while preserving the area. This is called a Bogoliubov transformation and corresponds closely to a rotation with hyperbolic trigonometric functions. It can be verified that the transformation preserves the commutator, $[b, b^\dagger] = 1$. Defining the unitary squeezing operator $S(r, \theta)$ which does this transformation, i.e. $SaS^{-1} = b$ or $Sa^\dagger S^{-1} = b^\dagger$, one finds

$$S = \exp\left[\frac{r}{2}\left(e^{-2i\theta}a^2 - e^{2i\theta}a^{\dagger 2}\right)\right]$$

Hence the transformed Hamiltonian $H' = SHS^{-1}$ is

$$H' = \hbar\omega(b^\dagger b + 1/2)$$

which has the same form as the original Hamiltonian H. The corresponding quanta are not eigensolutions of H, but correspond to a superposition state that reforms itself after one period, and which has squeezed variances that oscillate twice each period.

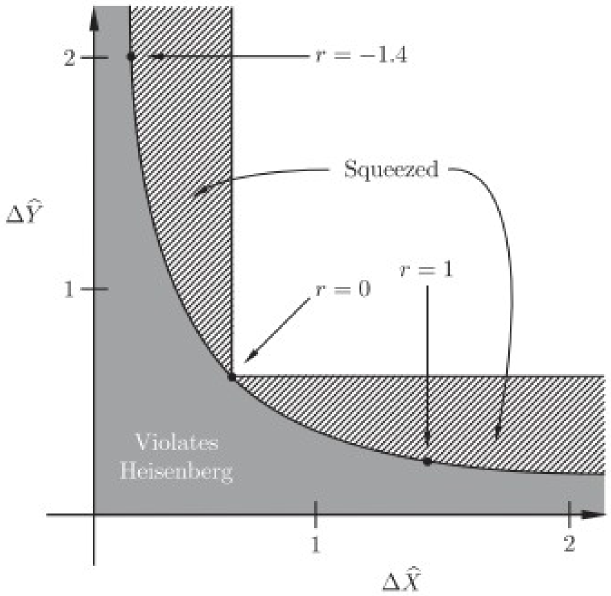

Figure 2.7: The solid line is the ideal squeezing achievable for various values of the squeeze parameter r (with $\theta = 0$). The shaded regions have significant but not ideal squeezing. The region with $\Delta\widehat{X} > 1/2$ and $\Delta\widehat{Y} > 1/2$ is unsqueezed.

In the following we specialize to $\theta = 0$ for clarity. The generalized quadrature operators are defined analogously to $\widehat{X}$ and $\widehat{Y}$

$$\widehat{X}_b = (b^\dagger + b)/2 = \widehat{X}e^{-r}$$
$$\widehat{Y}_b = i(b^\dagger + b)/2 = \widehat{Y}e^{r}$$

showing that the stretching occurs along the $\widehat{X}$ and $\widehat{Y}$ axes. The Hamiltonian then becomes

$$H' = \hbar\omega(\widehat{X}_b^2 + \widehat{Y}_b^2) = \hbar\omega(\widehat{X}^2 e^{-2r} + \widehat{Y}^2 e^{2r})$$

which may be interpreted in two ways.

(i) It may be written using the original position and momentum operators as

$$H' = \frac{P^2}{2me^{-2r}} + \frac{1}{2}me^{-2r}\omega^2 X^2$$

which is an oscillator with the same frequency but mass smaller by e^{2r}.

(ii) Alternatively, one can write

$$H' = \hbar\omega\left[e^{-2r}(\widehat{X}^2 + \widehat{Y}^2) + 2\widehat{Y}^2 \sinh 2r\right]$$

which is the HO Hamiltonian plus a nonlinear perturbation in $\widehat{Y}$.

2. Squeezed vacuum

Since both the commutator and the transformed Hamiltonian, when expressed in terms of b and $b^\dagger$, have exactly the same mathematical form as the HO Hamiltonian when a and $a^\dagger$ were used, the eigensolutions are the same. So we can immediately write down $\Delta\widehat{X}_b = \Delta\widehat{Y}_b = 1/2$. Hence

$$\langle 0_b|\Delta\widehat{X}|0_b\rangle = e^r/2$$
$$\langle 0_b|\Delta\widehat{Y}|0_b\rangle = e^{-r}/2$$

showing squeezing **but maintaining the uncertainty product**. Therefore the generalized vacuum state $|0_b\rangle$ represents a squeezed state with respect to the original oscillator.

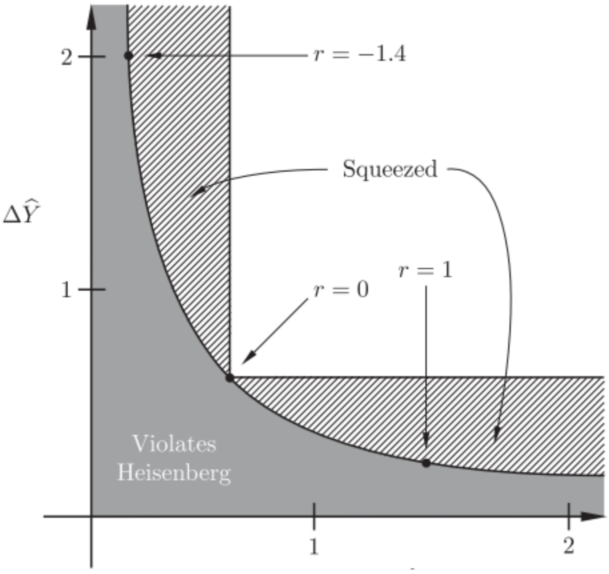

Figure 2.7: The solid line is the ideal squeezing achievable for various values of the squeeze parameter r (with $\theta = 0$). The shaded regions have significant but not ideal squeezing. The region with $\Delta\widehat{X} > 1/2$ and $\Delta\widehat{Y} > 1/2$ is unsqueezed.

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\varepsilon_0}, \qquad \nabla \cdot \mathbf{B} = 0, \qquad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \qquad \nabla \times \mathbf{B} = \varepsilon_0 \mu_0 \frac{\partial \mathbf{E}}{\partial t} + \mu_0 \mathbf{J},$$

similar to those of the experiment of Fizeau, that a shift will be observed in the fringe pattern by $2\Delta k$ fringes, where

$$\Delta k = \frac{2l}{\lambda}\frac{V}{c}(n^2 - 1). \tag{1.28}$$

Such a displacement would be easily observable given the speed of the Earth on its orbit, $V = 30$ km/s. For $\lambda = 400\,\text{nm}$, $l = 1$ m and $n = 1.333$, it would have been equal to $2\Delta k = 777$ fringes. No displacement of the fringe pattern was observed, however, during the rotation of the apparatus.

If we consider that the aether is partially dragged by the water in the pipe AB, the fact that a shift in the fringes does not occur on rotating the interferometer implies that the drag coefficient of the aether for the particular medium, f, is equal to

$$f = 1 - \frac{1}{n^2}. \tag{1.29}$$

This is exactly the relation suggested by Fresnel in the interpretation of Arago's observations. Hoek's experiment verifies Fresnel's formula, at least to an accuracy of first order in the ratio V/c.

The experiments just described are interpreted by the hypothesis that the aether is dragged by optical media. However, the dragging has the strange property of depending on the refractive index and therefore on the wavelength (color) of the light, something that is very difficult to justify. The question arises of whether it is possible to detect the motion of the Earth through the aether. Michelson, and later Michelson and Morley, tried to answer this question with their very important experiments. These experiments we will describe below.

1.9 Maxwell's Equations and the Wave Equation

The laws of electromagnetism are summarized in four equations, known as Maxwell's equations, which, in vacuum, take the form

$$\nabla \cdot \mathbf{E} = \frac{\rho}{\varepsilon_0}, \qquad \nabla \cdot \mathbf{B} = 0, \qquad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}, \qquad \nabla \times \mathbf{B} = \varepsilon_0 \mu_0 \frac{\partial \mathbf{E}}{\partial t} + \mu_0 \mathbf{J}, \tag{1.30}$$

where **E** and **B** are the electric and the magnetic fields, respectively, ρ is the volume charge density, **J** the current density, and ε_0 and μ_0 are the electric and the magnetic constants of vacuum, respectively. For more information on the notation, the reader is referred to Appendix 4 or to a book on vector analysis. The physical meaning of these equations is as follows:

$\nabla \cdot \mathbf{E} = \frac{\rho}{\varepsilon_0}$	This equation is derived from Coulomb's law and is a formulation of Gauss' law in differential form. The expression on the left is the flux of the electric field per unit of infinitesimal volume, which is shown to be proportional to the charge enclosed by this volume
$\nabla \cdot \mathbf{B} = 0$	This is Gauss' law for the magnetic field. Its flux per unit of infinitesimal volume is equated to zero due to the non-existence of magnetic monopoles, which would correspond to the positive and negative electric charges
$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t}$	This is the differential form of Faraday's law of electromagnetic induction or the fact that a magnetic field varying with time produces an electric field
$\nabla \times \mathbf{B} = \varepsilon_0 \mu_0 \frac{\partial \mathbf{E}}{\partial t} + \mu_0 \mathbf{J}$	The complete form of Ampère's law, according to which an electric field varying with time or an electric current, produce a magnetic field. The first term on the right is due to the displacement current, suggested by Maxwell

In vacuum and without free charges, $\rho = 0$, or currents, $\mathbf{J} = 0$, the equations simplify to

$$\nabla \cdot \mathbf{E} = 0 \qquad \nabla \cdot \mathbf{B} = 0 \qquad \nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t} \qquad \nabla \times \mathbf{B} = \varepsilon_0 \mu_0 \frac{\partial \mathbf{E}}{\partial t} \tag{1.31}$$

which may be combined to give an equation for the electric field **E**

$$\frac{\partial^2 \mathbf{E}}{\partial x^2} + \frac{\partial^2 \mathbf{E}}{\partial y^2} + \frac{\partial^2 \mathbf{E}}{\partial z^2} = \frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2} \qquad \text{or} \qquad \nabla^2 \mathbf{E} = \frac{1}{c^2}\frac{\partial^2 \mathbf{E}}{\partial t^2}, \tag{1.32}$$

and an equation for the magnetic field **B**

$$\frac{\partial^2 \mathbf{B}}{\partial x^2} + \frac{\partial^2 \mathbf{B}}{\partial y^2} + \frac{\partial^2 \mathbf{B}}{\partial z^2} = \frac{1}{c^2}\frac{\partial^2 \mathbf{B}}{\partial t^2} \qquad \text{or} \qquad \nabla^2 \mathbf{B} = \frac{1}{c^2}\frac{\partial^2 \mathbf{B}}{\partial t^2}. \tag{1.33}$$

These equations describe an electromagnetic wave moving with a speed of

$$c = \frac{1}{\sqrt{\varepsilon_0 \mu_0}} = 3 \times 10^8 \text{ m/s}, \tag{1.34}$$

which, it should be noted, does not depend on the speeds of the source of the wave or of the observer.

The flow of electromagnetic energy per unit time and per unit area, at a point, is given by the Poynting vector:

$$\mathbf{S} = \frac{1}{\mu_0}\mathbf{E} \times \mathbf{B}. \tag{1.35}$$

Necessary for the propagation of electromagnetic waves was considered to be the existence of the aether, although its properties were impossible to explain using mechanical models.

If, however, the ignorance concerning the structure of aether could be tolerated, there was another more serious problem with the laws of electromagnetism, which could not be ignored. Up till then, it was taken for granted that the laws of Physics satisfied the *Galilean principle of (mechanical) relativity*, i.e. they had the same form in all inertial frames of reference. As we have already demonstrated in the case of Newton's second law of motion, the transition from one inertial frame of reference to another, based on the Galilean transformation, leaves the law invariant. This is not true, however, for the laws of electromagnetism. Maxwell's equations and, thus, the wave equation also, are not invariant under the Galilean transformation. We will return to this subject in Chap. 9. For the moment, it is enough to mention that the transformation of the wave equation, Eq. (1.32), from one inertial frame of reference $S(x, y, z, t)$ to another, $S'(x', y', z', t')$, which is moving with a constant velocity $\mathbf{V}=V\hat{\mathbf{x}}$ relative to S, based on the Galilean transformation given by Eqs. (1.1), transforms the wave equation for the electric field to

$$\nabla'^2\mathbf{E} = \frac{1}{c^2}\frac{\partial^2\mathbf{E}}{\partial t'^2} + \frac{1}{c^2}\left(V^2\frac{\partial^2\mathbf{E}}{\partial x'^2} - 2V\frac{\partial^2\mathbf{E}}{\partial x'\partial t'}\right). \tag{1.36}$$

Obviously, it is not possible for the wave equation to have the form of Eq. (1.32) in one inertial frame of reference and the form of Eq. (1.36) in another, unless we accept that the frame of reference of the Earth is privileged, as it is from experiments in this frame of reference that the laws leading to the 'simple' form of Eq. (1.32) for the propagation of electromagnetic waves were found. Lorentz played the leading role in the adoption of the view that there is a stationary aether, which defines a privileged frame of reference in which the laws of electromagnetism assume their 'simpler' form. This would define Newton's absolute space, in which no fictitious forces appear. The question immediately arises of whether it is possible to detect experimentally the motion of a frame of reference, such as the Earth, relative to the aether.

1.10 The Experiment of Michelson and Morley

The most serious investigation of whether it is possible to detect the motion of the Earth relative to the aether, was performed by a series experiments by Michelson in 1881 [15] and, in an improved form, by Michelson and Morley in 1887 [16].

' "%, /< : * ; < !F

The reader must have noticed that, in the figures, the length of the train was taken as being different for the two observers: L_0 for the observer on the train and L for the observer on the platform. This is not accidental, as we will see in what follows. However, our ignorance, at present, of the exact lengths, does not influence the arguments developed above.

2.4 The Relativity of Time and Length

The invariance of the speed of light has very important consequences on time and length, as we will see in this section. We will begin by examining a quantity which remains invariant—any transverse dimension of a moving body. We will then examine the changes that have to be made to our understanding of time and length. We will return to these subjects in the next chapter, for a more general examination which will be based on the Lorentz transformation.

2.4.1 *The Invariance of the Dimensions of a Body Which Are Perpendicular to Its Velocity*

We examine two hollow cylinders, A and B (Fig. 2.6), which, when at rest, are identical, with radius r_0 and length L_0. Let the two cylinders be in relative motion with relative speed V, along their common axis. We will assume that to an observer a moving cylinder shrinks in directions perpendicular to its velocity, so that the radius of the moving cylinder is $r(V) < r_0$. The arguments that will follow would still hold had we assumed that the moving cylinder expands in directions perpendicular to its velocity. It will not affect our arguments, but we may assume that the

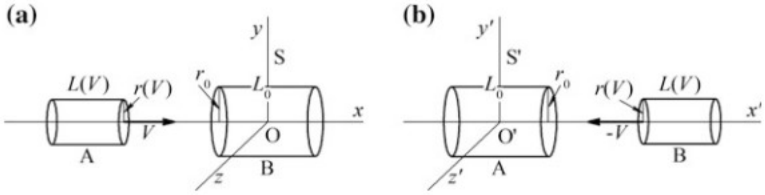

Fig. 2.6 Two identical *hollow cylinders*, A and B, in relative motion to each other, with their axes being coincident. The two cylinders, when at rest, have a radius equal to r_0. We will assume that when a cylinder is moving with speed V along its axis, its radius changes to $r(V)$ and its length to $L(V)$. Without loss of generality, we will take $r(V) < r_0$. In the reference frame of B, S, cylinder A moves with a velocity $\mathbf{V} = V\hat{\mathbf{x}}$ and its radius shrinks to $r(V)$. Cylinder A will, therefore, pass through cylinder B. In the reference frame of A, S′, cylinder B moves with a velocity $\mathbf{V} = -V\hat{\mathbf{x}}$ and its radius shrinks to $r(V)$. In the frame of reference S′, cylinder B will be expected to pass through cylinder A

length of the moving cylinder changes to $L(V)$. In the frame of reference S of cylinder B, cylinder A moves with a velocity $\mathbf{V} = V\hat{\mathbf{x}}$ and its radius is $r(V) < r_0$. Cylinder A will, therefore, pass through cylinder B (Fig. 2.6a).

In the frame of reference S′ of cylinder A, cylinder B moves with a velocity $\mathbf{V} = -V\hat{\mathbf{x}}$. Since space is isotropic, the radius of the moving cylinder will depend on its speed and so the radius of cylinder B will be $r(V) < r_0$. In this frame of reference, cylinder B is expected to pass through cylinder A (Fig. 2.6b).

Since it is impossible for both these predictions to be true, we must conclude that the transverse dimensions of a moving body do not change. This conclusion is purely a consequence of the non-existence of a privileged inertial frame of reference and the equivalence of all the inertial frames of reference.

2.4.2 The Relativity of Time

We will examine the rates of counting time by two clocks in relative motion to each other with a constant speed. The clocks we will consider work in the following way: Two mirrors, A and B in Fig. 2.7a, are at a distance D from each other. A very short light pulse (or a photon!) travels between the two mirrors. An observer, who is at rest relative to such a clock, will consider one unit of time, as measured by the clock, to be the time $T_0 = 2D/c$ needed for the pulse to travel from A to B and back to A, Fig. 2.7a.

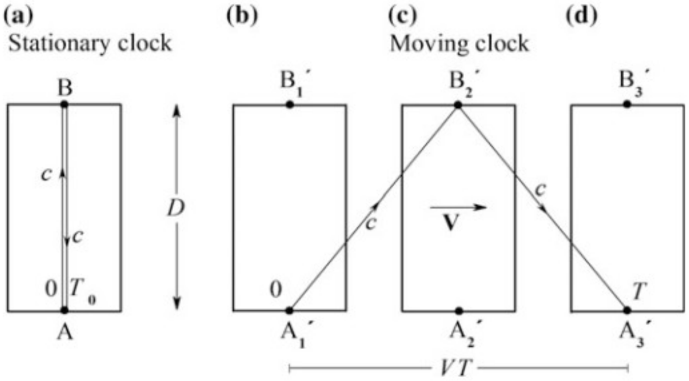

Fig. 2.7 *The dilation of time*. Two clocks, one at rest relative to an observer and one moving with a speed V relative to him. The operation of the clocks is based on a light pulse traveling between two mirrors, A and B (**a**). A unit of time (between two successive beats) is measured by the clock when the light pulse travels from A to B and then back to A. The moving clock moves in a direction perpendicular to the line joining the two mirrors of the clock at rest. The observer sees that the light in the moving clock has to cover a greater distance between successive beats than the light in the clock at rest relative to him (**b–d**). He therefore observes that more time passes between the successive beats of the moving clock as compared to the corresponding time in the clock at rest relative to him

Let now the observer who is at rest relative to a clock, observe another identical clock moving with speed V relative to himself in a direction perpendicular to the line AB, as shown in Figs. 2.7b, c, d. If for this observer the light needs a time T to travel from A to B and then back to A, the observer will see the moving clock shift by a distance $\mathrm{A}_1'\mathrm{A}_3' = VT$. The distance this observer will see as travelled by the light, always with a speed c, will be

$$cT = \mathrm{A}_1'\mathrm{B}_2'\mathrm{A}_3' = 2\sqrt{D^2 + (\mathrm{A}_1'\mathrm{A}_2')^2} = 2\sqrt{D^2 + (VT/2)^2}, \tag{2.1}$$

where we have taken into account the fact we have already proved, that the distance D does not change due to the motion of the clock. But $D = cT_0/2$ and, hence, substituting, we have

$$c^2T^2 = c^2T_0^2 + V^2T^2, \tag{2.2}$$

from which we find that

$$T = \frac{T_0}{\sqrt{1 - V^2/c^2}}, \tag{2.3}$$

which is a time greater than T_0.

It follows that the observer sees the moving clock count time at a slower rate than that of the clock at rest relative to himself. A clock at rest registers that the time needed for light to travel the path ABA, from one of its mirrors to the other and back (*proper time*), is smaller by a factor of $\sqrt{1 - V^2/c^2}$ compared to the time that the clock at rest registers as needed for the light to travel from one mirror of the moving clock to the other and back. This phenomenon is known as *dilation of time*. We will return to it in the next chapter and in the one after, where we will also examine its experimental verification.

As a numerical example, consider two identical clocks, one at rest in a frame of reference S and one at rest in a frame of reference S′. S′ moves relative to S with a speed $V = (4/5)c$, for which it is $\sqrt{1 - V^2/c^2} = 3/5$. Let the clock in S′ count a time interval $T_0 = 1$ unit of time, as its light pulse moves from mirror A to mirror B and back. To an observer relative to which this clock is moving, the time taken for this process to be completed in the moving clock will be $T = T_0\Big/\sqrt{1 - V^2/c^2} = 1/(3/5) = 5/3 = 1.67$ units of time. The observer in S sees that the moving clock needs 1.67 units of time to complete a procedure that corresponds to the counting of 1 unit of time. He, therefore, concludes that the moving clock is slow in counting time.

One may claim that the dilation of time was proved to apply only to a clock in which the light travels in a direction normal to the clock's velocity **V**. We will now show that the same result holds for a clock at any orientation relative to **V**. In Fig. 2.8 we have drawn two identical clocks, at rest in the same frame of reference,

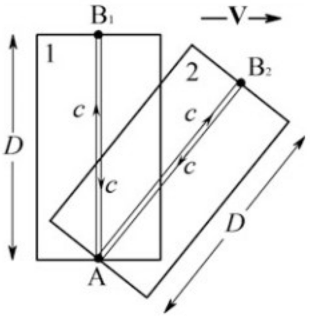

Fig. 2.8 Two identical clocks, similar to those of Fig. 2.7. The clocks are at rest in the same frame of reference and are oriented one (*1*) normal to the velocity **V** of an outside observer and the other (*2*) at some other angle. The two clocks emit their pulses of light at a common point, *A*

one (1) with its axis normal to **V** and the other (2) inclined at another angle. The two clocks have a common point of emission of their photons, A.

In the frame of reference of the clocks, if two pulses start simultaneously in the two clocks from point A, they will return to the same point simultaneously, because they have the same distance to travel, $2D$, and the speed of light is the same in all directions. In the frame of reference of the clocks, point A and the two pulses coincide initially and they will also coincide again when the two pulses return. It is obvious that the two pulses will also coincide at point A when viewed from any other frame of reference. If this did not happen, we might have a phenomenon, such as an interaction, in one frame of reference and not in the other. This would naturally be physically unacceptable. The two pulses will therefore coincide at point A in all other frames of reference as well. The rate at which the two clocks measure time will be the same and what is true for clock 1 will also be true for clock 2. The dilation of time is, therefore, the same, independent of the clock's orientation relative to the velocity **V**.

2.4.3 The Relativity of Length

We will now consider two clocks, similar to those of the previous section, one of which is at rest relative to some observer, and another that is moving with speed V, in a direction which is now parallel to the straight line AB between the two mirrors, as shown in Fig. 2.9. We must leave open the possibility that the length of the moving clock in the direction of its motion may differ from that of a stationary clock. If the distance measured by the observer between the two mirrors is L_0 for the clock at rest, let it be equal to L for the clock that moves relative to the observer (Fig. 2.9b, c, d).

In the clock which is at rest relative to the observer, light travels the distance ABA in time $T_0 = 2L_0/c$. We have already proved that the observer will measure

Fig. 2.9 *The contraction of length*. Two clocks, one at rest relative to an observer and one moving with a speed *V* relative to him. The operation of the clocks is based on a light pulse traveling between two mirrors, A and B. The moving clock moves in a direction parallel to the line AB. The distances travelled by the light in the one direction and in the other, as measured by the observer, are different in the moving clock

that for the moving clock the time needed for the light to travel from one mirror to the other and back is

$$T = \frac{T_0}{\sqrt{1 - V^2/c^2}}. \tag{2.4}$$

Alternatively, the observer sees light travel in the moving clock from mirror A to mirror B in time ΔT_+, covering a distance $\mathrm{A}_1'\mathrm{B}_2'$ (Fig. 2.9b, c) which, due to the motion of the clock with speed *V*, will be equal to

$$\mathrm{A}_1'\mathrm{B}_2' = c\Delta T_+ = L + \alpha_{12} = L + V\Delta T_+, \tag{2.5}$$

from which we find,

$$\Delta T_+ = \frac{L}{c - V}. \tag{2.6}$$

In the motion from mirror B to mirror A, light travels in time ΔT_- the distance $B_2'A_3'$ (Fig. 2.9c, d) which is equal to

$$B_2'A_3' = c\Delta T_- = L - \alpha_{23} = L - V\Delta T_-, \tag{2.7}$$

from which we find,

$$\Delta T_- = \frac{L}{c+V}. \tag{2.8}$$

The total time needed for light in the moving clock to travel from mirror A to mirror B and back is, according to the external observer,

$$T = \Delta T_+ + \Delta T_- = \frac{L}{c-V} + \frac{L}{c+V} = \frac{2cL}{c^2 - V^2} = \frac{2L/c}{1 - V^2/c^2}. \tag{2.9}$$

It follows from Eqs. (2.4) and (2.9) that

$$T = \frac{T_0}{\sqrt{1 - V^2/c^2}} = \frac{2L/c}{1 - V^2/c^2}. \tag{2.10}$$

However, it is $T_0 = 2L_0/c$, so that

$$\frac{2L_0/c}{\sqrt{1 - V^2/c^2}} = \frac{2L/c}{1 - V^2/c^2} \tag{2.11}$$

and, finally,

$$L = L_0\sqrt{1 - V^2/c^2}. \tag{2.12}$$

This equation describes the phenomenon of the *contraction of length*, according to which an observer finds that the length of a body that is moving with a speed V relative to him is, in the direction of motion of the body, smaller by a factor $\sqrt{1 - V^2/c^2}$ compared to the length of the same body in its own frame of reference, in which it is stationary (*rest length* or *proper length*). We will return to this effect in the next chapter.

2.5 The Inevitability of the Special Theory of Relativity

It is natural that someone learning about the Special Theory of Relativity for the first time will react to the proposition that he or she should accept the consequences of the theory. The conclusions of the theory are in direct contrast to our everyday experiences, given the limited means we have for acquiring them with our senses.

nonzero mass. For these, the $2S+1$ directions of polarization follow from the invariance of the theory with respect to proper Lorentz transformations. In particular, if the particle is at rest, the spin will have different orientations with respect to coordinate systems which have different orientations in space. Thus, the existence of all the states of polarization follow from the existence of one, if only the theory is invariant with respect to proper Lorentz transformations. For particles with zero rest-mass, there are only two states of polarization, and even the existence of the second one can be inferred only on the basis of reflection symmetry.

REFLECTION SYMMETRY

The problem and existence of reflection symmetry have been furthered in a brilliant way by recent theoretical and experimental research. There is nothing essential that can be added at present to the remarks and conjectures of Lee, Yang, and Oehme, and all that follows has been said, or at least implied, by Salam, Lee, Yang, and Oehme.[5] The sharpness of the break with past concepts is perhaps best illustrated by the cobalt experiment of Wu, Ambler, Hayward, Hoppes, and Hudson.

The ring current—this may be a permanent current in a superconductor—creates a magnetic field. The Co source is in the plane of the current and emits β particles (Fig. 3). The whole experimental arrangement, as shown in Fig. 3, has a symmetry plane and, if the principle of sufficient cause is valid, the symmetry plane should remain valid throughout the further fate of the system. In other words, since the right and left sides of the plane had originally identical properties, there is no sufficient reason for any difference in their properties at a later time. Nevertheless, the intensity of the β radiation is larger on one side of the plane than the other side. The situation is paradoxical no matter what the mechanism of the effect is—in fact, it is most paradoxical if one disregards its mechanism and theory entirely. If the experimental circumstances can be idealized as indicated, even the principle of sufficient cause seems to be violated.

It is natural to look for an interpretation of the experiment which avoids this very far-reaching conclusion and, indeed, there is such an interpretation.[6a] It is good to reiterate, however, that no matter what interpretation is adopted, we have to admit that the symmetry of the real world is smaller than we had thought. However, the symmetry may still include reflections.

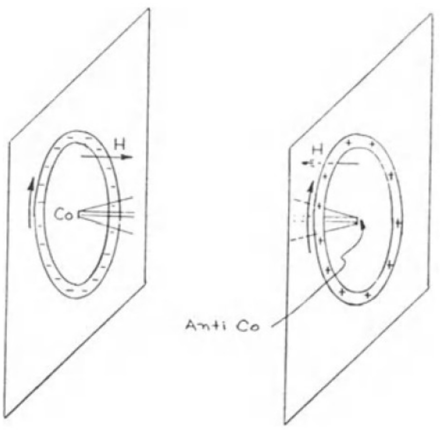

FIG. 3. The right side is the mirror image of the left side, according to the interpretation of the parity experiments[6a] which maintains the reflection as a symmetry element of all physical laws. It must be assumed that the reflection transforms matter into antimatter: the electronic ring current becomes a positronic ring current, the radioactive cobalt is replaced by radioactive anticobalt.

If it is true that a symmetry plane always remains a symmetry plane, the initial state of the Co experiment could not have contained a symmetry plane. This would not be the case if the magnetic vector were polar—in which case the electric vector would be axial. The charge density, the divergence of the electric vector, would then become a pseudoscalar rather than a simple scalar as in current theory. The mirror image of a negative charge would be positive, the mirror image of an electron a positron, and conversely. The mirror image of matter would be antimatter. The Co experiment, viewed through a mirror, would not present a picture contrary to established fact: it would present an experiment carried out with antimatter. The right side of Fig. 3 shows the mirror image of the left side. Thus, the principle of sufficient cause, and the validity of symmetry planes, need not be abandoned if one is willing to admit that the mirror image of matter is antimatter.

The possibility just envisaged would be technically described as the elimination of the operations of reflection and charge conjugation, as presently defined, as true symmetry operations. Their product would still be assumed to be a symmetry operation and proposed to be named, simply, reflection. A few further technical remarks are contained in Appendix II. The proposition just made has two aspects: a very appealing one, and a very alarming one.

Let us look first at the appealing aspect. Dirac has said that the number of elementary particles shows an alarming tendency of increasing. One is tempted to add to this that the number of invariance properties also showed a similar tendency. It is not equally alarming because, while the increase in the number of elementary particles complicates our picture of nature, that of the symmetry properties on the whole simplifies it. Nevertheless the clear correspondence between the invariance properties of the laws of nature, and the symmetry properties of space-time, was most clearly breached by the operation of charge conjugation. This postulated that the laws of nature remain the same if all positive charges are replaced by negative charges and vice versa, or more generally, if all particles are replaced by antiparticles. Reasonable as this postulate appears to us, it corresponds to no symmetry of the space-time continuum. If the preceding interpretation of the Co experiments should be sustained, the correspondence between the natural symmetry elements of space-time, and the invariance properties of the laws of nature, would be restored. It is true that the role of the planes of reflection would not be that to which we are accustomed—the mirror image of an electron would become a positron—but the mirror image of a sequence of events would still be a possible sequence of events. This possible sequence of events would be more difficult to realize in the actual physical world than what we had thought, but it would still be possible.

---

[5] Lee, Yang, and Oehme, Phys. Rev. **106**, 340 (1957).

[6a] The interpretation referred to has been proposed independently by numerous authors, including A. Salam, Nuovo cimento **5**, 229 (1957); L. Landau, Nuclear Phys. **3**, 127 (1957); H. D. Smyth and L. Biedenharn (personal communication). Dr. S. Deser has pointed out that the "perturbing possibility" was raised already by Wick, Wightman, and Wigner [Phys. Rev. **88**, 101 (1952)] but was held "remote at that time." Naturally, the apparent unanimity of opinion does not prove its correctness.

The restoration of the correspondence between the natural symmetry properties of space-time on one hand, and the laws of nature on the other hand, is the appealing feature of the proposition. It has, actually, two alarming features. The first of these is that a symmetry operation is, physically, so complicated. If it should turn out that the operation of time inversion, as we now conceive it, is not a valid symmetry operation (e.g., if one of the experiments proposed by Treiman and Wyld gave a positive result) we could still maintain the validity of this symmetry operation by reinterpreting it. We could postulate, for instance, that time inversion transforms matter into *meta*-matter which will be discovered later when higher energy accelerators will become available. Thus, maintaining the validity of symmetry planes forces us to a more artificial view of the concept of symmetry and of the invariance of the laws of physics.

The other alarming feature of our new knowledge is that we have been misled for such a long time to believe in more symmetry elements than actually exist. There was ample reason for this and there was ample experimental evidence to believe that the mirror image of a possible event is again a possible event with electrons being the mirror images of electrons and not of positrons. Let us recall in this connection first how the concept of parity, resulting from the beautiful though almost forgotten experiments of Laporte,[6] appeared to be a perfectly valid concept in spectroscopy and in nuclear physics. This concept could be explained very naturally as a result of the reflection symmetry of space-time, the mirror image of electrons being electrons and not positrons. We are now forced to believe that this symmetry is only approximate and the concept of parity, as used in spectroscopy and nuclear physics, is also only approximate. Even more fundamentally, there is a vast body of experimental information in the chemistry of optically active substances which are mirror images of each other and which have optical activities of opposite direction but exactly equal strength. There is the fact that molecules which have symmetry planes are optically inactive; there is the fact of symmetry planes in crystals.[7] All these facts relate properties of right-handed matter to left-handed *matter*, not of right-handed matter to left-handed *antimatter*. The new experiments leave no doubt that the symmetry plane in this sense is not valid for all phenomena, in particular not valid for β decay, that if the concept of symmetry plane is at all valid for all phenomena, it can be valid only in the sense of converting matter into antimatter.

Furthermore, the old-fashioned type of symmetry plane is not the only symmetry concept that is only approximately valid. Charge conjugation was mentioned before, and we are remainded also of isotopic spin, of the exchange character, that is multiplet system, for electrons and also of nuclei which latter holds so accurately that, in practice, parahydrogen molecules can be converted into orthohydrogen molecules only by first destroying them.[8] This approximate validity of laws of symmetry is, therefore, a very general phenomenon—it may be *the* general phenomenon. We are reminded of Mach's axiom that the laws of nature depend on the physical content of the universe, and the physical content of the universe certainly shows no symmetry. This suggests—and this may also be the spirit of the ideas of Yang and Lee—that all symmetry properties are only approximate. The weakest interaction, the gravitational force, is the basis of the distinction between inertial and accelerated coordinate systems, the second weakest known interaction, that leading to β decay, leads to the distinction between matter and antimatter. Let me conclude this subject by expressing the conviction that the discoveries of Wu, Ambler, Hayward, Hoppes, and Hudson,[9] and of Garwin, Lederman, and Weinreich[10] will not remain isolated discoveries. More likely, they herald a revision of our concept of invariance and possibly of other concepts which are even more taken for granted.

QUANTUM LIMITATIONS OF THE CONCEPTS OF GENERAL RELATIVITY

The last remarks naturally bring us to a discussion of the general theory of relativity. The main premise of this theory is that coordinates are only labels to specify space-time points. Their values have no particular significance unless the coordinate system is somehow anchored to events in space-time.

Let us look at the question of how the equations of the general theory of relativity could be verified. The purpose of these equations, as of all equations of physics, is to calculate, from the knowledge of the present, the state of affairs that will prevail in the future. The quantities describing the present state are called initial conditions; the ways these quantities change are called the equations of motion. In relativity theory, the state is described by the metric which consists of a network of points in space-time, that is a network of events, and the distances between these events. If we wish to translate these general statements into something concrete, we must decide what events are, and how we measure distances between *events*. The metric in the general theory of relativity is a metric in space-time, its elements are distances between space-time points, not between points in ordinary space.

The events of the general theory of relativity are coincidences, that is, collisions between particles. The founder of the theory, when he created this concept, had evidently macroscopic bodies in mind. Coincidences, that is, collisions between such bodies, are immediately observable. This is not the case for elementary particles; a collision between these is something much more evanescent. In fact, the point of a collision between two elementary particles can be closely localized in space-time only in case of high-energy collisions. (See Appendix III.) This shows that the establishment of a close network of points in space-time requires a reasonable energy density, a dense forest of world lines wherever the network is to be established. However, it is not necessary to discuss this in detail because the measurement of the distances between the points of the network gives more stringent requirements than the establishment of the network.

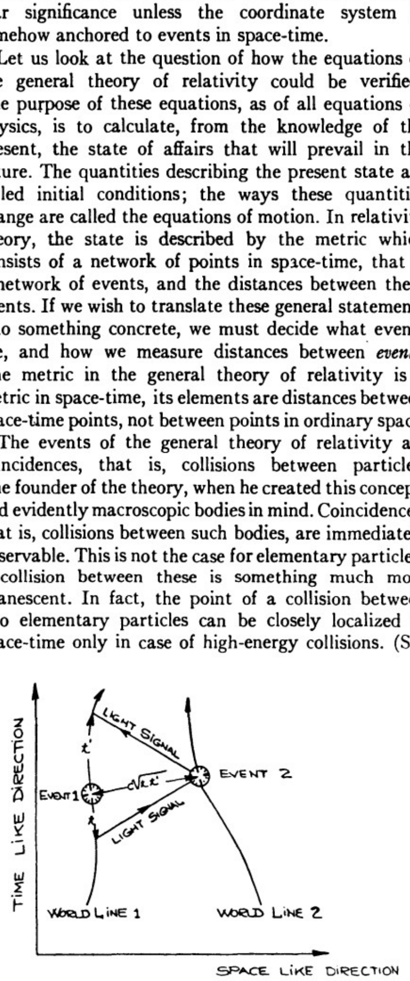

FIG. 4. Measurement of space-like distances by means of a clock. It is assumed that the metric tensor is essentially constant within the space-time region contained in the figure. The space-like distance between events 1 and 2 is measured by means of the light signals which pass through event 2 and a geodesic which goes through event 1. Explanation in Appendix IV.

It is often said that the distances between events must be measured by yardsticks and rods. We found that measurements with a yardstick are rather difficult to describe and that their use would involve a great deal of unnecessary complications. The yardstick gives the distance between events correctly only if its marks coincide with the two events simultaneously from the point of view of the rest-system of the yardstick. Furthermore, it is hard to image yardsticks as anything but macroscopic objects. It is desirable, therefore, to reduce all measurements in space-time to measurements by clocks. Naturally, one can measure by clocks directly only the distances of points which are in time-like relation to each other. The distances of events which are in space-like relation, and which would be measured more naturally by yardsticks, will have to be measured, therefore, indirectly.

It appears, thus, that the simplest framework in space-time, and the one which is most nearly microscopic, is a set of clocks, which are only slowly moving with respect to each other, that is, with world lines which are approximately parallel. These clocks tick off periods and these ticks form the network of events which we wanted to establish. This, at the same time, establishes the distance of those adjacent points which are on the same world line.

Figure 4 shows two world lines and also shows an event, that is, a tick of the clock, on each. The figure shows an artifice which enables one to measure the distance of space-like events: a light signal is sent out from the first clock which strikes the second clock at event 2. This clock, in turn, sends out a light signal which strikes the first clock at time t' after the event 1. If the first light signal had to be sent out at time t before the first event, the calculation given in Appendix IV shows that the space-like distance of events 1 and 2 is the geometric average of the two measured time-like distances t and t'. This is then a way to measure distances between space-like events by clocks instead of yardsticks.

It is interesting to consider the quantum limitations on the accuracy of the conversion of time-like measurements into space-like measurements, which is illustrated in Fig. 4. Naturally, the times t and t' will be well defined only if the light signal is a short pulse. This implies that it is composed of many frequencies and, hence, that its energy spectrum has a corresponding width. As a result, it will give an indeterminate recoil to the second clock, thus further increasing the uncertainty of its momentum. All this is closely related to Heisenberg's uncertainty principle. A more detailed calculation[1] shows that the added uncertainty is of the same order of magnitude as the uncertainty inherent in the nature of the best clock that we could think of, so that the conversion of time-like measurements into space-like measurements is essentially free.

We finally come to the discussion of one of the principal problems—the limitations on the accuracy of the clock. It led us to the conclusion that the inherent limitations on the accuracy of a clock of given weight and size, which should run for a period of a certain length, are quite severe. In fact, the result in summary is that a clock is an essentially nonmicroscopic object. In particular, what we vaguely call an atomic clock, a single atom which ticks off its periods, is surely an idealization which is in conflict with fundamental concepts of measurability. This part of our conclusions can be considered to be well established. On the other hand, the actual formula which will be given for the limitation of the accuracy of time measurement, a sort of uncertainty principle, should be considered as the best present estimate.

Let us state the requirements as follows. The watch shall run T seconds, shall measure time with an accuracy of $T/n=t$, its linear extension shall not exceed l, its mass shall be below m. Since the pointer of the watch must be able to assume n different positions, the system will have to run, in the course of the time T, over at least n orthogonal states. Its state must, therefore, be the superposition of at least n stationary states. It is clear, furthermore, that unless its total energy is at least $\hbar/t$, it cannot measure a time interval which is smaller than t. This is equivalent to the usual uncertainty principle. These two requirements follow directly from the basic principles of quantum theory; they are also the requirements which could well have been anticipated. A clock which conforms with these postulates is, for instance, an oscillator, with a period which is equal to the running time of the clock, if it is with equal probabilty in any of the first n quantum states. Its energy is about n times the energy of the first excited state. This corresponds to the uncertainty principle with the accuracy t as time uncertainty. Broadly speaking, the clock is a very soft oscillator, the oscillating particle moving very slowly and with a rather large amplitude. The pointer of the clock is the position of the oscillating particle.

The clock of the preceding paragraph is still very light. Let us consider, however, the requirement that the linear dimensions of the clock be limited. Since there is little point in dealing with the question in great generality, it may as well be assumed here that the linear dimension shall correspond to the accuracy in time. The requirement $l\approx ct$ increases the mass of the clock by n^3 which may be a very large factor indeed:

$$m>n^3\hbar t/l^2\approx n^3\hbar/c^2t. \tag{2}$$

For example, a clock, with a running time of a day and an accuracy of 10^{-8} second, must weigh almost a gram—for reasons stemming solely from uncertainty principles and similar considerations.

So far, we have paid attention only to the physical dimension of the clock and the requirement that it be able to distinguish between events which are only a distance t apart on the time scale. In order to make it usable as part of the framework which was described before, it is necessary to *read* the clock and to start it. As part of the framework to map out the metric of space-time, it must either register the readings at which it receives impulses, or transmit these readings to a part of space outside the region to be mapped out. This point was already noted by Schrödinger.[11] However, we found it reassuring that, in the most interesting case in which $l=ct$, that is, if space and time inaccuracies are about equal, the reading requirement introduces only an insignificant numerical factor but does not change the form of the expression for the minimum mass of the clock.

The arrangement to map the metric might consist, therefore, of a lattice of clocks, all more or less at rest with respect to each other. All these clocks can emit light signals and receive them. They can also transmit their reading at the time of the receipt of the light signal to the outside. The clocks may resemble oscillators, well in the nonrelativistic region. In fact, the velocity of the oscillating particle is about n times smaller than the velocity of light where n is the ratio of the *error* in the time measurement, to the *duration* of the whole interval to be measured. This last quantity is the spacing of the events on the time axis, it is also the distance of the clocks from each other, divided by the light velocity. The world lines of the clocks from the dense forest which was mentioned before. Its branches suffuse the region of space-time in which the metric is to be mapped out.

We are not absolutely convinced that our clocks are the best possible. Our principal concern is that we have considered only one space-like dimension. One consequence of this was that the oscillator had to be a one-dimensional oscillator. It is possible that the size limitation does not increase the necessary mass of the clock to the same extent if use is made of all three spatial dimensions.

The curvature tensor can be obtained from the metric in the conventional way, if the metric is measured with sufficient accuracy. It may be of interest, nevertheless, the describe a more direct method for measuring the curvature of space. It involves an arrangement, illustrated in Fig. 5, which is similar to that used for obtaining the metric. There is a clock, and a mirror, at such a distance from each other that the curvature of space can be assumed to be constant in the interven-

---

[11] E. Schrödinger, Ber. Preuss. Akad. Wiss. phys.-math. Kl. 1931, 238.

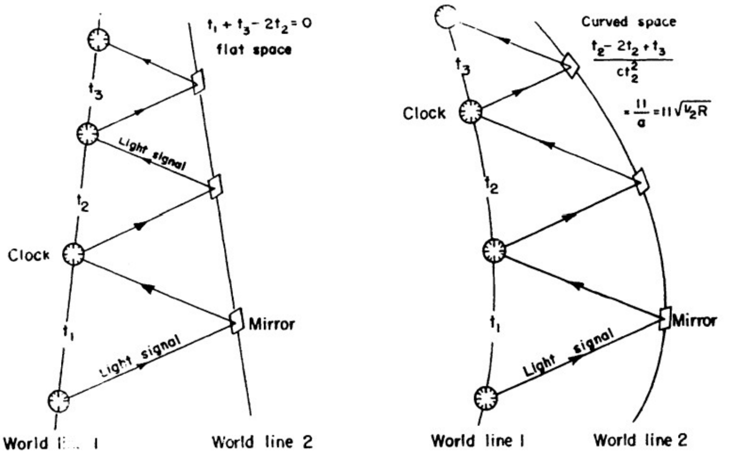

FIG. 5. Direct measurement of the curvature by means of a clock and mirror. Only one space-like dimension is considered and the curvature assumed to be constant within the space-time region contained in the figure. The explanation is given in Appendix V.

ing region. The two clocks need not be at rest with respect to each other, in fact, such a requirement would involve additional measurements to verify it. If the space is flat, the world lines of the clocks can be drawn straight. In order to measure the curvature, a light signal is emitted by the clock, and this is reflected by the mirror. The time of return is read on the clock—it is t_1—and the light signal returned to the mirror. The time which the light signal takes on its second trip to return to the clock is denoted by t_2. The process is repeated a third time, the duration of the last roundtrip denoted by t_3. As shown in Appendix V, the radius of curvature, a, and the relevant component R_{0101} of the Riemann tensor are given by

$$\frac{t_1 - 2t_2 + t_3}{t_2^2} = \frac{11}{a} = 11(\tfrac{1}{2}R_{0101})^{\frac{1}{2}}. \tag{2}$$

If classical theory would be valid also in the microscopic domain, there would be no limit on the accuracy of the measurement indicated in Fig. 5. If h is infinitely small, the time intervals t_1, t_2, t_3 can all be measured with arbitrary accuracy with an infinitely light clock. Similarly, the light signals between clock and mirror, however short, need carry only an infinitesimal amount of momentum and thus deflect clock and mirror arbitrarily little from their geodesic paths. The quantum phenomena considered before force us, however, to use a clock with a minimum mass if the measurement of the time intervals is to have a given accuracy. In the present case, this accuracy must be relatively high unless the time intervals t_1, t_2, t_3 are of the same order of magnitude as the curvature of space. Similarly, the deflection of clock and mirror from their geodesic paths must be very small if the result of the measurement is to be meaningful. This gives an effective limit for the accuracy with which the curvature can be measured. The result is, as could be anticipated, that the curvature at a *point* in space-time cannot be measured at all; only the average curvature over a finite region of space-time can be obtained. The error of the measurement[1] is inversely proportional to the two-thirds power of the area available in space-time, that is, the area around which a vector is carried, always parallel to itself, in the customary definition of the curvature. The error is also proportional to the cube root of the Compton wavelength of the clock. Our principal hesitation in considering this result as definitive is again its being based on the consideration of only one space-like dimension. The possibilities of measuring devices, as well as the problems, may be substantially different in three-dimensional space.

Whether or not this is the case, the essentially nonmicroscopic nature of the general relativistic concepts seems to us inescapable. If we look at this first from a practical point of view, the situation is rather reassuring. We can note first, that the measurement of electric and magnetic fields, as discussed by Bohr and Rosenfeld,[12] also requires macroscopic, in fact *very* macroscopic, equipment and that this does not render the electromagnetic field concepts useless for the purposes of quantum electrodynamics. It is true that the measurement of space-time curvature requires a finite region of space and there is a minimum for the mass, and even the mass uncertainty, of the measuring equipment. However, numerically, the situation is by no means alarming. Even in interstellar space, it should be possible to measure the curvature in a volume of a light second or so. Furthermore, the mass of the clocks which one will wish to employ for such a measurement is of the order of several micrograms so that the finite mass of elementary particles does not cause any difficulty. The clocks will contain many particles and there is no need, and there is not even an incentive, to employ clocks which are lighter than the elementary particles. This is hardly surprising since the mass which can be derived from the gravitational constant, light velocity, and Planck's constant, is about 20 micrograms.

---

[12] N. Bohr and L. Rosenfeld, Kgl. Danske Videnskab. Selskab Mat.-fys. Medd. 12, No. 8 (1933). See also further literature quoted in L. Rosenfeld's article in *Niels Bohr and the Development of Physics* (Pergamon Press, London, 1955).

It is well to repeat, however, that the situation is less satisfactory from a more fundamental point of view. It remains true that we consider, in ordinary quantum theory, position operators as observables without specifying what the coordinates mean. The concepts of quantum field theories are even more weird from the point of view of the basic observation that only coincidences are meaningful. This again is hardly surprising because even a 20-microgram clock is too large for the measurement of atomic times or distances. If we analyze the way in which we "get away" with the use of an absolute space concept, we simply find that we do not. In our experiments we surround the microscopic objects with a very macroscopic framework and observe *coincidences* between the particles emanating from the microscopic system, and parts of the framework. This gives the collision matrix, which is observable, and observable in terms of macroscopic coincidences. However, the so-called observables of the microscopic system are not only not observed, they do not even appear to be meaningful. There is, therefore, a boundary in our experiments between the region in which we use the quantum concepts without worrying about their meaning in face of the fundamental observation of the general theory of relativity, and the surrounding region in which we use concepts which are meaningful also in the face of the basic observation of the general theory of relativity but which cannot be described by means of quantum theory. This appears most unsatisfactory from a strictly logical standpoint.

APPENDIX I

It will be necessary, in this appendix, to compare various states of the same physical system. These states will be generated by looking at the same state—the standard state—from various coordinate systems. Hence every Lorentz frame of reference will define a state of the system—the state as which the standard state appears from the point of view of this coordinate system. In order to define the standard state, we choose an arbitrary but fixed Lorentz frame of reference and stipulate that, in this frame of reference, the particle in the standard state be at rest and its spin (if any) have the direction of the z axis. Thus, if we wish to have a particle moving with a velocity v in the z direction and with a spin also directed along this axis, we look at the particle in the standard state from a coordinate system moving with the velocity v in the $-z$ direction. If we wish to have a particle at rest but with its spin in the yz plane, including an angle α with the z axis, we look at the standard state from a coordinate system the y and z axes of which include an angle α with the y and z axes of the coordinate system in which the standard state was defined. In order to obtain a state in which both velocity and spin have the aforementioned direction (i.e., a direction in the yz plane, including the angles α and $\frac{1}{2}\pi-\alpha$ with the y and z axes), we look at the standard state from the point of view of a coordinate system in which the spin of the standard state is described as this direction and which is moving in the opposite direction.

Two states of the system will be identical only if the Lorentz frames of reference which define them are identical. Under this definition, the relations which will be obtained will be valid independently of the properties of the particle, such as spin or mass (as long as the mass in nonzero so that the standard state exists). Two states will be approximately the same if the two Lorentz frames of reference which define them can be obtained from each other by a very small Lorentz transformation, that is, one which is near the identity. Naturally, all states of a particle which can be compared in this way are related to each other inasmuch as they represent the same standard state viewed from various coordinate systems. However, we shall have to compare only these states.

Let us denote by $A(0,\varphi)$ the matrix of the transformation in which the transformed coordinate system moves with the velocity $-v$ in the z direction where $v=c\tanh\varphi$

$$A(0,\varphi)=\begin{Vmatrix} 1 & 0 & 0 \\ 0 & \cosh\varphi & \sinh\varphi \\ 0 & \sinh\varphi & \cosh\varphi \end{Vmatrix}. \tag{1.1}$$

Since the x axis will play no role in the following consideration, it is suppressed in (1.1) and the three rows and the three columns of this matrix refer to the y', z', ct' and to the y, z, ct axes, respectively. The matrix (1.1) characterizes the state in which the particle moves with a velocity v in the direction of the z axis and its spin is parallel to this axis.

Let us further denote the matrix of the rotation by an angle φ in the yz plane by

$$R(\vartheta)=\begin{Vmatrix} \cos\vartheta & \sin\vartheta & 0 \\ -\sin\vartheta & \cos\vartheta & 0 \\ 0 & 0 & 1 \end{Vmatrix}. \tag{1.2}$$

We refer to the direction in the yz plane which lies between the y and z axes and includes an angle ϑ with the z axis as the direction ϑ. The coordinate system which moves with the velocity $-v$ in the ϑ direction is obtained by the transformation

$$A(\vartheta,\varphi)=R(\vartheta)A(0,\varphi)R(-\vartheta). \tag{1.3}$$

In order to obtain a particle which moves in the direction ϑ and is polarized in this direction, we first rotate the coordinate system counterclockwise by ϑ (to have the particle polarized in the proper direction) and impart it then a velocity $-v$ in the ϑ direction. Hence, it is the transformation

$$T(\vartheta,\varphi)=A(\vartheta,\varphi)R(\vartheta) = \left\|\begin{matrix} \cos\vartheta & \sin\vartheta\cosh\varphi & \sin\vartheta\sinh\varphi \\ -\sin\vartheta & \cos\vartheta\cosh\varphi & \cos\vartheta\sinh\varphi \\ 0 & \sinh\varphi & \cosh\varphi \end{matrix}\right\| \tag{1.4}$$

which characterizes the aforementioned state of the particle. It follows from (1.3) that

$$T(\vartheta,\varphi)=R(\vartheta)A(0,\varphi)=R(\vartheta)T(0,\varphi) \tag{1.5}$$

so that the same state can be obtained also by viewing the state characterized by (1.1) from a coordinate system that is rotated by ϑ. It follows that the statement "velocity and spin are parallel" is invariant under rotations. This had to be expected.

If the state generated by $A(0,\varphi)=T(0,\varphi)$ is viewed from a coordinate system which is moving with the velocity u in the direction of the z axis, the particle will still appear to move in the z direction and its spin will remain parallel to its direction of motion, unless $u>v$ in which case the two directions will become antiparallel, or unless $u=v$ in which case the statement becomes meaningless, the particle appearing to be at rest. Similarly, the other states in which spin and velocity are parallel, i.e., the states generated by the transformations $T(\vartheta,\varphi)$, remain such states if viewed from a coordinate system moving in the direction of the particle's velocity, as long as the coordinate system is not moving faster than the particle. This also had to be expected. However, if the state generated by $T(0,\varphi)$ is viewed from a coordinate system moving with velocity $v'=c\tanh\varphi'$ in the $-y$ direction, spin and velocity will *not* appear parallel any more, *provided the velocity v of the particle is not close to light velocity.* This last proviso is the essential one; it means that the high velocity states of a particle for which spin and velocity are parallel (i.e., the states generated by (1.4) with a large φ) are states of this same nature if viewed from a coordinate system which is not moving too fast in the direction of motion of the particle itself. In the limiting case of the particle moving with light velocity, the aforementioned states become invariant under *all* Lorentz transformations.

Let us first convince ourselves that if the state (1.1) is viewed from a coordinate system moving in the $-y$ direction, its spin and velocity no longer appear parallel. The state in question is generated from the normal state by the transformation

$$A(\tfrac{1}{2}\pi,\varphi')A(0,\varphi) = \left\|\begin{matrix} \cosh\varphi' & \sinh\varphi\sinh\varphi' & \cosh\varphi\sinh\varphi' \\ 0 & \cosh\varphi & \sinh\varphi \\ \sinh\varphi' & \sinh\varphi\cosh\varphi' & \cosh\varphi\cosh\varphi' \end{matrix}\right\|. \tag{1.6}$$

This transformation does not have the form (1.4). In order to bring it into that form, it has to be multiplied on the right by $R(\epsilon)$, i.e., one has to rotate the spin ahead of time. The angle ϵ is given by the equation

$$\tan\epsilon=\frac{\tanh\varphi'}{\sinh\varphi}=\frac{v'}{v}(1-v^2/c^2)^{\frac{1}{2}} \tag{1.7}$$

and is called the angle between spin and velocity. For $v\ll c$, it becomes equal to the angle which the ordinary resultant of two perpendicular velocities, v and v', includes with the first of these. However, ϵ becomes very small if v is close to c; in this case it is hardly necessary to rotate the spin away from the z axis before giving it a velocity in the z direction. These statements express the identity

$$A(\tfrac{1}{2}\pi,\varphi')A(0,\varphi)R(\epsilon)=T(\vartheta,\varphi'') \tag{1.8}$$

which can be verified by direct calculation. The right side represents a particle with parallel spin and velocity, the magnitude and direction of the latter being given by the well-known equations

$$v''=c\tanh\varphi''=(v^2+v'^2-v^2v'^2/c^2)^{\frac{1}{2}} \tag{1.8a}$$

and

$$\tan\vartheta=\frac{\sinh\varphi'}{\tanh\varphi}=\frac{v'}{v(1-v'^2/c^2)^{\frac{1}{2}}}. \tag{1.8b}$$

Equation (1) given in the text follows from (1.7) and (1.8b) for $v\sim c$.

The fact that the states $T(\vartheta,\varphi)\psi_0$ (where ψ_0 is the standard state and $\varphi\gg 1$) are approximately invariant under all Lorentz transformations is expressed mathematically by the equations,

$$R(\vartheta)\cdot T(0,\varphi)\psi_0=T(\vartheta,\varphi)\psi_0, \tag{1.5a}$$

$$A(0,\varphi')\cdot T(0,\varphi)\psi_0=T(0,\varphi'+\varphi)\psi_0, \tag{1.9a}$$

and

$$A(\tfrac{1}{2}\pi,\varphi')\cdot T(0,\varphi)\psi_0\rightarrow T(\vartheta,\varphi'')\psi_0, \tag{1.9b}$$

which give the wave function of the state $T(0,\varphi)\psi_0$, as viewed from other Lorentz frames of reference. Naturally, similar equations apply to all $T(\alpha,\varphi)\psi_0$. In particular, (1.5a) shows that the states in question are invariant under rotations of the coordinate system, (1.9a) that they are invariant with respect to Lorentz transformations with a velocity not too high *in* the direction of motion (so that $\varphi'+\varphi\gg 0$, i.e., φ' not too large a negative number). Finally, in order to prove (1.9b), we calculate the transition probability between the states $A(\frac{1}{2}\pi,\varphi')\cdot T(0,\varphi)\psi_0$ and $T(\vartheta,\varphi'')\psi_0$ where ϑ and φ'' are given by (1.8a) and (1.8b). For this, (1.8) gives

$$\begin{aligned}(A(\tfrac{1}{2}\pi,\varphi')\cdot T(0,\varphi)\psi_0,\ T(\vartheta,\varphi'')\psi_0) &= (T(\vartheta,\varphi'')R(\epsilon)^{-1}\psi_0,\ T(\vartheta,\varphi'')\psi_0) \\ &= (R(\epsilon)^{-1}\psi_0,\psi_0)\rightarrow(\psi_0,\psi_0).\end{aligned}$$

The second line follows because $T(\vartheta,\varphi'')$ represents a coordinate transformation and is, therefore, unitary. The last member follows because $\epsilon\rightarrow 0$ as $\varphi\rightarrow\infty$ as can be seen from (1.7) and $R(0)=1$.

The preceding consideration is not fundamentally new. It is an elaboration of the facts (a) that the subgroup of the Lorentz group which leaves a null-vector invariant is different from the subgroup which leaves a time like vector invariant[4] and (b) that the representations of the latter subgroup decompose into one dimensional representations if this subgroup is "contracted" into the subgroup which leaves a null-vector invariant.[13]

APPENDIX II

Before the hypothesis of Lee and Yang[14] was put forward, it was commonly assumed that there are, in addition to the symmetry operations of the proper Poincaré group, three further independent symmetry operations. The proper Poincaré group consists of all Lorentz transformations which can be continuously obtained from unity and all translations in space-like and time-like directions, as well as the products of all these transformations. It is a continuous group; the Lorentz transformations contained in it do not change the direction of the time axis and their determinant is 1. The three independent further operations which were considered to be rigorously valid, were

Space inversion I, that is, the transformation $x, y, z\rightarrow -x, -y, -z$, without changing particles into antiparticles.

Time inversion T, more appropriately described by Lüders[15] as *Umkehr der Bewegungsrichtung*, which replaces every velocity by the opposite velocity so that the position of the particles at $+t$ becomes the same as it was, without time inversion, at $-t$. The time inversion T (also called time inversion of the first kind by Lüders[16]) does not convert particles into antiparticles either.

Charge conjugation C, that is, the replacement of positive charges by negative charges and more generally of particles by antiparticles, without changing either the position or the velocity of these particles.[17] The quantum-mechanical expressions for the symmetry operations I and C are unitary, that for T is antiunitary.

The three operations I, T, C, together with their products TC (Lüders' time inversion of the second kind), IC, IT, ITC and the unit operation form a group and the products of the elements of this group with those of the proper Poincaré group were considered to be the symmetry operations of all laws of physics. The suggestion given in the text amounts to eliminating the operations I and C separately while continuing to postulate their product IC as symmetry operation. The discrete symmetry group then reduces to the unit operation plus

$$IC,\ T,\ \text{and}\ ICT, \tag{2.1}$$

and the total symmetry group of the laws of physics becomes the proper Poincaré group plus its products with the elements (2.1). This group is isomorphic (essentially identical) with the unrestricted Poincaré group, i.e., the product of *all* Lorentz transformations with all the displacements in space and time. The quantum mechanical expressions for the operations of the proper Lorentz group and its product with IC are unitary, those for T and ICT (as well as for their products with the elements of the proper Poincaré group) antiunitary. Lüders[16] has pointed out that, under certain very natural conditions, ICT belongs to the symmetry group of every *local* field theory.

APPENDIX III

Let us consider, first, the collision of two particles of equal mass m in the coordinate system in which the average of the sum of their momenta is zero. Let us assume that, at a given time, the wave function of both particles is confined to a distance l in the direction of their average velocity with respect to each other. If we consider only this space-like direction, and the time axis, the area in space-time in which the two wave functions will substantially overlap is [see Fig. 6(a)]

$$a=l^2/2v_{\min}, \tag{3.1}$$

where $v_{\min}$ is the lowest velocity which occurs with substantial probability in the wave packets of the colliding particles. Denoting the average momentum by $\bar{p}$ (this has the same value for both particles) the half-width of the momentum distribution by δ, then $v_{\min}=(\bar{p}-\delta)(m^2+(\bar{p}-\delta)^2/c^2)^{-\frac{1}{2}}$. Since l cannot be below h/δ, the area (3.1) is at least

$$\frac{\hbar^2}{2\delta^2}\,\frac{(m^2+(\bar{p}-\delta)^2/c^2)^{\frac{1}{2}}}{\bar{p}-\delta}. \tag{3.1a}$$

(Note that the area becomes infinite if $\delta>\bar{p}$.) The

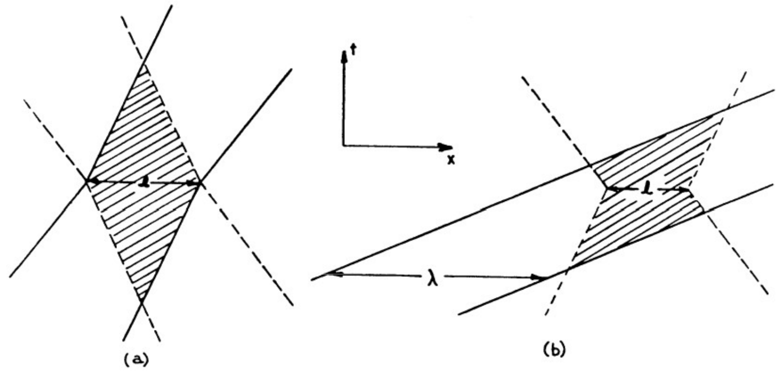

FIG. 6. (a) Localization of a collision of two particles of equal mass. The full lines indicate the effective boundaries of the wave packet of the particle traveling to the right, the broken lines the effective boundaries of the wave packet of the particle traveling to the left. The collision can take place in the shaded area of space-time. (b) Localization of a collision between a particle with finite mass and a particle with zero rest-mass. The full lines, at a distance λ apart in the x direction, indicate the boundary of the particle with zero rest-mass, the broken lines apply to the wave packet of the particle with nonzero rest-mass. The collision can take place in the shaded area.

minimum of (3.1a) is, apart from a numerical factor

$$a_{\min}\approx\frac{\hbar^2}{\bar{p}^3}(m^2+\bar{p}^2/c^2)^{\frac{1}{2}}\approx\frac{\hbar^2c}{E^{\frac{3}{2}}(E+mc^2)^{\frac{1}{2}}},\qquad(3.2)$$

where E is the kinetic energy (total energy minus rest-energy) of the particles.

The kinetic energy E permits the contraction of the wave functions of the colliding particles also in directions perpendicular to the average relative velocity, to an area $\hbar^2c^2/E(E+2mc^2)$. Hence, again apart from a numerical factor, the volume to which the collision can be confined in four dimensional space-time becomes

$$V_{\min}=\frac{\hbar^4c^3}{E^{\frac{5}{2}}(E+mc^2)^{\frac{3}{2}}}.\qquad(3.3)$$

E is the average kinetic energy of the particles in the coordinate system in which their center of mass is, on the average, at rest. Equation (3.3) is valid apart from a numerical constant of unit order of magnitude but this constant depends on E/mc^2.

Let us consider now the opposite limiting case, the collision of a particle with finite rest-mass m with a particle with zero rest-mass. The collision is viewed again in the coordinate system in which the average linear momentum is zero. In this case, one will wish to confine the wave function of the particle with finite rest-mass to a narrower region l than that of the particle with zero rest-mass. If the latter is confined to a region of thickness λ, [see Fig. 6(b)], its momentum and energy uncertainties will be at least $\hbar/\lambda$ and $\hbar c/\lambda$ and these expressions will also give, apart from a numerical factor, the average values of these quantities. Hence $\bar{p}\approx\hbar/\lambda$. The kinetic energy of the particle with finite restmass will be of the order of magnitude

$$\tfrac{1}{2}(m^2c^4+(\bar{p}+\hbar/l)^2c^2)^{\frac{1}{2}}+\tfrac{1}{2}(m^2c^4+(\bar{p}-\hbar/l)^2c^2)^{\frac{1}{2}}-mc^2,\qquad(3.4)$$

since $\hbar/l$ is the momentum uncertainty. Since $l\leq\lambda$, one can neglect $\bar{p}$ in (3.4) if one is interested only in the order of magnitude. This gives for the total kinetic energy,

$$E\approx\hbar c/\lambda+(m^2c^4+\hbar^2c^2/l^2)^{\frac{1}{2}}-mc^2,\qquad(3.5)$$

while the area in Fig. 6(b) is of the order of magnitude

$$a=(\lambda/c)(l+\Delta v\lambda/c),\qquad(3.6)$$

where Δv is the uncertainty in the velocity of the second particle

$$\Delta v=\frac{\bar{p}+\hbar/l}{(m^2+(\bar{p}+\hbar/l)^2/c^2)^{\frac{1}{2}}}-\frac{\bar{p}-\hbar/l}{(m^2+(\bar{p}-\hbar/l)^2/c^2)^{\frac{1}{2}}}.\qquad(3.6a)$$

This can again be replaced by $(\hbar/l)(m^2+\hbar^2/l^2c^2)^{-\frac{1}{2}}$.

For given E, the minimum value of a is assumed if the *kinetic energies* of the two particles are of the same order of magnitude. The two terms of (3.6) then become about equal and $l/\lambda\approx(E/(m+E))^{\frac{1}{2}}$. The minimum value of a, as far as order of magnitude is concerned, is again given by (3.2). Similarly, (3.3) also remains valid if one of the two particles has zero rest-mass.

The two-dimensional case becomes simplest if both particles have zero rest-mass. In this case the wave packets do not spread at all and (3.2) can be immediately seen to be valid. In the four-dimensional case, (3.3) again holds. However, its proof by means of explicitly constructed wave packets (rather than reference to the uncertainty relations) is by no means simple. It requires wave packets which are confined in every direction, do not spread too fast and progress essentially only into one half space (one particle going toward the right, the other toward the left). The construction of such wave packets will not be given in detail. They are necessary to prove (3.2) and (3.3) more rigorously also in the case of finite masses; the preceding proofs, based on the uncertainty relations show only that a and v cannot be *smaller* than the right sides of the corresponding equations. It is clear, in fact, that the limits given by (3.2) and (3.3) would be very difficult to realize, except in the two-dimensional case and for the collision of two particles with zero restmass. In all other cases, the relatively low values of $a_{\min}$ and $V_{\min}$ are predicated on the assumption that the wave packets of the colliding particles are so constituted that they assume a minimum size at the time of the collision. At any rate, (3.2) and (3.3) show that only collisions with a relatively high collision energy, and high energy uncertainty, can be closely localized in space-time.

APPENDIX IV

Let us denote the components of the vector from event 1 to event 2 by x_i, the components of the unit vector along the world line of the first clock at event 1 by e_i. The components of the first light signal are x_i+te_i, that of the second light signal $x_i-t'e_i$. Hence

$$g^{ik}(x_i+te_i)(x_k+te_k)=0 \tag{4.1}$$

$$g^{ik}(x_i-t'e_i)(x_k-t'e_k)=0. \tag{4.2}$$

Elimination of the linear terms in t and t' by multiplication of (4.1) with t' and (4.2) with t and addition gives

$$2g^{ik}x_ix_k+2tt'g^{ik}e_ie_k=0. \tag{4.3}$$

Since e is a unit vector $g^{ik}e_ie_k=1$ and (4.3) shows that the space-like distance between points 1 and 2 is $(tt')^{\frac{1}{2}}$.

APPENDIX V

Since the measurement of the curvature, described in the text, presupposes *constant curvature* over the space-time domain in which the measurement takes place, we use a space with constant curvature, or, rather, part of a space with constant curvature, to carry out the calculation. We consider only one spatial dimension, i.e., a two-dimensional deSitter space. This will be embedded, in the usual way, in a three-dimensional space[18] with coordinates x, y, τ. The points of the deSitter space then form the hyperboloid

$$x^2+y^2-\tau^2=a^2, \tag{5.1}$$

where a is the "radius of the universe." As coordinates of a point we use x and y, or rather the corresponding

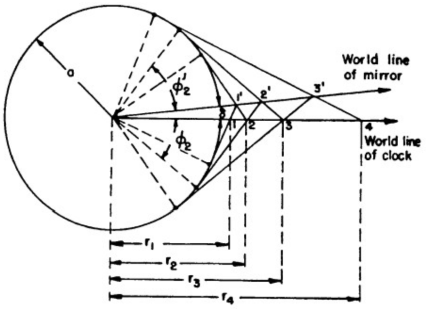

FIG. 7. Analysis of the experiment of Fig. 5. The figure represents a view of the hyperboloid of deSitter space, viewed along its axis. Every point of the plane which is outside the circle corresponds to two points of the deSitter world with one spatial dimension, those with oppositely equal times. The first light signal is emitted at 1, reaches the mirror at 1′, and returns to the clock at 2. The paths of the second and third light signals are 22′3 and 33′4.

polar angles r, ϕ. The metric form in terms of these is

$$ds^2=\frac{a^2}{r^2-a^2}dr^2-r^2d\phi^2. \tag{5.2}$$

Two points of deSitter space correspond to every pair r, ϕ (except $r=a$): those with positive and negative $\tau=(r^2-a^2)^{\frac{1}{2}}$. This will not lead to any confusion as all events take place at positive τ. The null lines (paths of light signals) are the tangents to the $r=a$ circle.

The experiment described in the text can be analyzed by means of Fig. 7. For the sake of simplicity, the clock and mirror are assumed to be "at rest," i.e., their world lines have constant polar angles which will be assumed as 0 and δ, respectively. The first light signal travels from 1 to 1′ and back to 2, the second from 2 to 2′ and back to 3, the third from 3 to 3′ and back to 4. The polar angle of the radius vector which is perpendicular to the first part 22′ of the world line of the second light signal is denoted by ϕ_2. The construction of Fig. 7 shows that angle ϕ_2' which the world line of the mirror includes with the radius vector perpendicular to the second part 2′3 of the second light signal's world line is

$$\phi_2'=\phi_2+\delta. \tag{5.3}$$

The angles ϕ_1, ϕ_1', ϕ_3, ϕ_3' have similar meanings; they are not indicated in the figure in order to avoid overcrowding. For reasons similar to those leading to (5.3), we have

$$\phi_3=\phi_2'+\delta=\phi_2+2\delta \tag{5.3a}$$

$$\phi_1=\phi_2-2\delta \tag{5.3b}$$

$$\phi_4=\phi_3+2\delta=\phi_2+4\delta. \tag{5.3c}$$

---

[18] See, e.g., H. P. Robertson, Revs. Modern Phys. 5, 62 (1933).

The radial coordinates of the points 1, 2, 3, 4 are denoted by r_1, r_2, r_3, r_4

$$r_i = a/\cos\phi_i. \tag{5.4}$$

The proper time t, registered by the clock, can be obtained by integrating the metric form (5.2) along the world line $\phi=0$ of the clock

$$t = a\ln[r+(r^2-a^2)^{\frac{1}{2}}]. \tag{5.5}$$

Hence, the traveling time t_2 of the second light signal becomes

$$t_2 = a\ln\frac{r_3+(r_3^2-a^2)^{\frac{1}{2}}}{r_2+(r_2^2-a^2)^{\frac{1}{2}}} = a\ln\frac{\cos\phi_2(1+\sin\phi_3)}{\cos\phi_3(1+\sin\phi_3)}. \tag{5.6}$$

Similar expressions apply for the traveling times of the first and third light signals; all ϕ can be expressed by means of (5.3a), (5.3b), (5.3c) in terms of ϕ_2 and δ. This allows the calculation of the expression (3). For small δ, one obtains

$$\frac{t_1-2t_2+t_3}{t_2^2} \approx \frac{11}{a}, \tag{5.7}$$

and Riemann's invariant $R=2/a^2$ is proportional to the square of (5.7). In particular, it vanishes if the expression (3) is zero.

CHAPTER 2

DEFORMED MINKOWSKI SPACE-TIME

As is well known, the Minkowski metric[a]

$$g = \mathrm{diag}(1, -1, -1, -1) \tag{2.1}$$

is a generalization of the Euclidean metric $\epsilon = \mathrm{diag}(1, 1, 1)$. On the basis of the discussion of Chap. 1, we assume that the metric describes, in an effective way, the interaction, and that there exist interactions more general than the electromagnetic ones (which, as well known, are long-range and derivable from a potential).

The simplest generalization of the space-time metric which accounts for such more general properties of interactions is provided by a *deformation*, η, of the Minkowski metric (2.1), defined as[3–5]

$$\eta = \mathrm{diag}(b_0^2, -b_1^2, -b_2^2, -b_3^2). \tag{2.2}$$

Of course, from a formal point of view metric (2.2) is not new at all. Deformed Minkowski metrics of the same type have already been proposed in the past[6–9] in various physical frameworks, starting from Finsler's generalization of Riemannian geometry[6] to Bogoslowsky's anisotropic space-time[7] to Santilli's isotopic Minkowski space.[8] A phenomenological deformation of the type (2.2) was also obtained by Nielsen and Picek[9] in the context of the electroweak theory. Moreover, although for quite different purposes, "quantum" deformed Minkowski spaces have been also considered in the context of quantum groups.[10] Leaving to later considerations the true specification of the exact meaning of the deformed metric (2.2) in our framework, let us right now stress two basic points.

---

[a] Throughout this book, lower Latin indices take the values $\{1, 2, 3\}$ and label spatial dimensions, whereas lower Greek indices vary in the range $\{0, 1, 2, 3\}$, with 0 referring to the time dimension. Ordinary 3-vectors are denoted in boldface. Moreover, we adopt the signature $(+, -, -, -)$, and employ the notation "*ESCon*" ("*ESCoff*") to mean that the Einstein sum convention on repeated indices is (is not) used.

1. Firstly, metric (2.2) is supposed to hold at a *local* (and not global) scale, *i.e.* to be valid not everywhere, but only in a suitable (local) space-time region (characteristic of both the system and the interaction considered). We shall therefore refer often to it as a "*topical*" deformed metric.

   In the present case, the term "local" must be understood in the sense that a deformed metric of the kind (2.2) describes the geometry of a 4-dimensional variety attached at a point x of the standard Minkowski space-time, in the same way as a local Lorentz frame is associated (as a tangent space) to each point of the (globally Riemannian) space of Einstein's GR. Another example, on some respects more similar to the present formalism, is provided by a space-time endowed with a vector fibre-bundle structure, where a (maximally symmetric) Riemann space with constant curvature is attached at each point x.[11]
2. Secondly, metric (2.2) is regarded to play a *dynamical role*. So, in order to comply with the solidarity principle, we assume that the parameters b_μ ($\mu = 0, 1, 2, 3$) are, in general, real and positive functions of a given set of observables $\{\mathcal{O}\}$ characterizing the system (in particular, of its total energy, as specified later):

   $$\{b_\mu\} = \{b_\mu(\{\mathcal{O}\})\} \in R_0^+, \quad \forall \{\mathcal{O}\}. \tag{2.3}$$

   The set $\{\mathcal{O}\}$ represents therefore, in general, a set of non-metric variables $(\{x_{n.m.}\})$.

Equation (2.2) therefore becomes:

$$\begin{aligned}\eta_{\mu\nu} &= \eta_{\mu\nu}(\{\mathcal{O}\})\\ &= \mathrm{diag}(b_0^2(\{\mathcal{O}\}), -b_1^2(\{\mathcal{O}\}), -b_2^2(\{\mathcal{O}\}), -b_3^2(\{\mathcal{O}\})) \overset{\text{ESC off}}{=}\\ &= \delta_{\mu\nu}(\delta_{\mu 0} b_0^2(\{\mathcal{O}\}) - \delta_{\mu 1} b_1^2(\{\mathcal{O}\}) - \delta_{\mu 2} b_2^2(\{\mathcal{O}\}) - \delta_{\mu 3} b_3^2(\{\mathcal{O}\})).\end{aligned} \tag{2.4}$$

However, for the moment the deformation of the Minkowski space will be discussed only from a formal point of view, by disregarding the problem of the observables on which the coefficients b_μ actually depend (it will be faced in Chap. 3).

Notice that the first point, *i.e.* the assumed local validity of (2.2), differentiates this approach from those based on Finsler's geometry or from the Bogoslowski's one (which, at least in their standard meaning, do consider deformed metrics at a *global* scale), and makes it similar, on some aspects, to the philosophy and methods of the isotopic generalizations of Minkowski spaces. However, it is well known that Lie-isotopic theories rely in an essential way, from the mathematical standpoint, on (and are strictly characterized by) the very existence of the so-called isotopic unit.[8] In the following, such a formal device will not be exploited (because unessential on all respects), so that the present formalism is not an isotopic one. Moreover, from a physical point of view, the isotopic formalism is expected to apply only to strong interactions.[8] On the contrary, it will be assumed that the (effective) representation of interactions through the deformed metric (2.2) does hold for *all* kinds of interactions (at least for their nonlocal component). In spite of such basic differences this formalism shares some common formal results — as we shall see in the following — with isotopic relativity (like the mathematical expression of the generalized Lorentz transformations).

It is now possible to define a generalized ("*deformed*") Minkowski space $\tilde{M}(x, \eta(\{\mathcal{O}\}))$ with the same local coordinates x of M (the four-vectors of the usual Minkowski space), but with metric given by the metric tensor η (2.4). The generalized interval in $\tilde{M}$ is therefore given by ($x^\mu = (x^0, x^1, x^2, x^3) = (ct, x, y, z)$, with c being the usual light speed in vacuum) (ESC on)[3–5]:

$$\begin{aligned} &ds^{\tilde{2}}(\{\mathcal{O}\}) \\ &\quad\equiv b_0^2(\{\mathcal{O}\})c^2dt^2 - b_1^2(\{\mathcal{O}\})(dx^1)^2 - b_2^2(\{\mathcal{O}\})(dx^2)^2 - b_3^2(\{\mathcal{O}\})(dx^3)^2 \\ &\quad= \eta_{\mu\nu}(\{\mathcal{O}\})dx^\mu dx^\nu = dx * dx. \end{aligned} \tag{2.5}$$

The last step in (2.5) defines the scalar product $*$ in the deformed Minkowski space $\tilde{M}$. Moreover, according to (2.5), we shall use the following notation for the deformed square norm of a four-vector:

$$|x|_*^2 \equiv x * x = \eta_{\mu\nu}(\{\mathcal{O}\})x^\mu x^\nu = x^{\tilde{2}}. \tag{2.5$'$}$$

In order to evidence some preliminary implications of metric (2.4), let us consider (for simplicity sake and without loss of generality) an isotropic 3-dimensional space, *i.e.*

$$b_1^2(\{\mathcal{O}\}) = b_2^2(\{\mathcal{O}\}) = b_3^2(\{\mathcal{O}\}) \equiv b^2(\{\mathcal{O}\}) \tag{2.6}$$

so that the corresponding deformed metric reads

$$\begin{aligned} \eta_{\mu\nu_{\mathrm{ISO}}}(\{\mathcal{O}\}) &= \mathrm{diag}(b_0^2(\{\mathcal{O}\}), -b^2(\{\mathcal{O}\}), -b^2(\{\mathcal{O}\}), -b^2(\{\mathcal{O}\})) \stackrel{\text{ESC off}}{=} \\ &= \delta_{\mu\nu}[\delta_{\mu 0}b^2(\{\mathcal{O}\}) - (\delta_{\mu 1} + \delta_{\mu 1} + \delta_{\mu 1})b^2(\{\mathcal{O}\})]. \end{aligned} \tag{2.7}$$

One gets, for null separation $ds^{\tilde{2}} = 0$:

$$\begin{aligned} ds^{\tilde{2}}(\{\mathcal{O}\}) = 0 &\Leftrightarrow b_0^2(\{\mathcal{O}\})c^2dt^2 - b^2(\{\mathcal{O}\})[(dx^1)^2 + (dx^2)^2 + (dx^3)^2] = 0 \\ &\Leftrightarrow \frac{(dx^2 + dy^2 + dz^2)}{dt^2} = c^2\frac{b_0^2(\{\mathcal{O}\})}{b^2(\{\mathcal{O}\})}. \end{aligned} \tag{2.8}$$

From Eq. (2.8) it is easily seen that the *maximal causal speed* in the generalized Minkowski space is given by:

$$u = \frac{b_0(\{\mathcal{O}\})}{b(\{\mathcal{O}\})}c. \tag{2.9}$$

It is worth noticing that a similar result (namely, a "maximum attainable speed", *a priori* different for different physical processes) was also obtained by Coleman and Glashow,[12] in the framework of a discussion of possible effects breaking Lorentz invariance (essentially on a local scale).

Let us remark that u depends explicitly on the metric parameters b_μ, which are *a priori* different for every physical system. However, since the deformation of the metric represents, on average, the effects of the nonlocal interactions involved, it is expected that physical systems with the same kind of interactions (besides the electromagnetic ones) are described by metric parameters of the same order of magnitude (or, at least, this holds true for the ratio b_0/b). In this sense it is possible to refer to u as a "speed of interaction", rather than "speed of the physical system" considered (of course, at the same energy scale).

In Eq. (2.9), the value of u is parametrized in terms of c, and depends on the physical system (and its interactions). Moreover, it is

$$u \gtreqless c \Leftrightarrow \frac{b_0(\{\mathcal{O}\})}{b(\{\mathcal{O}\})} \gtreqless 1. \tag{2.10}$$

In other words, there may be maximal causal speeds either *subluminal* or *superluminal*, depending on the interaction considered.

It is worth to recall that the deformation of the metric, resulting in the interval (2.5), represents a geometrization of a suitable space-time region (corresponding to the physical system considered) that describes, in the average, the effect of nonlocal interactions on a test particle. It is clear that there exist infinitely many deformations of the Minkowski space (precisely, ∞^4), corresponding to the different possible choices of the parameters b_μ, *a priori* different for each physical system.

Moreover, since the usual, "flat" Minkowski metric g (2.1) is related in an essential way to the electromagnetic interaction, we shall always mean in the following — unless otherwise specified — that electromagnetic interactions imply the presence of a fully Minkowskian metric. Actually, as it will be seen, a deformed metric of the type (2.7) is required if one wants to account for possible nonlocal electromagnetic effects (like those occurring in the superluminal wave propagation in waveguides: see Chap. 7).

CHAPTER 4

GENERALIZED PRINCIPLE OF RELATIVITY AND LORENTZ TRANSFORMATIONS

4.1. Deformed Special Relativity

In order to develop the relativity theory in a deformed Minkowski space-time, one has to suitably generalize and clarify the basic concepts which are at the very foundation of SR.

Let us first of all define a “topical inertial frame”:

(i) a *topical “inertial” frame* (TIF) is a reference frame in which space-time is homogeneous, but space is not necessarily isotropic.

Then, a “*generalized principle of relativity*” (or “*principle of metric invariance*”) can be stated as follows:

(ii) all physical measurements within every topical “inertial” frame must be carried out via the *same* metric.

We shall call “*Deformed Special Relativity*” (DSR) the generalization of SR based on the above two postulates, and whose space-time structure is given by the deformed Minkowski space $\tilde{M}$ introduced in Chap. 2.

4.2. Deriving the Deformed Lorentz Transformations

It follows from the above points (i), (ii) that the transformation equations connecting topical “inertial” frames, *i.e.* the generalized Lorentz transformations, are those which leave invariant the deformed metric when passing from a topical “inertial” frame K, to another frame K', moving with constant velocity with respect to K. Then, physical laws are to be covariant with respect to such generalized transformations.

In other words, the generalized Lorentz transformations are the isometries of the deformed Minkowski space $\tilde{M}$. We shall refer to them in the following as *deformed Lorentz transformations* (DLT). Their explicit form can be derived by the same procedure followed in order to find the Lorentz transformations in the usual Minkowski space.

Consider two TIF, K and K'; by definition, the DLT's leave invariant the deformed interval (2.5), *i.e.*

$$b_0^2c^2t^2 - b_1^2x^2 - b_2^2y^2 - b_3^2z^2 = b_0^2c^2t'^2 - b_1^2x'^2 - b_2^2y'^2 - b_3^2z'^2. \tag{4.1}$$

Moreover, it can be assumed, without loss of generality, that the frames K and K' are in standard configuration (*i.e.* their spatial frames coincide at $t = t' = 0$). By choosing the boost direction along $\hat{x}^1 = \hat{x}$, we have therefore $y' = y$, $z' = z$ and Eq. (4.1) reduces to

$$b_0^2c^2t^2 - b_1^2x^2 = b_0^2c^2t'^2 - b_1^2x'^2. \tag{4.2}$$

From space-time homogeneity it follows that the functional relations between the two sets of coordinates $\{x, y, z, t\}$ and $\{x', y', z', t'\}$ must be linear. Then, in general, the deformed coordinate transformations are to be searched in the form

$$\begin{cases} x' = A_{11}x + A_{14}t \\ y' = y \\ z' = z \\ t' = A_{41}x + A_{44}t \end{cases} \tag{4.3}$$

where the coefficients $A_{11}, A_{14}, A_{41}, A_{44}$ depend *a priori* in general on $\mathbf{v}$ and $\hat{x}$ (and, parametrically, on the energy).

Notice that the origin O' of TIF K' must move in K with velocity $\mathbf{v} = v^1\hat{x}$, and therefore:

$$x' = 0, \quad x = vt \Leftrightarrow A_{14} = -vA_{11} \Leftrightarrow x' = A_{11}(x - vt). \tag{4.4}$$

Replacing (4.3), (4.4) in (4.2) yields

$$b_0^2c^2t^2 - b_1^2x^2 = b_0^2c^2(A_{41}x + A_{44}t)^2 - A_{11}^2b_1^2x^2(x - vt)^2 \tag{4.5}$$

which implies the following 3×3 quadratic system:

$$\begin{cases} c^2 = c^2A_{44}^2 - \left(\dfrac{b_1}{b_0}\right)^2 A_{11}^2v^2 \\ -1 = c^2\left(\dfrac{b_0}{b_1}\right)^2 A_{41}^2 - A_{11}^2 \\ 0 = c^2\left(\dfrac{b_0}{b_1}\right)^2 A_{41}A_{44} + A_{11}^2v \end{cases} \tag{4.6}$$

with general solution

$$A_{11} = A_{44} = \pm \left(1 - \left(\frac{vb_1}{cb_0}\right)^2\right)^{-1/2} \tag{4.7}$$

$$A_{41} = \mp \left(\frac{vb_1^2}{c^2b_0^2}\right)\left(1 - \left(\frac{vb_1}{cb_0}\right)^2\right)^{-1/2} = -\left(\frac{vb_1^2}{c^2b_0^2}\right)A_{11}. \tag{4.8}$$

The final result is

$$\begin{cases} x' = \tilde{\gamma}(x - vt) = \tilde{\gamma}\left(x - \tilde{\beta}\frac{b_0}{b_1}ct\right) \\ y' = y \\ z' = z \\ t' = \tilde{\gamma}\left(t - \frac{vb_1^2}{c^2b_0^2}x\right) = \tilde{\gamma}\left(t - \frac{\tilde{\beta}^2}{v}x\right) \end{cases} \tag{4.9}$$

where v is the relative speed of the reference frames, and

$$\tilde{\beta} = \frac{v}{u}; \tag{4.10}$$

$$\tilde{\gamma} = (1 - \tilde{\beta}^2)^{-1/2}. \tag{4.11}$$

Transformations (4.9) do formally coincide with the isotopic Lorentz transformations. However, in the present context their physical meaning is different, as it is easily seen e.g. by the identification of the maximal causal speed u with the speed characteristic of the quanta of a given interaction (see Sec. 3). In particular, the parametrization (4.10) of the deformed velocity parameter $\tilde{\beta}$ in terms of u immediately shows that is always $\tilde{\beta} < 1$, so that $\tilde{\gamma}$ never takes imaginary values (contrarily to the isotopic case). Moreover, no reference at all is made, in this framework, to the existence of an underlying "medium".

It must be carefully noted that, like the metric, also the generalized Lorentz transformations depend on the energy. This means that one gets different transformation laws for different values of E, but still with the same functional dependence on the energy, so that the invariance of the deformed interval (2.5) is always ensured (provided that the process considered does always occur via the same interaction).

Indeed, the energy E can be considered fixed also because, from a quantum point of view, energy can be transferred only by finite amounts.

Differentiating Eqs. (4.9), we get therefore

$$\begin{cases} udt' + t'du = \tilde{\gamma}(udt - \tilde{\beta}dx) + [d\tilde{\gamma}(ut - \tilde{\beta}x) + \tilde{\gamma}(tdu - xd\tilde{\beta}]; \\ dx' = \tilde{\gamma}(dx - \tilde{\beta}udt) + [d\tilde{\gamma}(x - \tilde{\beta}ut) - \tilde{\gamma}(t\tilde{\beta}du + td\tilde{\beta})], \end{cases} \tag{4.12}$$

where, by the above argument, $dE = 0$ and therefore $d\tilde{\gamma} = d\tilde{\beta} = du = 0$. Squaring (4.12) and subtracting, we find

$$dx'^2 - u^2dt'^2 = \tilde{\gamma}^2[(dx - \tilde{\beta}dt)^2 - (udt - \tilde{\beta}dx)^2] = dx^2 - u^2dt^2 \tag{4.13}$$

where in the last step use has been made of Eq. (4.2). Exploiting the explicit expression of u, Eq. (2.9), one has finally

$$ds'^2 = ds^2, \tag{4.14}$$

i.e. the deformed Lorentz transformations (4.9) are actually the isometries of the deformed Minkowski space $\tilde{M}$, in spite of their dependence on the energy.

As already stressed in Chap. 2 (see Eq. (2.10)), it is possible to have $u \geq c$ and therefore $c \leq v \leq u$, *i.e.* superluminal motions are allowed. Let us remark that the possibility of tachyonic speeds is accomplished, within this framework, without any recourse neither to imaginary quantities nor to singularities in the transformation laws (unlike the standard case), because it is always $v \leq u$ (even if $v \geq c$), so that the relativistic factor $\tilde{\gamma}$ (Eq. (4.11)) takes only real values, as already noted above.

4.3. Maximal Causal Speed Revisited

In $\tilde{M}$, it is possible *a priori* to consider two scalar products between 3-vectors $\mathbf{v}_1, \mathbf{v}_2$: the standard, Euclidean one $\cdot$, defined by means of the metric tensor $g_{ik} = \delta_{ik}$, and the deformed one, induced by the deformed scalar product $*$ in $\tilde{M}$, and defined by means of the metric tensor $-\eta_{ik}(E) \overset{\text{ESC off}}{=} b_i^2(E)\delta_{ik}$ (where the sign $-$ is obviously introduced in order to get a positive 3-vector norm) as follows (cf. Eq. (2.5)):

$$\begin{aligned} \mathbf{v}_1 * \mathbf{v}_2 &\equiv -\sum_{i=1}^{3} \eta_{ij}(E)(v_1)^i(v_2)^j \\ &= \sum_{i=1}^{3} b_i^2(E)\delta_{ij}(v_1)^i(v_2)^j \\ &= b_1^2(E)(v_1)^1(v_2)^1 + b_2^2(E)(v_1)^2(v_2)^2 + b_3^2(E)(v_1)^3(v_2)^3. \end{aligned} \tag{4.15}$$

CHAPTER 11

METRICS OF INTERACTIONS

The metric representation derived in the previous Chapters are, obviously, not ultimate. They constitute a mere phenomenological attempt at applying the formalism of the DSR (developed in Parts I and II), by showing explicitly how to pass from a deformed Minkowski metric to a metric representation of a given interaction.

The main aim of the present Chapter is just to provide a review of the phenomenological metrics derived for all four fundamental interactions, by stressing their general structure and their features as a premise for further developments.

11.1. Review of Phenomenological Metrics

11.1.1. *Energy-Dependent Phenomenological Metrics for the Four Interactions*

In Chaps. 7–10 it was shown that a local breakdown of Lorentz invariance may be envisaged for all four fundamental interactions (electromagnetic, weak, strong and gravitational) whereby one gets evidence for a departure of the space-time metric from the Minkowskian one (at least in the energy range examined). Let us review the basic features of the energy-dependent phenomenological metrics derived above:

(1) Both the electromagnetic and the weak metric show the same functional behavior, namely

$$\eta(E) = \mathrm{diag}(1, -b^2(E), -b^2(E), -b^2(E)); \tag{11.1}$$

$$b^2(E) = \begin{cases} (E/E_0)^{1/3}, & 0 < E \le E_0 \\ 1, & E_0 < E \end{cases} \tag{11.2}$$

$$= 1 + \theta(E_0 - E)\left[\left(\frac{E}{E_0}\right)^{1/3} - 1\right], \quad E > 0 \tag{11.3}$$

(where $\theta(x)$ is the Heaviside theta function) with the only difference between them being the threshold energy E_0, *i.e.* the energy value at which the metric parameters are constant (namely the metric becomes Minkowskian: $\eta_{\mu\nu}(E \geq E_0) \equiv g_{\mu\nu} = \mathrm{diag}(1,-1,-1,-1)$); the fits to the experimental data yield

$$E_{0,\mathrm{e.m}} = (4.5 \pm 0.2)\ \mu\mathrm{eV}; \quad \mathrm{E}_{0,\mathrm{weak}} = (80.4 \pm 0.2)\ \mathrm{GeV}. \tag{11.4}$$

Notice that for either interaction the metric is isochronous, spatially isotropic and subminkowskian, *i.e.* it approaches the Minkowskian limit from below (for $E < E_0$). Both metrics are therefore Minkowskian for $E > E_{0w} \simeq 80\,\mathrm{GeV}$, and then our formalism is fully consistent with electroweak unification, which occurs at an energy scale $\sim$100 GeV.

(2) The strong metric reads

$$\begin{aligned}\eta_{\mathrm{strong}}(E) = \mathrm{diag}(&b^2_{0,\mathrm{strong}}(E), -b^2_{1,\mathrm{strong}}(E),\\ &- b^2_{2,\mathrm{strong}}(E), -b^2_{3,\mathrm{strong}}(E));\end{aligned} \tag{11.5}$$

$$b^2_{1,\mathrm{strong}}(E) = \left(\frac{\sqrt{2}}{5}\right)^2; \quad b^2_{2,\mathrm{strong}}(E) = \left(\frac{2}{5}\right)^2, \quad \forall E > 0 \tag{11.6}$$

$$\begin{aligned}b^2_{0,\mathrm{strong}}(E) = b^2_{3,\mathrm{strong}}(E) &= \begin{cases}1, & 0 < E \leq E_{0,\mathrm{strong}}\\ (E/E_{0,\mathrm{strong}})^2, & E_{0,\mathrm{strong}} < E\end{cases}\\ &= 1 + \theta(E - E_{0,\mathrm{strong}})\left[\left(\frac{E}{E_{0,\mathrm{strong}}}\right)^2 - 1\right], \quad E > 0\end{aligned} \tag{11.7}$$

with

$$E_{0,\mathrm{strong}} = (367.5 \pm 0.4)\,\mathrm{GeV}. \tag{11.8}$$

In this case, contrarily to the electromagnetic and the weak ones, a deformation of the time coordinate occurs; moreover, the three-space is anisotropic, with two spatial parameters constant (but different in value) and the third one variable with energy like the time one.

(3) The explicit form of the gravitational energy-dependent metric is:

$$\eta_{\mathrm{grav}}(E) = \mathrm{diag}(b^2_{0,\mathrm{grav}}(E), -b^2_{1,\mathrm{grav}}(E), -b^2_{2,\mathrm{grav}}(E), -b^2_{3,\mathrm{grav}}(E)); \tag{11.9}$$

$$
\begin{aligned}
b^2_{0,\mathrm{grav}}(E) = b^2_{3,\mathrm{grav}}(E) &= \begin{cases} 1, & 0 < E \leq E_{0,\mathrm{grav}} \\ \dfrac{1}{4}(1 + E/E_{0,\mathrm{grav}})^2, & E_{0,\mathrm{grav}} < E \end{cases} \\
&= 1 + \theta(E - E_{0,\mathrm{grav}}) \left[\frac{1}{4} \left(1 + \frac{E}{E_{0,\mathrm{grav}}} \right)^2 - 1 \right], \quad E > 0
\end{aligned}
\tag{11.10}
$$

(the coefficients $b^2_{1,\mathrm{grav}}(E)$ and $b^2_{2,\mathrm{grav}}(E)$ are presently undetermined at phenomenological level), with

$$E_{0,\mathrm{grav}} = (20.2 \pm 0.1)\,\mu\mathrm{eV}. \tag{11.11}$$

It is worth stressing the analogy between the strong and the gravitational metrics. In both cases, a deformation of the time coordinate occurs. Moreover, one of the spatial parameters (we conventionally assumed as the third one) varies with energy as the time one in an overminkowskian way, namely, they approach the Minkowskian limit from above ($E_0 < E$). The other two spatial parameters are constant, but different in value for the strong case (*i.e.* the three-space is anisotropic for strong interactions), whereas nothing can be said for the gravitational case on an experimental basis.

The general pattern of the four phenomenological metrics is shown in Fig. 11.1.

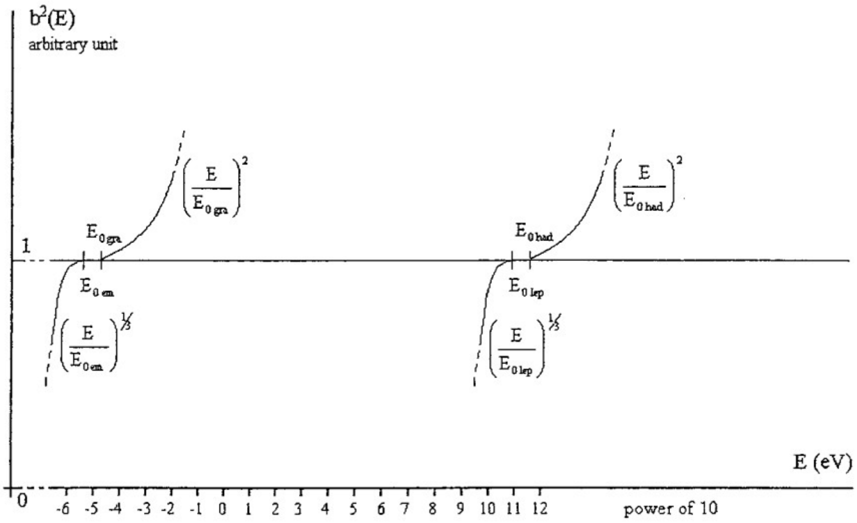

Fig. 11.1. General pattern of the phenomenological metrics for the four fundamental interactions.

in the anisotropic case, one exploits the values of the maximal causal speeds derived from the analysis of the strong interaction based on BE correlation (the only interaction at present described by a spatially anisotropic metric) (cf. Chap. 10).

13.5. Appendix — Einstein and the Aether

When Einstein started his scientific life as a young physicist, the aether was conceived as a material medium allowing propagation of the electromagnetic signals and filling the interplanetary and interstellar spaces. This was for instance the idea of Maxwell, as formulated by him in the article he wrote in the *Encyclopedia Britannica.* According to Drude and Cohn, the aether might also be thought as the vacuum, endowed with suitable physical properties.

Einstein was so convinced about the reality of the aether, that he devised as early as 1895 an experiment aimed to detect the drift of the aether. He pursued such an idea when a student at Zurich ETH in 1897. However, he was not allowed to carry out such an experiment by his professor H. F. Weber. Later, he sent to his uncle C. Koch a manuscript (remained unpublished) entitled *On the Examination of the State of the Aether in a Magnetic field.* In the experiment therein proposed, he wanted to investigate the reciprocal effect between the magnetic field generated by a steady current and the aether, regarded as an elastic medium.

Another experimental proposal was exposed by Einstein in a letter to M. Grossmann from Winterthur in 1901. Subsequently, Einstein abandoned the idea of the aether in the old sense, and rather identified it, within General Relativity, as a substratum without mechanical and kinematical properties, but able to codetermine mechanical and electromagnetic events. In a modern view, we can state that such a new concept of aether is nothing but a static gravitational field (locally the Minkowski space-time).[82]

The possible existence of the aether is indeed nothing, in today language, than the possibility of LLI breakdown. We can therefore conclude that Einstein asked the right question, but looking for the wrong answer. His experiment based on the feedback between a steady current and the aether has strong analogies with Bartocci's one we discussed above. In particular, it belongs to the same class of LLI breakdown tests, namely those based on electromagnetic effects.

CHAPTER 14

THE GRAVITATIONAL MASS OF ELECTRON FROM GEOMETRY

In this Chapter, it will be shown that the DSR formalism yields an expression of the electron mass m_e in terms of the parameter δ of local Lorentz invariance (LLI) breakdown and of the threshold energy for the gravitational metric, $E_{0,\text{grav}}$ (*i.e.* as by now familiar, the energy value under which the metric becomes Minkowskian). This allows one to evaluate m_e from the (experimental) knowledge of such parameters.[83]

14.1. LLI Breaking Factor and Relativistic Energy in DSR

The breakdown of standard local Lorentz invariance (LLI) is expressed by the LLI breaking factor parameter δ discussed in Sec. 13.4. In particular, the isotropic parameter is expressed by Eq. (13.14). To the present aims, one can also define δ as follows:

$$\delta_{\text{int}} \equiv \frac{m_{\text{in,int}} - m_{\text{in,grav}}}{m_{\text{in,int}}} = 1 - \frac{m_{\text{in,grav}}}{m_{\text{in,int}}} \tag{14.1}$$

where $m_{\text{in,int}}$ is the inertial mass of the particle considered with respect to the given interaction.[a] In other words, we assume that the *local* deformation of space-time corresponding to the interaction considered, and described by the metric (3.3), gives rise to a *local violation* of the Principle of Equivalence for interactions different from the gravitational one. Such a departure, just expressed by the parameter δ_{int}, does constitute also a measure of the amount of LLI breakdown. In the framework of DSR, δ_{int} embodies the geometrical contribution to the inertial mass, thus discriminating between two different metric structures of space-time.

---

[a] In the following, "int" denotes a physically detectable fundamental interaction, which can be operationally defined by means of a phenomenological energy-dependent metric of deformed minkowskian type.

Of course, if the interaction considered is the gravitational one, the Principle of Equivalence strictly holds, *i.e.*

$$m_{\text{in,grav}} = m_g \tag{14.2}$$

where m_g is the gravitational mass of the physical object considered, *i.e.* it is its "gravitational charge" (namely its coupling constant to the gravitational field).

Then, (14.1) can be rewritten as:

$$\delta_{\text{int}} \equiv \frac{m_{\text{in,int}} - m_g}{m_{\text{in,int}}} = 1 - \frac{m_g}{m_{\text{in,int}}} \tag{14.3}$$

and therefore, when the particle is subjected only to gravitational interaction, it is

$$\delta_{\text{grav}} = 0. \tag{14.4}$$

Let us recall the expression (5.10) of the deformed relativistic energy, for a particle subjected to a given interaction and moving along $\hat{x}^i$:

$$\begin{aligned} E_{\text{int}} &= m_{\text{in,int}} u_{i,\text{int}}^2(E) \tilde{\gamma}_{\text{int}}(E) \\ &= m_{\text{in,int}} c^2 \frac{b_{0,\text{int}}^2(E)}{b_{i,\text{int}}^2(E)} \left[1 - \left(\frac{v_i b_{i,\text{int}}(E)}{c b_{0,\text{int}}(E)} \right)^2 \right]^{-1/2} \end{aligned} \tag{14.5}$$

(with $\mathbf{u}_{\text{int}}(E)$ the maximal causal velocity for the interaction considered), which, in the non-relativistic (NR) limit of DSR (*i.e.* $v_i \ll u_{i,\text{int}}(E)$), reduces to (cf. Eq. (5.12))

$$E_{\text{int,NR}} = m_{\text{in,int}} u_{i,\text{int}}^2(E) = m_{\text{in,int}} c^2 \frac{b_{0,\text{int}}^2(E)}{b_{i,\text{int}}^2(E)}. \tag{14.6}$$

In the case of the gravitational metric (see Eq. (8.28)), we have

$$\frac{b_{0,\text{grav}}^2(E)}{b_{3,\text{grav}}^2(E)} = 1, \quad \forall E \in R_0^+. \tag{14.7}$$

Therefore, for $i = 3$, Eqs. (14.5) and (14.6) become, respectively ($v_3 = v$):

$$E_{\text{grav}} = m_g c^2 \left[1 - \left(\frac{v}{c} \right)^2 \right]^{-1/2} = m_g c^2 \gamma \tag{14.8}$$

$$E_{\text{grav,NR}} = m_g c^2 \tag{14.9}$$

namely, the gravitational energy takes its standard, special-relativistic values.

This means that the special characterization (corresponding to the choice $i = 3$) of Eqs. (14.5) and (14.6) within the framework of DSR relates the gravitational interaction with SR, which is — as well known — based on the electromagnetic interaction in its Minkowskian form.

14.2. The Electron as a Fundamental Particle and its "Geometrical" Mass

Let us consider for E the threshold energy of the gravitational interaction:

$$E = E_{0,\text{grav}}. \tag{14.10}$$

By definition of $E_{0,\text{grav}}$, one has therefore:

$$\begin{aligned}\eta_{\mu\nu,\text{grav}}(E) &= \operatorname{diag}(1, -b^2_{1,\text{grav}}(E), -b^2_{2,\text{grav}}(E), -1)\\ &\overset{\text{ESC off}}{=} \delta_{\mu\nu}\left[\delta_{\mu 0} - \delta_{\mu 1} b^2_{1,\text{grav}}(E) - \delta_{\mu 2} b^2_{2,\text{grav}}(E) - \delta_{\mu 3}\right],\\ &\quad \forall E \in (0, E_{0,\text{grav}}].\end{aligned}$$

Notice that at the energy $E = E_{0,\text{grav}}$ the electromagnetic metric (7.8) is Minkowskian, too (because $E_{0,\text{grav}} > E_{0,\text{em}}$).

On the basis of the previous considerations, it seems reasonable to assume that the physical object (particle) p with a rest energy (*i.e.* gravitational mass) just equal to the threshold energy $E_{0,\text{grav}}$, namely

$$E_{0,\text{grav}} = m_{g.,p}c^2, \tag{14.11}$$

must play a fundamental role for either e.m. and gravitational interaction. We can e.g. hypothesize that p corresponds to the lightest mass eigenstate which experiences both force fields (*i.e.* from a quantum viewpoint, coupling to the respective interaction carriers, the photon and the graviton). As a consequence, p must be intrinsically stable, due to the impossibility of its decay in lighter mass eigenstates, even in the case such a particle is subject to weak interaction, too (*i.e.* it couples to all gauge bosons of the Glashow–Weinberg–Salam group $SU(2)\times U(1)$, not only to its electromagnetic charge sector).

Since, as above seen, for $E = E_{0,\text{grav}}$ the electromagnetic metric is Minkowskian, too, it is natural to assume, for p:

$$m_{\text{in},p,\text{e.m.}} = m_{\text{in},p} \tag{14.12}$$

namely its inertial mass is that measured with respect to the electromagnetic metric.

Then, due to the Equivalence Principle (see Eq. (14.2)), the mass of p is characterized by

$$p:\begin{cases} m_{\mathrm{in},p,\mathrm{grav}} = m_{g,p} \\ m_{\mathrm{in},p,\mathrm{e.m.}} = m_{\mathrm{in},p}. \end{cases} \tag{14.13}$$

Therefore, for such a fundamental particle the LLI breaking factor (14.1) of the e.m. interaction becomes:

$$\delta_{\mathrm{e.m.}} = \frac{m_{\mathrm{in,p}} - m_{\mathrm{g,p}}}{m_{\mathrm{in,p}}} = 1 - \frac{m_{\mathrm{g,p}}}{m_{\mathrm{in,p}}} \Leftrightarrow m_{\mathrm{g,p}} = m_{\mathrm{in,p}}\left(1 - \delta_{\mathrm{e.m.}}\right). \tag{14.14}$$

Replacing (14.11) in (14.14) yields:

$$E_{0,\mathrm{grav}} = m_{in,\mathrm{p}}\left(1 - \delta_{\mathrm{e.m.}}\right)c^2 \Leftrightarrow m_{in,\mathrm{p}} = \frac{E_{0,\mathrm{grav}}}{c^2}\frac{1}{1 - \delta_{\mathrm{e.m.}}}. \tag{14.15}$$

Equation (14.15) allows one to evaluate the inertial mass of p from the knowledge of the electromagnetic LLI breaking parameter $\delta_{\mathrm{e.m.}}$ and of the threshold energy $E_{0,\mathrm{grav}}$ of the gravitational metric.

The lowest limit to the LLI breaking factor of electromagnetic interaction has been determined by the experiment (based on the detection of a DC voltage across a conductor induced by the steady magnetic field of a coil), discussed in Chap. 13. On account of the definition (13.14) of the isotropic LLI breaking parameter, and the definition (14.1), the value found corresponds to

$$1 - \delta_{\mathrm{e.m.}} \cong 4 \cdot 10^{-11}. \tag{14.16}$$

Then, inserting the value (8.24) for $E_{0,\mathrm{grav}}$ and (14.16) in (14.15), one gets

$$m_{\mathrm{in},p} = \frac{E_{0,\mathrm{grav}}}{c^2}\frac{1}{1 - \delta_{\mathrm{e.m.}}} \geq \frac{2 \cdot 10^{-5}}{4 \cdot 10^{-11}}\frac{\mathrm{eV}}{c^2} = 0.5\frac{\mathrm{MeV}}{c^2} = m_{\mathrm{in},e} \tag{14.17}$$

(with $m_{\mathrm{in,e}}$ being the electron mass) where the $\geq$ is due to the fact that in general the LLI breaking factor constitutes an *upper limit* (*i.e.* it sets the scale *under which* a violation of LLI is expected). If the coil experiment does indeed provide evidence for a LLI breakdown (as it seems the case, although further confirmation is needed), Eq. (14.17) yields $m_{\mathrm{in},p} = m_{\mathrm{in,e}}$. We find therefore the amazing result that *the fundamental particle p is nothing but the electron e^- (or its antiparticle e^+).*[b] The electron is indeed the lightest massive lepton (pointlike, non-composite particle) with electric charge, and therefore subjected to gravitational, electromagnetic and weak interactions, but unable to weakly decay due to its small mass. Consequently, e^- (e^+) shares all the properties we required for the particle p, whereby it plays a fundamental role for gravitational and electromagnetic interactions.

---

[b] Of course, this last statement does strictly holds only if the CPT theorem mantains its validity in the DSR framework, too. Although this problem has not yet been addressed in general on a formal basis, it can be stated that it holds true in the case considered, since the energy value $E = E_{0,\mathrm{grav}}$ corresponds to the minkowskian form of both electromagnetic and gravitational metric.

It was therefore shown that within DSR it is possible — on the basis of simple and plausible assumptions — to evaluate the inertial mass of the electron e^- (and therefore of its antiparticle, the positron e^+) by exploiting the expression of the relativistic energy in the deformed Minkowski space $\tilde{M}_4(E)_{E \in R_0^+}$, the explicit form of the phenomenological metric describing the gravitational interaction (in particular its threshold energy), and the LLI breaking parameter for the electromagnetic interaction $\delta_{\text{e.m.}}$. Let us stress that no use has been made of the electric charge e of the electron.

Therefore, the inertial properties of one of the fundamental constituents of matter and of Universe do find a "geometrical" interpretation in the context of DSR, by admitting for local violations of standard Lorentz invariance.

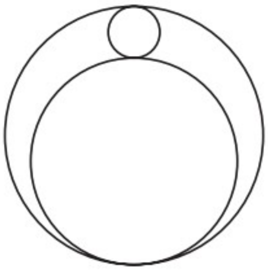
Leonia

...de año en año la ciudad se expande y los basurales deben retroceder más lejos; la importancia de los desperdicios aumenta..., se despliegan en un perímetro cada vez más vasto.

Las ciudades continuas. 1

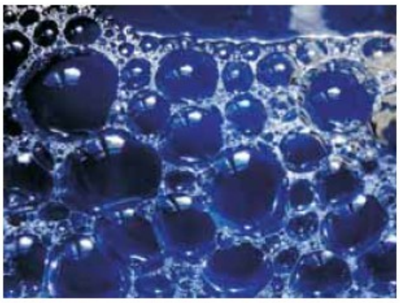
En Leonia los desperdicios rodean la ciudad. El visitante se encuentra en el centro de una circunferencia de inmundicia que se desarrolla de año en año según la ciudad se expande. Y lo hace en un perímetro cada vez más vasto. Esa expansión y ese perímetro cada vez mayores, plantean una cuestión fundamental. Si la expansión significa un aumento del área ocupada por la ciudad, ¿el aumento de ése área implica un aumento de su perímetro?

Supongamos que Leonia es plana y su basural circular. El área A de un círculo puede escribirse como función de su perímetro P: $A=P/(4\pi)$. Y entonces, $A'(P)=P/(2\pi)=r$. Por tanto, el radio mide el cambio de área con respecto al perímetro. Y si el radio r se aumenta en r_0, su perímetro y área aumentan en $2\pi r_0$ y $\pi r_0^2+2\pi r r_0$ respectivamente. Es decir, que el aumento del perímetro equivale al perímetro del círculo correspondiente al aumento del radio ($2\pi r_0$), mientras que el aumento de área es mayor que el área del círculo correspondiente a ése aumento. Esto se observa en la figura al margen. El perímetro del círculo mayor, de radio $R=r+r_0$, es la suma de los perímetros de los dos círculos interiores, mientras que su área sobrepasa en mucho la de ambos.



El mundo sobre el que se extiende Leonia no es plano, sino esférico. Si nada limita su expansión, el perímetro y área circulares de Leonia crecerán de la mano, pero sólo hasta que el perímetro iguale el del ecuador terrestre. A partir de ahí el perímetro decrecerá mientras la expansión de la ciudad continúa. Un fenómeno ya señalado por Frabetti (1999) en la *ciudad incontenible*, cuyas murallas crecían hasta un punto en el que con las piedras de la muralla precedente podía construirse un muro que encerraba un área todavía mayor. De ahí en adelante, el perímetro de la ciudad encierra su basural en el polo opuesto al centro de aquella.

Los desperdicios de Leonia ... invadirían el mundo si no estuvieran presionando, más allá de la última cresta, basurales de otras ciudades que también rechazan lejos de sí montañas de deshechos.



Leonia : *la ciudad que crece como la espuma*

Pero los basurales de Leonia están limitados por la presión de los de otras ciudades como las pompas achatadas de la espuma. ■

Gauss y el polígono regular de 17 lados

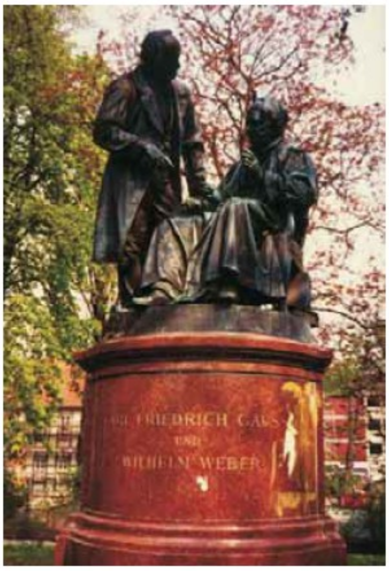
Cuando se finaliza un noble edificio no deben quedar visibles los andamios

C.F. Gauss

El sorprendente encuentro entre la Aritmética, el Álgebra y la Geometría.

El 18 de febrero de 1792, antes de cumplir los 15 años el joven Carl Friedrich Gauss hace su inscripción en el Collegium Carolinum de Brunswick. En este colegio da clases de matemáticas y ciencias naturales E. A. W. Von Zimmermann (1743-1815) su valedor ante el duque de Brunswick.

Gauss permanecerá en él hasta 1795, estudiando lenguas clásicas, literatura, filosofía y, por supuesto, matemáticas superiores, siendo un alumno brillante en todas ellas. Entre sus lecturas de matemáticas de esta época están los *Principia Mathematica* de Newton, el *Ars Conjectandi* de Jackob Bernoulli y algunas de las memorias de Euler. En el Collegium Carolinum Gauss iniciará alguna de sus futuras investigaciones matemáticas, según sus propias confesiones posteriores, como la distribución de los números primos o los fundamentos de la geometría.



Antonio Pérez Sanz
IES Salvador Dalí (Madrid)
decabeza@revistasuma.es

Cuando en el otoño de 1795 se traslada a la Universidad Georgia Augusta de Göttingen, con una beca del Duque, Gauss aún no ha decidido su futuro académico dudando entre los estudios de Filología clásica y las Matemáticas. Las lecciones de matemáticas, no muy buenas según la opinión de Gauss, las impartía el anciano profesor Gotthelf Abraham Kästner que tenía entonces 76 años. En esta época conoce a Wolfgang (Farkas) Bolyai, que se incorporó a la universidad un año después que él. Gauss, unos años más tarde llegó a afirmar: *Bolyai fue el único que supo interpretar mis criterios metafísicos sobre las Matemáticas.* Y también que Bolyai fue el *espíritu más complicado que jamás conocí*.

Bolyai es más explícito al hablar de su amistad:

> Nos unía la pasión por las Matemáticas y nuestra conciencia moral, y así paseábamos durante largas horas en silencio, cada uno ocupado en sus propios pensamientos.

> *Justo un mes antes de cumplir los 19 años, Gauss se decantará definitivamente por las matemáticas y hará su primera anotación en su diario de notas, un pequeño cuaderno de 19 páginas, que acompañará a Gauss hasta 1814, el diario científico más importante de la historia de las matemáticas*

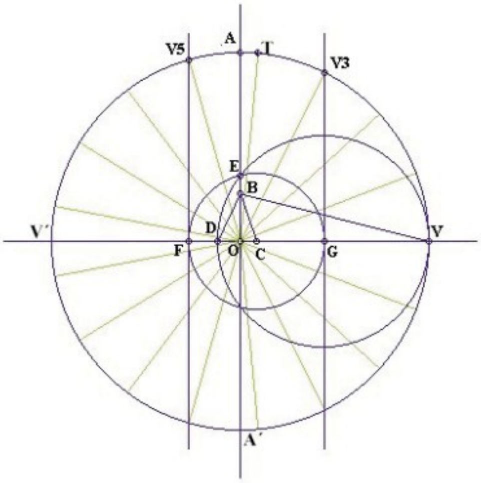
Construcción con regla y compás del polígono regular de 17 lados

Desde su llegada a Göttingen el joven Gauss siguió desarrollando de forma autónoma sus investigaciones sobre números que había iniciado en el Collegium. Sin duda, más fruto de estas investigaciones que de las enseñanzas de Kästner, cuando Gauss estaba en su casa de Brunswick, se va a producir un descubrimiento que será clave, no sólo en la carrera de Gauss, sino en el futuro de las matemáticas: **el heptadecágono, el polígono regular de 17 lados se puede construir con regla y compás.**

Él mismo, muchos años más tarde, recordará el momento en una carta que dirige a Gerling fechada el 6 de enero de 1819:

> Fue el día 29 de marzo de 1796, durante unas vacaciones en Brunswick, y la casualidad no tuvo la menor participación en ello ya que fue fruto de esforzadas meditaciones; en la mañana del citado día, antes de levantarme de la cama, tuve la suerte de ver con la mayor claridad toda esta correlación, de forma que en el mismo sitio e inmediatamente apliqué al heptadecágono la correspondiente confirmación numérica.

El día siguiente, el 30 de marzo, justo un mes antes de cumplir los 19 años, Gauss se decantará definitivamente por las matemáticas y hará su primera anotación en su diario de notas, un



Construcción del polígono regular de 17 lados

Método de Gauss(1796), simplificada por H.W. Richmond (1893)

1. Se construye la circunferencia con centro en O. Se dibujan los diámetros perpendiculares AA´ y VV´
2. Se obtiene un punto B, sobre el radio OA, tal que el segmento OB es la cuarta parte de OA
3. Se obtiene el punto C, sobre OV, tal que el ángulo OBC es la cuarta parte del ángulo OBV (hay que bisectar dos veces un ángulo)
4. Se obtiene un punto D, sobre el diámetro VV´, tal que el ángulo DBV sea de 45° (se puede hacer bisectando un ángulo recto)
5. Se obtiene G, mitad del segmento DV, se dibuja la circunferencia con centro G y radio GV. Esta circunferencia corta al radio OA en el punto E.
6. Se dibuja la circunferencia con centro C y radio CE, dicha circunferencia corta a VV´ en dos puntos: F y G
7. Se levantan perpendiculares a VV´, pasando por F y G , que cortan a la circunferencia en V3 y V5.
8. La mitad del arco V3V5, nos da un punto T. El segmento V 3T es el lado del polígono regular de 17 lados.

pequeño cuaderno de 19 páginas, que acompañará a Gauss hasta 1814, el diario científico más importante de la historia de las matemáticas, en el que irá anotando, a veces de forma críptica, los resultados matemáticos que le vienen a la cabeza, en total 144 anotaciones. Por este diario desfilará un alto porcentaje de los descubrimientos matemáticos del siglo XIX. En este libro no fueron recogidos todos los descubrimientos de Gauss en el período prolífico de 1796 a 1814. Pero muchos de los anotados bastarían para establecer la prioridad de Gauss en campos, donde algunos de sus contemporáneos se niegan a creer que Gauss les precediera.

Muchos hallazgos que quedaron enterrados durante décadas en este diario habrían encumbrado a media docena de grandes matemáticos de haber sido publicados. Algunos jamás se hicieron públicos durante la vida de Gauss, y nunca pretendió la prioridad cuando otros autores se le anticiparon. Sus anotaciones constituían descubrimientos esenciales de la Matemática del siglo XIX. Un documento que por desgracia para la ciencia no verá la luz hasta casi 50 años después de la muerte de Gauss.

> Principia quibus innititur sectio circuli, ac divisibilitas eiusdem geometrica in septemdecim partes, etc. Mart. 30 Brunsv.

Con tan sólo 18 años, el joven Gauss había hecho un descubrimiento que por sí solo le habría hecho pasar a la historia de las matemáticas. Un descubrimiento que constituía sólo la punta del iceberg de una teoría mucho más amplia que dará origen tres años más tarde a las *Disquisitiones Arithmeticae,* obra que Gauss va madurando durante su estancia en la universidad de Gottingën.

En esa misma carta a Gerling, Gauss relata en primera persona cómo llegó a este descubrimiento:

> Por una reflexión muy profunda sobre la relación existente entre el conjunto de raíces de la ecuación
>
> $$\frac{x^p-1}{x-1}=0$$
>
> por razones aritméticas, he llegado a vislumbrar muy claramente la naturaleza de esta relación, tras unos días de vacaciones en Brunswick, la mañana de este día, justo antes de levantarme, de manera que he podido hacer sobre el terreno la aplicación particular al polígono regular de 17 lados y ejecutar los cálculos numéricos correspondientes.

Gauss tiene ya en su cabeza una visión clara del modelo geométrico de representación de los números complejos y de su potencial revolucionario para atacar ecuaciones ciclotómicas. Y justo en un momento de la historia en que la colectividad matemática tiene serios reparos a la utilización alegre de los números imaginarios que Euler ha realizado cincuenta años antes al proponer su revolucionaria fórmula (Prop. 138), que relaciona las cantidades imaginarias con la cantidades trascendentes nacidas del círculo, que así se llama el capítulo correspondiente de la *Introductio in Analisin infinitorum* (1748)

$$e^{+v\sqrt{-1}}=\cos v+\sqrt{-1}\,sen\,v$$

Que tras la introducción de la letra i como notación de la unidad imaginaria, será una de las fórmulas más populares de las matemáticas: $e^{iv}=\cos v+i\,sen\,v$, sobre todo para el valor particular de $v=\pi$

$$e^{i\pi}=\cos\pi+i\,sen\,\pi=-1$$

Porque en la cabeza del joven Gauss las raíces de la ecuación, de la forma

$$e^{i\frac{2k\pi}{p}}$$

se perfilan claramente como los vértices de un polígono regular de p lados.

La Aritmética modular viene en ayuda del Álgebra

Gauss se ocupa del caso especial p = 17.

Si una de las raíces es $r=e^{i\frac{2\pi}{17}}$, las otras raíces son las potencias sucesivas de r, es decir r^m.

Gauss crea una tabla con las 17 raíces ordenadas según las potencias de 3 expresadas en módulo 17.

k	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
m=3k(mod 17)	1	3	9	10	13	5	15	11	16	14	8	7	4	12	2	6	1

Los valores de m forman una permutación de los números enteros del 1 al 16.

¿Por qué ordena Gauss las raíces de esta forma un tanto arbitraria? Sencillamente, esto le permite comprobar las funciones de las raíces que permanecen invariantes para un cierto número de permutaciones.

Los antecedentes algebraicos

La idea de relacionar las funciones de las raíces que permanecen invariantes o que toman un número pequeño de valores al permutar las raíces, con las soluciones de la ecuación, la desarrolla ampliamente Lagrange en una memoria de 1771.

La idea parte del hecho de un resultado explicitado por Vandermonde: todos los radicales que intervienen en las fórmulas de resolución de las ecuaciones de grado menor que 4 se pueden expresar como función de las raíces.

En la ecuación de segundo grado $ax^2 + bx + c = 0$, el discriminante

$$\Delta = \sqrt{b^2 - 4ac} = a\sqrt{(x_1 - x_2)^2}$$

Es una función simétrica de las raíces.

En la ecuación de tercer grado $ax^3 + b\,x^2 + c\,x + d = 0$, la función $T = (x_1 + jx_2 + j^2x_3)^3$ sólo toma dos valores distintos al hacer:

$$j = e^{i\frac{2\pi}{3}}$$

$$T_1 = (x_1 + jx_2 + j^2x_3)^3 \text{ y } T_2 = (x_1 + j^2x_2 + jx_3)^3$$

Por lo tanto, las funciones $T_1 + T_2$, y $T_1 \bullet T_2$ son simétricas respecto de las raíces de la ecuación y por ello calculables utilizando sólo los coeficientes de la ecuación.

Las tres raíces se pueden calcular resolviendo el sistema

$$\begin{cases} x_1 + x_2 + x_3 = -b \\ x_1 + jx_2 + j^2x_3 = \sqrt[3]{T_1} \\ x_1 + j^2x_2 + jx_3 = \sqrt[3]{T_2} \end{cases}$$

La existencia de funciones T_i de las raíces, que toman menos valores distintos que el grado de la ecuación, permiten encontrar las soluciones mediante ecuaciones auxiliares construidas a partir de funciones simétricas de las T_i . A estas ecuaciones se las conoce como *ecuaciones resolventes*.

La genialidad de Gauss

La tabla de Gauss le permite construir ecuaciones resolventes agrupando las raíces de 8 en 8, de 4 en 4 o de 2 en 2.

Gauss comienza con dos periodos de 8 raíces

$$p_1 = \omega_1 + \omega_9 + \omega_{13} + \omega_{15} + \omega_{16} + \omega_8 + \omega_4 + \omega_2$$

$$p_2 = \omega_3 + \omega_{10} + \omega_5 + \omega_{11} + \omega_{14} + \omega_7 + \omega_{12} + \omega_6$$

Tanto p_1 como p_2 contienen al mismo tiempo a ω_n y a su inversa ω_{17-n} .

La suma de $p_1 + p_2 = -1$, ya que la suma de las 17 raíces de $x^{17} - 1 = 0$, las 16 de p_1 y p_2 más la raíz 1, ha de ser 0

Y como $\omega_a \cdot \omega_b = \omega_c \quad \textit{donde} \quad c \equiv a + b \pmod{17}$

El producto de $p_1 \bullet p_2 = -4$

De modo que p_1 y p_2 son las raíces de la ecuación:

$$x^2 + x - 4 = 0$$

A continuación Gauss agrupa las raíces de p_1 y p_2 en cuatro periodos de 4 raíces

$$\begin{cases} q_1 = \omega_1 + \omega_{13} + \omega_{16} + \omega_4 \\ q_2 = \omega_9 + \omega_{15} + \omega_8 + \omega_2 \end{cases} \text{ y } \begin{cases} q_3 = \omega_3 + \omega_5 + \omega_{14} + \omega_{12} \\ q_4 = \omega_{10} + \omega_{11} + \omega_7 + \omega_6 \end{cases}$$

Podemos comprobar que
$q_1 + q_2 = p_1$; $\qquad q_1 \bullet q_2 = p_1 + p_2 = -1$

Y por tanto q_1 y q_2 son las raíces de la ecuación:

$$x^2 - p_1\,x - 1 = 0$$

Análogamente

$q_3 + q_4 = p_2$; $\qquad q_3 \bullet q_4 = p_1 + p_2 = -1$

Y por tanto q_3 y q_4 son las raíces de la ecuación:

$$x^2 - p_2\,x - 1 = 0$$

Es fácil comprobar que $\omega_a + \omega_{17-a} = 2\cos\frac{2a\pi}{17}$

Así que $q_1 = 2\cos\frac{2\pi}{17} + 2\cos\frac{8\pi}{17}$ y $q_2 = 2\cos\frac{4\pi}{17} + 2\cos\frac{16\pi}{17}$

Con la ecuación $x^2 - p_2\,x - 1 = 0$

Obtenemos que:

$$q_3 = 2\cos\frac{6\pi}{17} + 2\cos\frac{10\pi}{17} \text{ y } q_4 = 2\cos\frac{12\pi}{17} + 2\cos\frac{14\pi}{17}$$

Por fin, formando periodos de 2 en 2 tendremos

$$r_1 = \omega_1 + \omega_{16} \quad ; \quad r_2 = \omega_{13} + \omega_4$$

Y por tanto:

$$\begin{cases} r_1 + r_2 = q_1 \\ r_1 \cdot r_2 = q_3 \end{cases}$$

$$\text{Así: } \quad r_1 = 2\cos\frac{2\pi}{17} \quad \text{y} \quad r_2 = 2\cos\frac{8\pi}{17}$$

Y reemplazando en los valores de p_i tendremos... es sólo un problema de paciencia...

$$p_1 = \frac{\sqrt{17} - 1}{2} \quad ; \quad p_2 = -\frac{\sqrt{17} + 1}{2}$$

Y q_i:

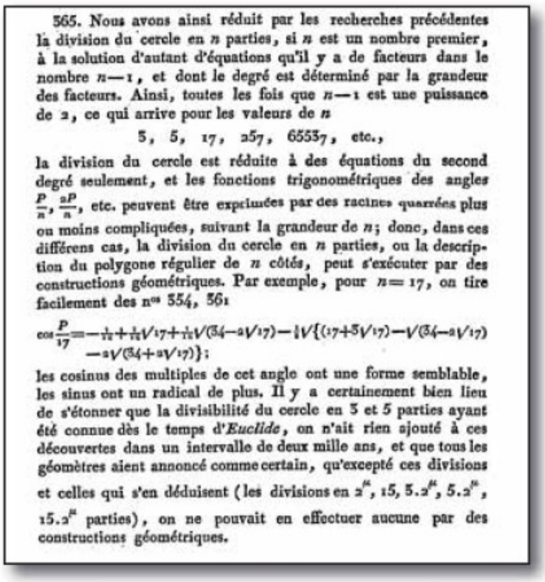
$$q_1=\frac{p_1+\sqrt{p_1^2+4}}{2}=\frac{\sqrt{17}-1+\sqrt{34-2\sqrt{17}}}{4}\quad;$$
$$q_2=\frac{p_1-\sqrt{p_1^2+4}}{2}=\frac{\sqrt{17}-1-\sqrt{34-2\sqrt{17}}}{4}$$

$$q_3=\frac{p_2+\sqrt{p_2^2+4}}{2}=\frac{-\sqrt{17}-1+\sqrt{34+2\sqrt{17}}}{4}\quad;$$
$$q_4=\frac{p_2-\sqrt{p_2^2+4}}{2}=\frac{-\sqrt{17}-1-\sqrt{34+2\sqrt{17}}}{4}$$

y por fin r_i:

$$\frac{r_1}{2}=\cos\frac{2\grave{A}}{17}=-\frac{1}{16}+\frac{1}{16}\sqrt{17}+\frac{1}{16}\sqrt{34-2\sqrt{17}}+$$
$$+\frac{1}{8}\sqrt{17+3\sqrt{17}-\sqrt{34-2\sqrt{17}}-2\sqrt{34+2\sqrt{17}}}$$

Sustituyendo en las sucesivas ecuaciones podemos calcular las 16 raíces de la ecuación.



365. Nous avons ainsi réduit par les recherches précédentes la division du cercle en n parties, si n est un nombre premier, à la solution d'autant d'équations qu'il y a de facteurs dans le nombre $n-1$, et dont le degré est déterminé par la grandeur des facteurs. Ainsi, toutes les fois que $n-1$ est une puissance de 2, ce qui arrive pour les valeurs de n

3, 5, 17, 257, 65537, etc.,

la division du cercle est réduite à des équations du second degré seulement, et les fonctions trigonométriques des angles $\frac{P}{n}$, $\frac{2P}{n}$, etc. peuvent être exprimées par des racines quarrées plus ou moins compliquées, suivant la grandeur de n; donc, dans ces différens cas, la division du cercle en n parties, ou la description du polygone régulier de n côtés, peut s'exécuter par des constructions géométriques. Par exemple, pour $n=17$, on tire facilement des n^os 354, 361

$$\cos\frac{P}{17}=-\tfrac{1}{16}+\tfrac{1}{16}\sqrt{17}+\tfrac{1}{16}\sqrt{(34-2\sqrt{17})}-\tfrac{1}{8}\sqrt{\{(17+3\sqrt{17})-\sqrt{(34-2\sqrt{17})}-2\sqrt{(34+2\sqrt{17})}\}};$$

les cosinus des multiples de cet angle ont une forme semblable, les sinus ont un radical de plus. Il y a certainement bien lieu de s'étonner que la divisibilité du cercle en 3 et 5 parties ayant été connue dès le temps d'*Euclide*, on n'ait rien ajouté à ces découvertes dans un intervalle de deux mille ans, et que tous les géomètres aient annoncé comme certain, qu'excepté ces divisions et celles qui s'en déduisent (les divisions en 2^μ, 15, 5.2^μ, 5.2^μ, 15.2^μ parties), on ne pouvait en effectuer aucune par des constructions géométriques.

Disquisitiones Arithmeticae. Ed. Francesa de 1809

Del Álgebra a la Geometría

Al final sólo hemos tenido que resolver de forma sucesiva ecuaciones de 2º grado, es decir todo el proceso se puede realizar geométricamente con regla y compás. Esto ha sido así ya que para n = 17 tenemos n – 1 = 16 = 2 • 2 • 2 • 2

La alegría del joven Gauss, ese 30 de marzo de 1796 aún tiene 18 años, está más que justificada. Acaba de resolver un problema de más 2 milenios de antigüedad.

Este hecho, por sí sólo, le haría pasar a la Historia de las Matemáticas. Definitivamente las lenguas clásicas habían perdido un genio para siempre. Las matemáticas y todas las ciencias habían ganado la batalla en la cabeza de Gauss.

Gauss terminará sus *Disquisitiones Arithmeticae*, con las proposiciones 365 y 366, tantas como los días del año, rebosante de alegría, facilitando la lista de los polígonos de menos de 300 lados que se pueden construir con regla y compás. El joven genio ha tocado la gloria y lo sabe.

> Para que la división geométrica del círculo en N partes sea posible, N debe ser 2, o una potencia de 2, o bien un número primo de la forma 2m +1 o bien le producto de una potencia de 2 por uno o varios números primos diferentes de esta forma

Y todo ello antes de cumplir los 19 años... Cuesta creer que todo lo hiciera DE CABEZA...

DE CABEZA ■

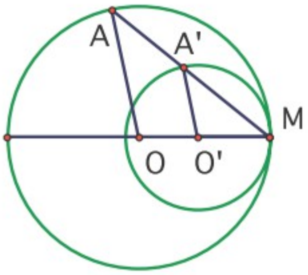
(a)



Solution. If line AA' passes through the point M of tangency of the circles O and O' (Figures t58a and 58b), then $\widehat{OAM} = \widehat{OMA} = \widehat{O'MA'} = \widehat{O'A'M}$, so that OA is parallel to $O'A'$.

Notes. This is another good problem for students to cut their teeth on. If they have solved Exercise 57, they may be able to recognize the need to consider both internally and externally tangent circles.

ou, en remarquant que $xdx + ydy + zdz = rdr$,

$$Xdx + Ydy + Zdz = -mKdr - mgdz.$$

Il en résulte qu'il existe une fonction des forces U, définie par

$$U = -m(Kr + gz) = -m(K\sqrt{x^2+y^2+z^2} + gz),$$

et par suite l'équation générale des surfaces de niveau est

$$K\sqrt{x^2+y^2+z^2} + gz = h,$$

ou

$$x^2+y^2+z^2 = \frac{1}{K^2}(gz-h)^2,$$

ou

$$x^2+y^2+z^2 = \frac{g^2}{K^2}\left(z - \frac{h}{g}\right)^2.$$

Cette équation représente le lieu des points dont le rapport des distances à l'origine et au plan (P), $z - \frac{h}{g} = 0$, est constant et égal à $\frac{g}{K}$.

Ce lieu est une quadrique de révolution autour de Oz, dont la méridienne dans le plan des zx a pour foyer l'origine, pour directrice la droite (D), $z - \frac{h}{g} = 0$, et pour excentricité $\frac{g}{K}$. Cette conique a pour axe focal Oz.

Donc si $g < K$, la conique est une ellipse, et les surfaces de niveau sont des ellipsoïdes de révolution allongés ;

si $g > K$, ce sont des hyperboloïdes de révolution à deux nappes ;

si $g = K$, ce sont des paraboloïdes de révolution.

Cas particulier. — Si $h = 0$, la conique se réduit à deux droites, et la surface à un cône de révolution. Ce cône n'est réel que si $g > K$.

André Courtois, à Avesnes-sur-Helpe (Nord).

Bonnes solutions par MM. J. Dagnaux, à Dijon ; G. Lach, à Douai ; A. Rousseau, à Fournes-en Weppes ; Marcel Ullmann, 47e d'artillerie, à Héricourt.

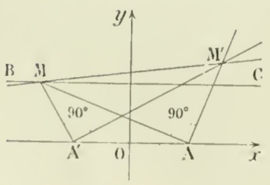
◆

CONCOURS DE 1913

ÉCOLE CENTRALE

Géométrie analytique.

2177. — Soient deux axes de coordonnées rectangulaires Ox et Oy ; sur Ox, un point A d'abscisse positive donnée a et un point A' d'abscisse négative $-a$. On considère la droite BC dont l'équation est $y - a = 0$, et un point M d'abscisse λ sur cette droite. On mène la droite MA et, en A, la perpendiculaire AM' à AM ; puis la droite MA' et, en A', la perpendiculaire A'M' à MA'. On demande de résoudre, dans l'ordre que l'on voudra, les deux questions suivantes :

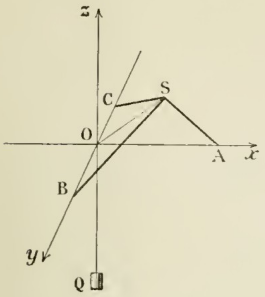


1° Lorsque λ varie, trouver et construire le lieu du point M' ;

2° Exprimer en fonction de λ les coordonnées du point de contact de la droite MM' avec son enveloppe, et construire cette enveloppe en faisant varier λ.

Mécanique.

2178. — Soient trois axes de coordonnées rectangulaires Ox, Oy, Oz, dont l'un Oz est vertical et dirigé positivement en sens contraire de la pesanteur. On donne, sur Ox, le point A d'abscisse positive a ; sur Oy,



le point B d'ordonnée positive $\frac{a}{2}$ et le point C d'ordonnée négative $-\frac{a}{3}$. Soit, en outre, un point S de coordonnées $x = \frac{a}{2}$, $y = 0$, $z = \frac{a}{2}$. On considère trois barres SA, SB, SC, rectilignes, homogènes, de poids respectifs connus P, P′, P″ et dont on néglige les épaisseurs. Elles sont soudées en S et forment un trièdre de figure invariable qui s'appuie sur le plan xOy, supposé non-déformable, aux points A, B, C.— Au point S est attaché un cordon de poids négligeable qui passe en O, sans frottement, sur une petite poulie fixe que l'on supposera réduite à ce point O. Ce fil est tendu par un poids Q. Il n'y a pas de frottement en B et en C, mais il y a en A un frottement de coefficient $f = 1$.

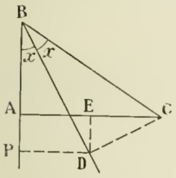
Trouver en fonction de P, P′, P″, la plus grande valeur de Q pour laquelle le trièdre peut rester en équilibre dans la position donnée et, pour cette valeur de Q, calculer les réactions du plan xOy en B et en C.

Effectuer les calculs, à un gramme près, sachant que $a = 60^{cm}$ et qu'un centimètre de longueur de chaque barre pèse 10^g.

(11 juin, de 7 h. à 11 h.)

Trigonométrie.

2179. — On considère un triangle ABC rectangle en A dont l'hypoténuse BC est égale à une longueur donnée a, et on prend sur la bissectrice intérieure de l'angle ABC une longueur BD égale à une longueur donnée l; on désigne par x la moitié de l'angle ABC.



1° Étudier la variation de la distance DE du point D au côté AC quand on fait varier x de 0 à $\frac{\pi}{4}$.

2° Déterminer l'angle x de façon que le rapport $\frac{DC}{DP}$ des distances du point D au point C et au côté AB soit égal à un nombre donné K. Discuter.

Nota. — On pourra traiter ces deux parties dans l'ordre que l'on voudra.

(13 juin, de 3 h. à 5 h.)

Calcul.

2180. — On donne

$$a = 223,$$
$$b = 283,$$
$$c = 324,$$
$$m = 830.$$

Calculer au moyen de la règle à calcul :

1° Les nombres r, u, v, w définis par

$$r = \sqrt{\frac{abc}{m}}, \qquad u = \sqrt{\frac{mbc}{a}}, \qquad v = \sqrt{\frac{mca}{b}}, \qquad w = \sqrt{\frac{mab}{c}};$$

les cubes r^3, u^3, v^3, w^3 et les inverses $\frac{1}{r}$, $\frac{1}{u}$, $\frac{1}{v}$, $\frac{1}{w}$, de ces quatre nombres ;

2° Les plus petits angles positifs x, y, z tels que $\operatorname{tg} x = \frac{r}{a}$, $\operatorname{tg} y = \frac{r}{b}$, $\operatorname{tg} z = \frac{r}{c}$;

3° Les sinus et cosinus de ces trois angles x, y, z.

Avis : La composition de calcul est faite avec une règle à calcul de 26^{cm} environ. Défense d'apporter en même temps une table de logarithmes.

(14 juin, de 3 h. à 4 h.)

Épure.

2181. — Cadre 27^{cm} sur 45^{cm}. Ligne de terre xy (en trait noir fin) petit axe ; ω centre. Les plans de projection existent et sont opaques. Titre extérieur : Ombres. — Titre intérieur : Ellipsoïde et Paraboloïde.

3° *On considère les triangles* ABC *variables, tels que les points* ω', ω'' *qui leur correspondent soient fixes et pour lesquels le produit des longueurs des médianes est donné. Trouver le lieu des sommets de ces triangles.* (*On pourra se borner à construire ce lieu dans le cas où les données sont telles que l'un des triangles* ABC *ait deux sommets confondus.*)

Étant donné un point A *du lieu, construire le triangle* ABC *qui lui correspond.*

1. Si p_1 est nul, il est évident que la fonction des racines $u = z_1^2 - z_2 z_3$ est égale à $z_2^2 + z_3^2 + z_2 z_3$; pour le voir, il n'y a qu'à remplacer z_1 par $-(z_2 + z_3)$ dans l'expression de u. On a donc alors

$$2u = z_1^2 - z_2 z_3 + z_2^2 + z_3^2 + z_2 z_3 = \Sigma z_1^2,$$

ce qui montre bien que u est une fonction symétrique des racines; dans le cas actuel, $u = -p_2$.

Considérons maintenant un polynome homogène et du second degré en z_1, z_2, z_3

$$u = a z_1^2 + b z_2^2 + c z_3^2 + 2a' z_2 z_3 + 2b' z_3 z_1 + 2c' z_1 z_2;$$

s'il est équivalent à une fonction symétrique des racines de l'équation du troisième degré, il ne doit pas changer par l'échange de z_1 avec z_2 et nous aurons aussi

$$u = az_2^2 + bz_1^2 + cz_3^2 + 2a'z_1z_3 + 2b'z_2z_3 + 2c'z_1z_2,$$

par suite, $$a(z_1^2 - z_2^2) - b(z_1^2 - z_2^2) - 2a'z_3(z_1 - z_2) + 2b'z_3(z_1 - z_2) = 0.$$

Supposons maintenant que l'équation ne soit pas une équation particulière ayant une racine double; nous pourrons diviser par $z_1 - z_2$ et nous aurons

$$(a - b)(z_1 + z_2) + 2(b' - a')z_3 = 0, \qquad \text{ou} \qquad (a - b)p_1 + [2(b' - a') + b - a]z_3 = 0.$$

Or ici z_3 désigne évidemment l'une quelconque des racines de l'équation du troisième degré; nous devrons donc avoir

$$(a - b)p_1 = 0, \qquad 2(b' - a') + b - a = 0.$$

Si p_1 n'est pas nul, nous aurons $b = a$ et $b' = a'$; de même, $c = a$, $c' = a'$; le polynome u est alors un polynome symétrique.

Si $p_1 = 0$, nous avons aussi

$$2(b' - a') + b - a = 0;$$

nous aurons de même

$$2(c' - b') + c - b = 0 \qquad \text{et} \qquad 2(a' - c') + a - c = 0.$$

Il est facile de voir que ces trois relations se réduisent à deux et que deux des six coefficients se déterminent à l'aide des quatre autres. En tenant compte de l'homogénéité du polynome par rapport aux six coefficients, nous voyons qu'il y a une triple infinité de tels polynomes, non symétriques par rapport aux lettres, mais équivalents à des fonctions symétriques des racines de l'équation du 3^e^ degré. Ceci n'a lieu d'ailleurs que dans le cas où p_1 est nul.

Les polynomes indiqués au début de l'énoncé : $z_1^2 - z_2z_3$, $z_2^2 - z_1z_3$, $z_3^2 - z_1z_2$, $z_1^2 + z_2^2 + z_1z_2$, etc., sont des cas particuliers de ceux que nous venons d'obtenir. Il est facile alors, en faisant $a = 1$ et remplaçant b par $1 + 2(a' - b')$, c par $1 + 2(a' - c')$, de vérifier que tous ces polynomes sont équivalents à des fonctions symétriques.

Appelons maintenant x, y, z les trois racines de l'équation et cherchons celle qui admet pour racines les valeurs de

$$t = x^2 + xy + y^2 = (x + y)^2 - xy.$$

Nous avons $$x + y = p_1 - z, \qquad xy = \frac{p_3}{z},$$

et $$t = (p_1 - z)^2 - \frac{p_3}{z} = \frac{z^3 - 2p_1z^2 + p_1^2z - p_3}{z};$$

puis, comme $z^3 - p_1z^2 + p_2z - p_3 = 0$,

$$t = \frac{-p_1z^2 + p_1^2z - p_2z}{z} = -p_1z + p_1^2 - p_2.$$

Il suffit donc de faire la transformation

$$z = \frac{p_1^2 - p_2 - t}{p_1},$$

ce qui donne l'équation du troisième degré en t

$$(p_1^2 - p_2 - t)^3 - p_1^2(p_1^2 - p_2 - t)^2 + p_1^2p_2(p_1^2 - p_2 - t) - p_1^3p_3 = 0.$$

Cette équation, développée, s'écrit

$$t^3 - (2p_1^2 - 3p_2)t^2 + (p_1^4 - 3p_1^2p_2 + 3p_2^2)t - (p_1^2p_2^2 - p_2^3 - p_1^3p_3) = 0,$$

et il n'y a plus qu'à l'identifier avec l'équation donnée pour obtenir les relations qui doivent exister entre p_1, p_2, p_3 :

$$2p_1^2 - 3p_2 = p_1, \qquad p_1^4 - 3p_1^2p_2 + 3p_2^2 = p_2, \qquad p_1^2p_2^2 - p_2^3 - p_1^3p_3 = p_3.$$

Ces relations nous donnent

$$p_2 = \frac{2p_1^2 - p_1}{3}, \qquad p_3 = \frac{p_1^2p_2^2 - p_2^3}{1 + p_1^3},$$

et enfin $$p_1^4 - p_1^2(2p_1^2 - p_1) + \frac{(2p_1^2 - p_1)^2}{3} - \frac{2p_1^2 - p_1}{3} = 0;$$

cette dernière donne p_1 et les autres donnent ensuite p_2 et p_3.

Développons l'équation en p_1 ; elle s'écrit

$$p_1^4 - p_1^3 - p_1^2 + p_1 = 0,$$

puis

$$p_1(p_1 - 1)^2(p_1 + 1) = 0.$$

Elle donne successivement : $p_1 = 0$, $p_1 = 1$, $p_1 = -1$; mais puisque $p_1 = 0$, il n'y a que deux valeurs acceptables, les valeurs $p_1 = 1$ et $p_1 = -1$.

Pour $p_1 = 1$, nous avons $p_2 = \frac{1}{3}$, $p_3 = \frac{1}{27}$ et l'équation en z est

$$z^3 - z^2 + \frac{z}{3} - \frac{1}{27} = 0 ;$$

la transformation est alors, $z = \frac{2}{3} - t$; deux des racines, z et t, ont pour somme $\frac{2}{3}$, l'autre est égale à $\frac{1}{3}$, le produit zt à $\frac{1}{9}$, les trois racines sont égales à $\frac{1}{3}$. Ceci se vérifie immédiatement en remarquant que le polynome $z^3 - z^2 + \frac{z}{3} - \frac{1}{27}$ est le cube de $z - \frac{1}{3}$.

Pour $p_1 = -1$, nous voyons que p_2 est égal à 1 et que p_3 est indéterminé. L'équation est alors

$$z^3 + z^2 + z - p_3 = 0 ;$$

la transformation est la transformation identique $z = t$, et ceci est facile à expliquer, car nous avons évidemment

$$z_1^3 + z_1^2 + z_1 = z_2^3 + z_2^2 + z_2, \qquad \text{ou} \qquad (z_1 - z_2)(z_1^2 + z_1 z_2 + z_2^2 + z_1 + z_2 + 1) = 0.$$

Ceci nous montre que

$$z_1^2 + z_1 z_2 + z_2^2 + z_1 + z_2 + 1 = 0, \qquad \text{ou} \qquad z_1^2 + z_1 z_2 + z_2^2 = z_3 ;$$

les trois valeurs de la fonction $x^2 + xy + y^2$ sont donc égales aux trois racines de l'équation proposée.

2. Les médianes des triangles ABC se coupant au point O, la somme des affixes de ces trois points, $z_1 + z_2 + z_3$, est nulle et ces trois nombres sont racines d'une équation du troisième degré de la forme $z^3 + p_2 z - p_3 = 0$. Nous savons alors que la quantité $z_1^2 + z_1 z_2 + z_2^2$ est équivalente à une fonction symétrique des racines ; c'est donc un invariant relatif aux sommets du triangle. D'autre part, nous avons

$$I = z_2^2 + z_1 z_2 + z_1^2 = (z_2 - \alpha z_1)(z_2 - \alpha^2 z_1),$$

α et α^2 étant les deux racines cubiques imaginaires de l'unité, par exemple $\alpha = \cos\frac{2\pi}{3} + i \sin\frac{2\pi}{3}$.

Appelons alors z_1' et z_1'' les affixes des points A' et A'' : nous aurons

$$z_1' = z_1\left(\cos\frac{\pi}{3} + i \sin\frac{\pi}{3}\right), \qquad \alpha z_1' = - z_1 ;$$

nous aurons de même $\alpha^2 z_1'' = - z_1$: par suite, $z_1 = - \alpha^2 z_1$, $z_1'' = - \alpha z_1$.

L'invariant I est donc égal à $(z_2 + z_1')(z_2 + z_1'')$.

Soient alors z' et z'' les affixes des milieux de BA′ et BA″ ; nous voyons que

$$I = 4z'z'', \qquad z'z'' = \frac{I}{4},$$

et qu'en posant $z^2 = \frac{I}{4} = z'z''$, nous définirons un couple de points ω' et ω'', qui sera le même pour tous les couples de milieux, tels que A_1' et A_1''. Ces deux points sont symétriques par rapport au point O, sur la bissectrice de l'angle (OA_1', OA_1'') et à des distances de O égales à $\sqrt{|z'|\,|z''|} = \frac{1}{2}\sqrt{|I|}$.

Figurons alors les cinq points O, A_1', A_1'', ω' et ω''. Nous savons que

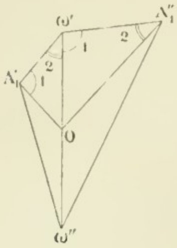

Fig 1.

$$\overline{A'_1 O\omega'} = \overline{\omega' O A''_1} \qquad \text{et} \qquad \overline{O\omega'}^2 = OA'_1 . OA''_1 ;$$

par conséquent $\frac{O\omega'}{OA'_1} = \frac{OA''_1}{O\omega'}$ et les deux triangles $OA'_1\omega'$, $O\omega'A''_1$ sont semblables, les angles 1 et 1, ainsi que 2 et 2, sont égaux ; l'angle ω' est donc le supplément de l'angle $A'_1O\omega'$; de même l'angle ω'' est le supplément de l'angle $A'_1O\omega''$, et le quadrilatère $\omega' A''_1 \omega'' A'_1$ est inscriptible. Il en est de même de tous ceux qu'indique l'énoncé (*fig.* 1 et 2).

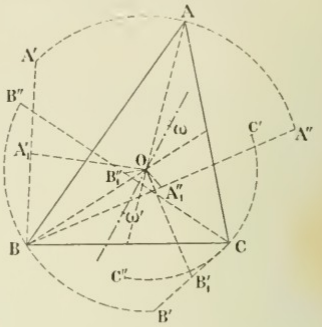

Fig. 2.

Soit λ le rapport d'homothétie du triangle $A_1B_1C_1$ au triangle ABC, les affixes des sommets de ce nouveau triangle sont λz_1, λz_2, λz_3. D'autre part, appelons maintenant z'_1 l'imaginaire conjugué de z_1, z_0 l'affixe du point ω' et z'_0 son imaginaire conjugué, enfin k la puissance d'inversion ; nous aurons, pour transformer un point quelconque du plan, $Z - z_0 = \frac{k}{z' - z'_0}$, $Z = X + iY$ étant l'affixe du point transformé de $z = x + iy$.

Appliquons aux trois points A_1, B_1, C_1, qui se transforment en A_2, B_2, C_2, et appelons Z_1, Z_2, Z_3 les affixes de ces nouveaux points ; nous aurons

$$Z_1 - z_0 = \frac{k}{\lambda z'_1 - z'_0}, \qquad Z_2 - z_0 = \frac{k}{\lambda z'_2 - z'_0}, \qquad Z_3 - z_0 = \frac{k}{\lambda z'_3 - z'_0};$$

puis,

$$Z_1 + Z_2 + Z_3 - 3z_0 = \frac{k}{\lambda z'_1 - z'_0} + \frac{k}{\lambda z'_2 - z'_0} + \frac{k}{\lambda z'_3 - z'_0}.$$

Si nous voulons que le point ω' soit le centre des moyennes distances des trois points A_2, B_2, C_2, il faudra que $Z_1 + Z_2 + Z_3 - 3z_0 = 0$, ou

$$\frac{1}{\lambda z'_1 - z'_0} + \frac{1}{\lambda z'_2 - z'_0} + \frac{1}{\lambda z'_3 - z'_0} = 0 ;$$

ce qui donne

$$\lambda^2 \Sigma z'_1 z'_2 - 2\lambda z'_0 \Sigma z'_1 + 3 z_0'^2 = 0.$$

Or $\Sigma z'_1 = 0$, $\Sigma z'_1 z'_2 = z'_1 z'_2 + z'_3(z'_1 + z'_2) = z'_1 z'_2 - (z'_1 + z'_2)^2$, $\Sigma z'_1 z'_2 = - z_1'^2 - z'_1 z'_2 - z_2'^2 = - I'$; d'autre part, $4z_0^2 = I$, $4z_0'^2 = I'$; donc l'équation qui donne λ devient

$$4 z_0'^2 \lambda^2 - 3 z_0'^2 = 0, \qquad \lambda^2 = \frac{3}{4}.$$

Il suffit donc de prendre $\lambda = \pm \frac{\sqrt{3}}{2}$.

3. Nous prendrons ici pour axe des x la droite $\omega'\omega''$ et pour origine des coordonnées le milieu de ce segment. Nous savons que z_0^2, qui se réduit ici à $\overline{O\omega'}^2$, est égal à $\frac{1}{4}$; d'autre part, nous avons vu au début que I ou u est égal à $\frac{z_1^2 + z_2^2 + z_3^2}{2}$, c'est-à-dire ici à $-p_2$, puisque $z_1 + z_2 + z_3$ est nul ; donc p_2 est constant et réel, et même négatif. D'ailleurs le produit des médianes étant constant, cela veut dire que le produit des longueurs OA, OB, OC est constant ; donc le module de p_3 est constant et égal à a^3.

Posons $x = \rho \cos \omega$, $y = \rho \sin \omega$, $z = \rho(\cos \omega + i \sin \omega)$; l'équation $z^3 + p_2 z - p_3 = 0$ deviendra

$$\rho^3(\cos 3\omega + i \sin 3\omega) + p_2\rho(\cos \omega + i \sin \omega) = p_3 = a^3(\cos \lambda + i \sin \lambda) ;$$

elle se décompose en deux :

$$\rho^3 \cos 3\omega + p_2\rho \cos \omega = a^3 \cos \lambda,$$
$$\rho^3 \sin 3\omega + p_2\rho \sin \omega = a^3 \sin \lambda,$$

et l'élimination de λ entre ces deux équations est immédiate ; elle donne l'équation du lieu des sommets

$$\rho^6 + 2p_2\rho^4 \cos 2\omega + p_2^2\rho^2 = a^6.$$

Quand deux des sommets B et C sont confondus, le triangle s'aplatit sur une droite AB, le point O est sur cette droite aux $\frac{2}{3}$ à partir de A, et la droite $\omega'\omega''$, c'est-à-dire Ox, est sur cette droite AB, qui correspond à ce triangle particulier. Nous avons alors $4p_2^3 + 27p_3^2 = 0$, le p_3 de ce triangle est réel et se réduit à a^3. Changeons de notation et posons alors $p_3^2 = 4l^6$; nous aurons $p_2^3 = -27l^6$, $p_2 = -3l^2$, et l'équation du lieu deviendra, dans ce cas particulier,

$$\rho^6 - 6l^2\rho^4 \cos 2\omega + 9l^4\rho^2 - 4l^6 = 0.$$

Pour construire cette courbe, au moins sommairement, remarquons que l'équation en ρ a des coefficients périodiques, et que leur période est π ; il suffit donc de faire varier ω dans un intervalle d'étendue 2π. Or le changement de ω en $-\omega$ laisse l'équation invariable ; donc la courbe est symétrique par rapport à Ox, et en tenant compte de cette symétrie, il suffit de faire varier ω de 0 à π ; le changement de ω en $\pi - \omega$ laisse encore l'équation invariable ; la courbe est symétrique par rapport à Oy, et, en tenant compte aussi de cette nouvelle symétrie, il suffit de faire varier ω de 0 à $\frac{\pi}{2}$.

Pour $\omega = 0$, l'équation devient

$$\rho^6 - 6l^2\rho^4 + 9l^4\rho^2 - 4l^6 = 0,$$

ou

$$\rho^2(\rho^2 - 3l^2)^2 - 4l^6 = 0 ;$$

elle se décompose en

$$\rho^3 - 3l^2\rho + 2l^3 = 0.$$
$$\rho^3 - 3l^2\rho - 2l^3 = 0 ;$$

la première admet la racine positive double $\rho = l$, et la seconde, la racine positive simple $\rho = 2l$; le premier point de Ox, A, est un point double, le second, B, est un point simple.

Quand ω augmente, $\cos 2\omega$ diminue, la somme des valeurs de ρ^2 diminue ; pour $\omega = \frac{\pi}{4}$, l'équation n'a déjà plus qu'une seule racine positive et cela se poursuit jusqu'à $\omega = \frac{\pi}{2}$. A ce moment, l'équation devient

$$\rho^6 + 6l^2\rho^4 + 9l^4\rho^2 - 4l^6 = 0, \qquad \text{ou} \qquad \rho^2(\rho^2 + 3l^2)^2 - 4l^6 = 0 ;$$

elle se décompose en

$$\rho^3 + 3l^2\rho - 2l^3 = 0, \qquad \text{et} \qquad \rho^3 + 3l^2\rho + 2l^3 = 0,$$

qui n'admettent qu'une racine positive, comprise entre 0 et l.

Pour savoir à quel moment l'équation cesse d'avoir trois racines positives, il suffit d'annuler le discriminant de l'équation cubique en ρ^2. Ceci donne, en posant $\cos 2\omega = u$, la relation

$$32u^3 - 27u^2 - 36u + 31 = 0,$$

qui se décompose en $u - 1 = 0$ et $32u^2 + 5u - 31 = 0$.

L'unique valeur positive de u est donc

$$u = \cos 2\omega = \frac{-5 + \sqrt{3993}}{64}, \qquad \cos 2\omega = \frac{63,1 - 5}{64} = \frac{58,1}{64} = 0,90 ;$$

cette valeur de 2ω est voisine de 65°, et ω a pour valeur correspondante un nombre α voisin de 37 ou 38°.

Alors de 0 à α, il y a trois valeurs positives de ρ ; pour $\omega = \alpha$, deux d'entre elles sont confondues ; la droite $\omega = \alpha$ est tangente à la courbe ; enfin, au delà, de $\omega = \alpha$ à $\omega = \frac{\pi}{2}$, il n'y a plus qu'un seul ρ qui soit positif, les deux autres ont cessé d'être réels.

Vérifions enfin que le point A est un point double. Pour cela, formons tg V en ce point : nous avons

$$\operatorname{tg} V = \rho \frac{d\omega}{d\rho}; \qquad \text{d'autre part} \qquad \cos 2\omega = \frac{\rho^6 + 9l^4\rho^2 - 4l^6}{6l^2\rho^4},$$

$$\cos 2\omega = \frac{\rho^2}{6l^2} + \frac{3}{2} l^2 \frac{1}{\rho^2} - \frac{2}{3} \frac{l^4}{\rho^4}, \qquad -2\sin 2\omega \frac{d\omega}{d\rho} = \frac{\rho}{3l^2} - \frac{3l^2}{\rho^3} + \frac{8}{3} \frac{l^4}{\rho^5} = \frac{\rho^6 - 9l^4\rho^2 + 8l^6}{3l^2\rho^5},$$

$$\frac{d\omega}{d\rho} = - \frac{(\rho^2 - l^2)(\rho^4 + l^2\rho^2 - 8l^4)}{6l^2\rho^5 \sin 2\omega}.$$

Dans le second nombre, l'un des facteurs, $-\frac{\rho^4 + l^2\rho^2 - 8l^4}{6l^2\rho^5}$, a pour limite $\frac{1}{l^3}$. quand ω tend vers 0 et ρ vers l; l'autre facteur, $\frac{\rho^2 - l^2}{\sin 2\omega}$, prend une forme indéterminée, et en lui appliquant la règle de L'Hospital, et appelant λ la limite de $\frac{d\omega}{d\rho}$, on a $\lambda = \frac{1}{l^3}\frac{l}{\lambda}$, $\lambda^2 = \frac{1}{l^2}$, $\lambda = \pm \frac{1}{l}$.

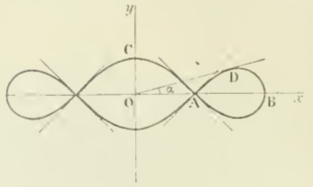

Fig. 3.

Les deux valeurs de $\operatorname{tg} V$ sont donc $\operatorname{tg} V = \pm 1$. La courbe a la forme ci-contre (*fig.* 3).

Lorsqu'on se donne le point A, on se donne l'affixe, z_1, de ce point, et il suffit de trouver les affixes des deux autres points, z_2 et z_3.

Or on a $z_2 + z_3 = - z_1$, $\quad I = - p_2 = 3l^2 = z_2^2 + z_3^2 + z_2 z_3$, $\quad I = 3l^2 = z_1^2 - z_2 z_3$;
ceci donne

$$z_2 z_3 = z_1^2 - 3l^2,$$

et nous sommes ramenés à construire deux affixes dont la somme et le produit sont donnés.

◆

GÉOMÉTRIE ANALYTIQUE

2106 — *On considère un faisceau ponctuel de coniques et une droite* Δ *: le pôle de* Δ *décrit une conique* Γ *harmoniquement circonscrite au faisceau. Les tangentes à* Γ *aux sommets du triangle conjugué rencontrent les côtés opposés en trois points situés sur une même droite* Δ' *: les deux droites* Δ *et* Δ' *sont réciproques. Soit* Γ' *la conique qui correspond à* Δ'.

Démontrer que si l'une des droites Δ, Δ' *tourne autour d'un point fixe, l'autre enveloppe une conique harmoniquement inscrite au faisceau; que le point d'intersection de* Δ *et de* Δ' *décrit une cubique, et que le quatrième point de rencontre des coniques* Γ *et* Γ' *décrit une sextique ayant trois points triples aux sommets du triangle conjugué.*

Prenons pour triangle de référence le triangle conjugué commun à toutes les coniques du faisceau donné : si nous désignons par

$$x^2 + y^2 + z^2 = 0, \qquad Ax^2 + By^2 + Cz^2 = 0$$

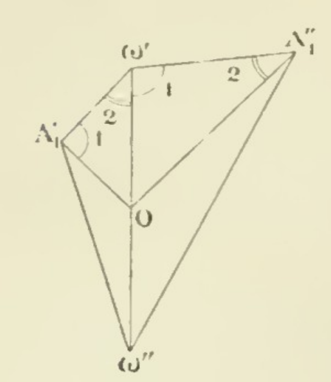
les équations de deux de ces coniques, l'équation générale des coniques de ce faisceau sera

$$(A + \lambda)x^2 + (B + \lambda)y^2 + (C + \lambda)z^2 = 0.$$

Le pôle de la droite Δ, $ux + vy + wz = 0$, est défini par les équations

$$\frac{(A + \lambda)x}{u} = \frac{(B + \lambda)y}{v} = \frac{(C + \lambda)z}{w};$$

on aura le lieu de ce point en éliminant λ entre ces trois équations. Pour faire cette élimination, nous égalons ces trois rapports à un paramètre $-\rho$, nous obtenons trois équations linéaires en λ et ρ et



ω'

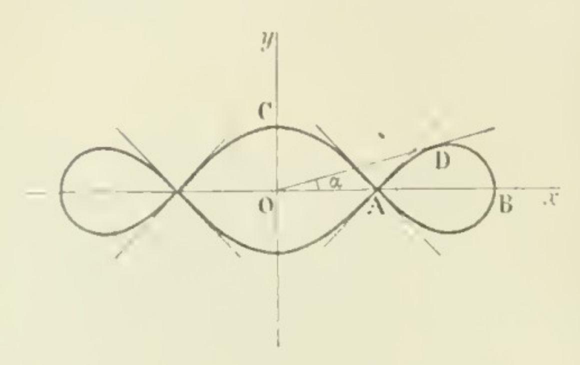
C
C''
B'_1
B'



y
C
D
α
O
A
B
x

' "/ 0

Enfin, pour avoir le lieu du quatrième point de rencontre des coniques Γ et Γ′, nous éliminons u, v, w entre les équations

$$ux_0 + vy_0 + wz_0 = 0,$$
$$auyz + bvzx + cwxy = 0,$$
$$\frac{yz}{u} + \frac{zx}{v} + \frac{xy}{w} = 0.$$

Des deux premières nous tirons

$$\frac{u}{x(cyy_0 - bzz_0)} = \frac{v}{y(azz_0 - cxx_0)} = \frac{w}{z(bxx_0 - ayy_0)},$$

et en portant dans la troisième nous avons

$$\frac{yz}{x(cyy_0 - bzz_0)} + \frac{zx}{y(azz_0 - cxx_0)} + \frac{xy}{z(bxx_0 - ayy_0)} = 0,$$

ou

$$\frac{y^2z^2}{cyy_0 - bzz_0} + \frac{z^2x^2}{azz_0 - cxx_0} + \frac{x^2y^2}{bxx_0 - ayy_0} = 0.$$

Sous cette forme on reconnait l'équation d'une sextique ayant trois points triples aux sommets du triangle conjugué.

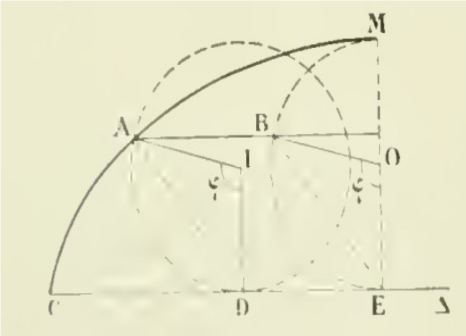
CONCOURS DE 1913 (*Suite.*)

ÉCOLE DES PONTS ET CHAUSSÉES

(Cours spéciaux et places réservées aux sous-ingénieurs et conducteurs.)

Algèbre et Analyse.

I. — **2191.** Un tore circulaire circonscrit à une sphère de rayon R satisfait aux conditions suivantes : le plan du parallèle inférieur passe par le centre de la sphère; le diamètre y du méridien est inférieur ou égal à R; le



. 9(:69 9 92 9 , * ! 3 3!
' ,/ " :) v v)

En revenant aux coordonnées X, Y, ($x = aX$, $y = bY$), cette équation devient

$$abXY - \alpha bY - \beta aX = 0.$$

Posons, pour la symétrie des notations, $\alpha = aA$, $\beta = bB$, en remarquant que, par suite, on a la condition $A + B = 1$; l'hyperbole lieu de M devient

$$XY - AX - BY = 0.$$

Pour qu'on puisse trouver sur ce lieu deux points M et M′, il faut que cette hyperbole puisse appartenir au faisceau des deux hyperboles

$$XY - X + R = 0, \qquad XY - Y + S = 0.$$

En multipliant la première équation par S et en retranchant la seconde multipliée par R, on en déduit par identification :

$$A = \frac{S}{S - R}, \qquad B = \frac{R}{R - S},$$

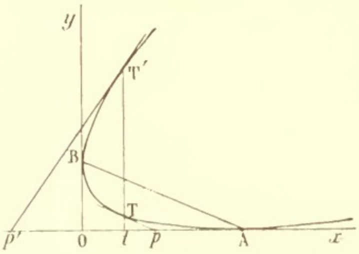
qui vérifie bien

$$A + B = 1.$$

A et B étant connus, on voit que R et S sont soumis à une seule condition ; on peut la mettre sous la forme symétrique

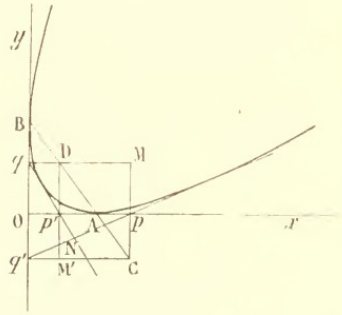
$$AR + BS = 0.$$

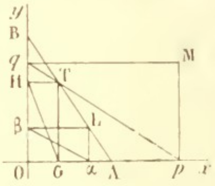
ou, avec les anciennes notations, $\frac{\alpha r}{a^2} + \frac{\beta s}{b^2} = 0$, ce qui exprime que le lieu de N est le diamètre conjugué par rapport à l'ellipse de centre O, de sommets A et B, de la droite joignant l'origine au point de AB qui a pour coordonnées α, β.



Remarques géométriques. — 1° Il est bien évident, d'après la figure même, qu'à un point p ne correspond qu'un point t ; mais qu'à un point t correspondent deux points T et T′, et par suite deux points p, p', qui forment une involution. Considérons les quatre tangentes fixes à (P) : Tp, T′p', Oy et la droite de l'infini. Le rapport anharmonique qu'elles interceptent sur une tangente quelconque est constant. En prenant la tangente infiniment voisine de Oy et remarquant que TT′ est parallèle à Oy, on en déduit que ce rapport est -1. Donc si nous coupons par Ox tangente à (P) on voit que O est le milieu de pp', ce qui montre que l'involution de ces deux points est une symétrie.

2° La figure montre immédiatement qu'à un point M correspond un seul point N et à un point N deux points M. Si l'on remarque que toute tangente à P, pq', est telle que p et q' soient les projections sur les axes d'un point C de AB, on voit que MCM′D est un rectangle dont AB est une diagonale ; on en déduit immédiatement la construction de M′ connaissant M, telle qu'elle a été donnée ci-dessus. On sait de plus que, dans un rectangle tel que MCM′D, les trois diagonales de MCM′D, pCq'O et qOp'D sont concourantes ; donc N est sur MM′.





Si M et M′ sont confondus, ils sont sur AB, et p, p' sont confondus ainsi que q, q'. Les deux tangentes pq', $p'q$ étant confondues, leur point de rencontre est leur point de contact ; donc N décrit (P).

Si M et N sont confondus, pM et pN étant confondus, pN est une tangente verticale à (P). On trouverait de même la tangente horizontale à (P), résultats déjà obtenus par le calcul.

3° On sait que si l'on projette un point quelconque L de AB sur les axes en α et β, la droite $\alpha\beta$ est tangente à la parabole bitangente aux axes en A et B. De même pour tout point de la droite pq. Si donc on veut une tangente commune autre que les axes, ou la droite de l'infini, aux deux paraboles de l'énoncé, il suffira de prendre le point de rencontre de AB et pq, **T**, et de le projeter sur les axes, en G, H. GH est Δ_M.

Si cette droite est fixe, T' l'est aussi, et par suite pq passe par un point fixe T. On en déduit qu'il y a correspondance homographique entre p et q, et que par suite M décrit une hyperbole équilatère de directions asymptotiques Ox, Oy.

MÉCANIQUE

1918. — 1° *On considère un point* M *mobile dont la trajectoire est la cubique gauche* Γ, $x = at$, $y = bt^2$, $z = ct^3$, *a, b, c étant les coordonnées d'un point* P *fixe et t désignant le temps. On suppose a, b, c positifs et non nuls. On suppose dans la suite que le point* P *reste sur une surface* (S) *telle que pour les valeurs ainsi définies de a, b, c, le vecteur-vitesse en chaque point de* Γ *fasse un angle constant, que l'on calculera, avec une droite* Δ *convenablement choisie.*

P *étant fixe, étudier en chaque point de* Γ *la vitesse. Hodographe. (On déterminera en vraie grandeur les éléments de l'hodographe.)*

2° *Calculer en chaque point de* Γ *l'accélération totale et l'accélération tangentielle du mobile. Déduire de leur comparaison le rayon de courbure de* Γ. *Variations de ce rayon de courbure.*

3° *A chaque point* P *de* S *correspond un certain mouvement.* P *étant supposé arbitraire sur* S, *y a-t-il un nombre fini ou infini de mouvements faisant passer le point* M *par un point* Q *donné de l'espace (deux mouvements distincts pouvant d'ailleurs correspondre à une même trajectoire). Discuter suivant la position de* Q.

4° *Étant donné un point* Q *on considère le mouvement qui fait passer* M *en* Q *au temps t', le temps* 0 *correspondant au passage du mobile à l'origine. On suppose que ce mobile quitte sa trajectoire en* Q *suivant la tangente avec une vitesse uniforme égale précisément à sa vitesse au passage par* Q. *Lieu des points* Q' *occupés dans cette hypothèse par le mobile au temps* $t' + 1$ *quand* Q *occupe toutes les positions possibles (On suppose que t' a une valeur fixe donnée).*

1° Soient α, β, γ les cosinus directeurs de la direction cherchée ; l'angle V de la tangente à Γ avec cette direction est donné par

$$\cos^2 V = \frac{(a\alpha + 2b\beta t + 3ct^2\gamma)^2}{a^2 + 4b^2t^2 + 9c^2t^4}.$$

Ce rapport doit être indépendant de t ; en particulier les termes en t et t^3 doivent disparaître au numérateur, ce qui donne, a, b, c ne pouvant pas être nuls, $\alpha = \gamma = 0$, ou $\beta = 0$. La première hypothèse ne convient pas. La seconde donne, en écrivant que les divers coefficients sont proportionnels au numérateur et au dénominateur,

$$\alpha^2 = \frac{6ac\alpha\gamma}{4b^2} = \gamma^2.$$

On a $\alpha = \gamma$, ou $\alpha = -\gamma$. Mais a, b, c devant être positifs, on en déduit $\alpha = \gamma$, ce qui fixe la direction demandée et l'angle V (45°) ; on trouve en outre la condition

$$3ac = 2b^2,$$

équation d'un cône qui est le lieu cherché de P. P étant sur ce cône (S), toute la cubique Γ y est également, comme on le vérifie aisément.

La vitesse en un point de Γ est donnée par $X = a$, $Y = 2bt$, $Z = 3ct^2$. L'hodographe est la parabole du plan $X = a$, d'équation $Y^2 = \frac{4b^2}{3c} Z$ ou $Y^2 = 2aZ$.

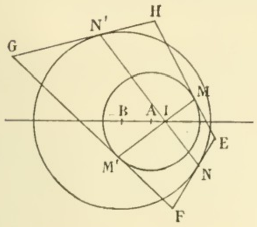
CONCOURS DE 1911 *(Suite.)*

AGRÉGATION DES SCIENCES MATHÉMATIQUES

Mathématiques élémentaires [1].



1° Si l'on mène à une ellipse (C) de centre C deux cercles bitangents, l'un (A) ayant son centre A sur l'axe focal, l'autre (B) ayant son centre B sur l'axe non focal, le point d'intersection I des cordes de contact MM' et NN' est un point limite pour le système des deux cercles. (On demande aux candidats une démonstration indépendante de la théorie des pôles et polaires dans les coniques ; s'ils emploient l'équation de la droite AB, rapportée aux axes de l'ellipse, pour montrer d'abord que le point I est sur cette droite, ils établiront géométriquement les formules qui expriment $\overline{\mathrm{CA}}$ et $\overline{\mathrm{CB}}$ au moyen des coordonnées $\overline{\mathrm{CP}}$ et $\overline{\mathrm{CQ}}$ du point I. Ils pourront donner *subsidiairement* une démonstration fondée sur la théorie des pôles et polaires dans les coniques).

2° On donne deux cercles (A) et (B), de centres A et B, dont l'un (A) est intérieur à l'autre ; soit I celui des deux points limites du faisceau (A, B) qui est intérieur aux deux cercles. (Ce choix du point I a pour but d'écarter une discussion que les candidats n'auraient pas le temps de faire convenablement).

Si l'on mène par I deux cordes rectangulaires MM' et NN' appartenant respectivement aux deux cercles, il existe une ellipse (C) doublement tangente aux deux cercles, les cordes de contact étant MM' et NN' ; le démontrer. Les cordes variant, les pôles R et S de ces cordes sont sur une droite fixe Δ perpendiculaire à la droite AB en un point J ; les circonférences qui ont pour diamètres les segments RS sont orthogonales à la circonférence de diamètre AB qui est le lieu des centres des ellipses (C) ; les carrés a^2 et b^2 des demi-axes des ellipses (C) sont, les uns et les autres, proportionnels aux distances CD des centres C à la droite Δ : les ellipses (C) sont, par suite, semblables entre elles.

3° Les données restant les mêmes, les tangentes en M et M' sont rencontrées par les tangentes en N et N' aux points E, F, G, H. Désignant par λ l'angle que fait IM avec le prolongement de BA, on établira les *six* relations qui déterminent en fonction des constantes de la figure $\left(r,\ \mathrm{R},\ \frac{\mathrm{IA}}{r} = \mathrm{A},\ \frac{\mathrm{IB}}{\mathrm{R}} = \mathrm{B}\right)$ et du paramètre λ les éléments essentiels du quadrilatère IMEN, à savoir les angles $\mathrm{IME} = \alpha$, $\mathrm{INE} = \beta$, les côtés IM et IN, les côtés EM et EN ; les deux dernières de ces relations sont

$$\mathrm{EM} \sin \alpha + \mathrm{EN} \cos \beta = \frac{\mathrm{R} \sin (\beta - \lambda)}{\cos \lambda},$$

$$\mathrm{EM} \cos \alpha + \mathrm{EN} \sin \beta = \frac{- r \cos (\lambda + \alpha)}{\sin \lambda}.$$

Vérifier au moyen de ces relations l'égalité $\frac{\mathrm{EM}}{\mathrm{EN}} = \frac{\mathrm{B}}{\mathrm{A}}$, et en déduire que le quadrilatère EFGH reste inscrit à un cercle fixe (O) du faisceau (A, B) lorsque les cordes MM' et NN' varient. On determinera la position du centre O de ce cercle en fonction des longueurs IA, IB, JA, JB, JI, en calculant successivement $\frac{\mathrm{OA}}{\mathrm{OB}}$, OA, OB ; on calculera aussi la distance JO, on interprètera géometriquement la formule obtenue, et l'on en déduira une conséquence pour les circonférences décrites sur les segments RS comme diamètres.

Comparant deux expressions différentes de la valeur du rapport $\frac{\mathrm{ME}}{\mathrm{MH}}$ en fonction des quantités IE, IH, $\widehat{\mathrm{MIE}} = \gamma$, $\widehat{\mathrm{MIH}} = \delta$, on obtiendra $\gamma = \delta$, et on interpretera ce resultat en considerant les diagonales EG et FH. De quelle nature est la correspondance entre les droites EG et FH ?

Mathématiques spéciales.

1968. — On considère dans un plan la parabole (P) et la droite (D) dont les equations sont, en coordonnées rectangulaires,

$$y^2 - 2px = 0, \qquad y - a = 0.$$

REVUE
DE
MATHÉMATIQUES SPÉCIALES

11e Année. — N° 1. Octobre 1900.

PREMIÈRE PARTIE

DÉMONSTRATION DU THÉORÈME DE PONCELET SUR LES POLYGONES INSCRITS DANS UNE CONIQUE ET CIRCONSCRITS A UNE AUTRE

par M. **E. Cahen**, professeur de Mathématiques spéciales au Collège Rollin.

Dans le n° 9 de l'année 1900 de ce journal, M. Fontené considère deux points d'une conique V, dont les paramètres t et t' sont liés par une relation *doublement quadratique* et *symétrique*

$$A t^2 t'^2 + B t t'(t + t') + C(t^2 + t'^2) + D t t' + E(t + t') + F = 0. \tag{1}$$

La droite qui joint ces deux points enveloppe une conique U *et, réciproquement.*

Si la droite qui joint deux points d'une conique V *est tangente à une conique* U, *les paramètres de ces deux points sont liés par une relation de la forme précédente.*

Bien entendu, les énoncés corrélatifs sont vrais.

Comme application, M. Fontené indique le *lieu du troisième sommet d'un triangle circonscrit à une conique* U *et dont les deux autres sommets décrivent une conique* S et l'enveloppe corrélative.

Ceci peut se généraliser :

Soient deux coniques V *et* U. *Un polygone de* p *côtés est inscrit dans* V *et* $p - 1$ *de ses côtés sont tangents à* U. *Quelle est l'enveloppe du* p^e *côté ?* (Sur la figure $p = 5$).

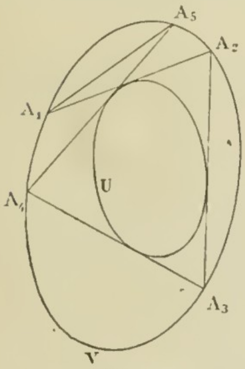

Fig. 1.

Or, il y a entre les paramètres des points A_1 et A_p sur la conique V, une relation qui est évidemment *algébrique* et *symétrique*. D'autre part, cette relation est du second degré. En effet, si l'on se donne A_1 il y a deux positions possibles pour A_2; mais si l'on choisit l'une de ces positions il y a une position déterminée pour A_3 puis une pour A_4 et ainsi de suite. Donc si l'on se donne A_1, il y a deux positions possibles pour A_p. La relation *algébrique*, *symétrique* entre les paramètres de A_1 et de A_p est donc, de plus, du second degré. Donc A_1A_p *enveloppe une conique*.

Corrélativement : *Un polygone de* p *côtés étant circonscrit à une conique et* $p - 1$ *de ses sommets étant sur une autre, le lieu du* p^e *sommet est une conique.*

Pour arriver au théorème de Poncelet, cherchons s'il existe un polygone de p côtés inscrit dans V et circonscrit à U. Or, si d'un point A_1 de U, on déduit, au moyen de p tangentes consécutives, un point A_{p+1}, il y a entre les paramètres de A_1 et de A_{p+1}, une relation

$$A^{(p+1)} t^2 t'^2 + B^{(p+1)} t t'(t + t') + C^{(p+1)}(t^2 + t'^2) + D^{(p+1)} t t' + E^{(p+1)}(t + t') + F^{(p+1)} = 0,$$

$A^{(p+1)}$, $B^{(p+1)}$, ... $F^{(p+1)}$ étant des coefficients qui dépendent de p.

Pour que le point A_1 soit sommet d'un polygone cherché, il faut et il suffit qu'il coïncide avec A_{p+1}.

On obtient donc son t, en faisant $t' = t$ dans l'équation précédente, ce qui donne

$$(2) \qquad A^{(p+1)}t^4 + 2B^{(p+1)}t^3 + [2C^{(p+1)} + D^{(p+1)}]t^2 + 2E^{(p+1)}t + F^{(p+1)} = 0.$$

Cette équation est du quatrième degré ; on trouve donc quatre positions pour le point A_1.

Mais il faut remarquer qu'il y a, quel que soit p, quatre positions du point A_1 dont les paramètres doivent satisfaire à l'équation (2), sans que ces points donnent de vrais polygones répondant à la question. Ce sont les *quatre points de contact avec* V, *des tangentes communes à* U *et* V.

Si on considère un tel point A_1 (voir la figure 2 où les tangentes communes à U et V sont réelles), il est évident qu'il coïncide avec les points A_2, A_3, ... A_{p+1}, ...

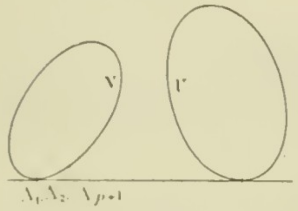

Fig. 2.

Donc l'équation (2) doit donner ces quatre solutions singulières, et comme elle est du quatrième degré, elle n'en donne, en général, pas d'autres.

Donc, en général, *il n'y a pas de vrai polygone de p côtés inscrit dans* V *et circonscrit à* U.

Mais on voit que s'il y en a un, l'équation (2) ayant plus de quatre racines est une identité. *Donc s'il y a un de ces polygones il y en a une infinité.* C'est le théorème de Poncelet.

On peut choisir arbitrairement un sommet du polygone sur V.

Corrélativement, on peut choisir arbitrairement un côté du polygone tangent à U (*).

Voici quelques remarques que suggère la méthode précédente.

Considérons un polygone de p côtés inscrit dans V et circonscrit à U ; si partant d'un sommet, on joint les sommets de q en q, jusqu'à ce qu'on revienne au point de départ, on forme un polygone de $\frac{p}{d}$ côtés (d étant le plus grand commun diviseur de p et q).

Or, entre les paramètres de deux sommets dont les rangs diffèrent de q, existe une relation doublement quadratique et symétrique, qui est la même, quelle que soit la position de ces sommets. Donc le polygone obtenu est circonscrit à une conique $U^{(q)}$, et cette conique reste la même si le polygone primitif varie en restant inscrit dans V et circonscrit à U. Au système de deux coniques U et V, correspondent ainsi p coniques

$$U^{(1)}, \qquad U^{(2)}, \ldots \qquad U^{(p)},$$

(dont la première est V, et la dernière U).

Sur ces p coniques, il y en a $\varphi(p)$ qui correspondent à des polygones de p côtés ; et plus généralement $\varphi\left(\frac{p}{d}\right)$ qui correspondent à des polygones de $\frac{p}{d}$ côtés.

(*) La démonstration précédente ne prouve pas qu'il existe effectivement des polygones de Poncelet. Il est clair qu'il en existe pour $p \leq 5$, car si l'on circonscrit un pentagone, par exemple, à une conique U, on peut faire passer une conique V par les cinq sommets de ce pentagone. Mais pour $p > 5$, ce raisonnement ne s'applique pas. On peut se borner à un exemple. Soit la parabole V,
$$x = t, \qquad y = t^2$$
et la parabole U dont l'équation est
$$x^2(1 + \cos\varphi) - 2y = 0.$$

On trouve facilement que la relation qui doit exister entre les paramètres t et t' de deux points A_1, A_2 de V pour que la droite A_1A_2 soit tangente à U est
$$t^2 + t'^2 - 2tt'\cos\varphi = 0.$$

Quant à la relation entre les paramètres t et $t^{(p)}$ de A_1 et de A_{p+1}, on voit (de proche en proche) que c'est
$$t^2 + t^{(p)2} - 2tt^{(p)}\cos p\varphi = 0.$$

L'équation (2) se réduit donc ici à
$$2(1 - \cos p\varphi)t^2 = 0.$$

Elle est une identité lorsque
$$\cos p\varphi = 1, \qquad \text{ou} \qquad \varphi = \frac{2k\pi}{p}.$$

Pour ces valeurs de φ, il existe des polygones de p côtés inscrits dans V et circonscrits à U.

En particulier, si p est pair, en faisant $q = \frac{p}{2}$, on est amené à joindre deux sommets opposés du polygone. Pour ces deux sommets la relation quadratique se réduit à une relation du premier degré symétrique, c'est-à-dire à une involution (car à un sommet du polygone ne correspond qu'un sommet opposé). Donc

Quand un polygone d'un nombre pair de côtés est inscrit dans une conique et circonscrit à une autre, les diagonales qui joignent les sommets opposés se coupent en un même point qui est fixe quand le polygone varie.

Dans les cas de l'hexagone, ce point est le point de Brianchon.

Tous ces théorèmes ont d'ailleurs leurs corrélatifs.

Par exemple, dans les polygones précédents, les points de rencontre des côtés opposés sont tous sur une même droite fixe. Dans le cas de l'hexagone, c'est la droite de Pascal.

◆

ALGÈBRE

904. — *Étant donnée une équation du quatrième degré* $f(x) = ax^4 + 4bx^3 + 6cx^2 + 4b'x + a' = 0$, *trouver les conditions qui doivent être remplies pour que l'équation* $f(y + h) = 0$ *soit réciproque pour trois valeurs de* h.

Dans ce cas, trouver les valeurs de h *et les racines de l'équation* $f(x) = 0$.

Si dans l'équation proposée, on effectue la substitution indiquée $x = y + h$, cette équation devient

$$ay^4 + 4(ah + b)y^3 + 6(ah^2 + 2bh + c)y^2 + 4(ah^3 + 3bh^2 + 3ch + b')y + ah^4 + 4bh^3 + 6ch^2 + 4b'h + a' = 0.$$

En écrivant que cette équation est une équation réciproque ordinaire, nous avons les deux relations

$$ah^4 + 4bh^3 + 6ch^2 + 4b'h + a' - a = 0,$$
$$ah^3 + 3bh^2 + (3c - a)h + b' - b = 0$$

qui doivent être vérifiées simultanément pour trois valeurs de h. Or, en multipliant la seconde par h et retranchant le résultat ainsi obtenu de la première, celle-ci s'abaisse au troisième degré et devient

$$bh^3 + (3c + a)h^2 + (3b' + b)h + a' - a = 0,$$

et nous avons alors à exprimer que les deux équations du troisième degré en h ont trois racines communes, par suite, qu'elles ont leurs coefficients proportionnels. Cela nous donne les relations

$$\frac{b}{a} = \frac{3c + a}{3b} = \frac{3b' + b}{3c - a} = \frac{a' - a}{b' - b}.$$

Posons alors $\frac{b}{a} = k$; nous aurons $\frac{3c}{a} = 3k^2 - 1$, $\frac{3b' + b}{a} = k(3k^2 - 2)$, d'où $\frac{b'}{a} = k(k^2 - 1)$;

et enfin $$\frac{a' - a}{a} = k^2(k^2 - 2) \quad \text{et} \quad \frac{a'}{a} = (k^2 - 1)^2.$$

L'équation du quatrième degré est donc

$$x^4 + 4kx^3 + 2(3k^2 - 1)x^2 + 4k(k^2 - 1)x + (k^2 - 1)^2 = 0;$$

elle peut s'écrire $(x + k)^4 - 2(x + k)^2 + 1 = 0$ ou $[(x + k)^2 - 1]^2 = 0$.

Elle a deux racines doubles qui sont $1 - k$ et $-1 - k$.

11e Année. N° 2. Novembre 1900.

REVUE DE MATHÉMATIQUES SPÉCIALES

PREMIÈRE PARTIE

PARAMÈTRE TANGENTIEL D'UN CONE DU SECOND ORDRE

par M. **G. Fontené**.

1. Je me propose principalement d'établir le fait suivant :

Soit une conique fixe S, *et soit un cercle* C *dont le plan est parallèle au plan de la conique et dont le centre est sur la perpendiculaire au plan de la conique menée par le centre de cette courbe ; si l'on considère les cônes du second ordre qui passent par la conique et qui ont leurs sommets sur le cercle* C, *si on les suppose indéformables, et si on les fait passer par une conique quelconque* S' *de manière que leurs sommets soient encore dans un plan parallèle au plan de la conique, ces sommets seront encore sur un cercle* C' *ayant son centre sur la perpendiculaire au plan de la conique* S' *menée par le centre de cette courbe.* Si S ou S' est une parabole, le cercle correspondant est remplacé par une parallèle à la directrice.

2. La forme d'un cône du second ordre dépend de deux paramètres, dont l'un est particulièrement intéressant. Les axes étant rectangulaires, l'équation du cône étant $f = 0$ avec le sommet à l'origine, l'équation du cône isotrope de même sommet étant $\varphi \equiv x^2 + y^2 + z^2 = 0$ *sans facteur constant parasite*, soient Δ, Θ, Θ' les coefficients de λ^3, λ^2, λ dans le discriminant de la forme $\lambda f + \varphi$; ces invariants étant des degrés 3, 2, 1 par rapport aux coefficients de f, *les rapports des quantités*

$$\sqrt[3]{\Delta}, \qquad \sqrt[2]{\Theta}, \qquad \Theta'$$

sont indépendants du facteur arbitraire qui entre dans f et sont, par suite, complètement déterminés par la forme du cône.

Nous appellerons *paramètre tangentiel* d'un cône du second ordre la quantité

$$I = \frac{\Theta}{\sqrt[3]{\Delta^2}} ;$$

dans l'hypothèse $I = 0$, ou $\Theta = 0$, le cône est harmoniquement inscrit au cône isotrope de même sommet, c'est-à-dire qu'il admet des trièdres trirectangles circonscrits.

3. Voici une expression géométrique de l'invariant I.

Soit un cône du second ordre sur lequel on trace une conique. S'il s'agit d'une conique à centre, en désignant par a^2 et b^2 les carrés des demi-axes de la conique, par γ la distance du sommet du cône au plan *de la conique, par* P *la puissance du sommet du cône par rapport à la sphère orthoptique de la conique, on a*

$$(1) \qquad I = \frac{P}{\sqrt[3]{a^2 b^2 \gamma^2}}.$$

S'il s'agit d'une parabole, en désignant par p le paramètre de la parabole, par γ la distance du sommet du cône au plan de la parabole, par d la distance du sommet du cône au plan orthoptique de la parabole, distance comptée positivement lorsque ce sommet est séparé de la courbe par le plan orthoptique, on a

$$(1') \qquad I = \frac{2d}{\sqrt[3]{p\gamma^2}}.$$

Soit d'abord une conique à centre. L'origine des coordonnées étant au sommet du cône, les axes Ox et Oy étant pour plus de simplicité parallèles aux axes de la conique, les équations de la conique sont

$$z = \gamma, \qquad A(x-\alpha)^2 + B(y-\beta)^2 + C = 0.$$

et l'on a les deux cônes

$$\left\{\begin{aligned} f &\equiv A(\gamma x - \alpha z)^2 + B(\gamma y - \beta z)^2 + Cz^2 = 0,\\ \varphi &\equiv x^2 + y^2 + z^2 = 0.\end{aligned}\right.$$

On peut écrire $f \equiv ax^2 + by^2 + cz^2 + 2fyz + 2gzx,$

avec $a = A\gamma^2, \qquad b = B\gamma^2, \qquad c = A\alpha^2 + B\beta^2 + C, \qquad f = -B\beta\gamma, \qquad g = -A\alpha\gamma,$

et l'on a $\Delta = abc - af^2 - bg^2 = AB\gamma^4(A\alpha^2 + B\beta^2 + C) - AB^2\beta^2\gamma^4 - BA^2\alpha^2\gamma^4,$

ou $\Delta = ABC\gamma^4,$

$$\Theta = (bc - f^2) + (ac - g^2) + ab = B\gamma^2(A\alpha^2 + B\beta^2 + C) - B^2\beta^2\gamma^2 + A\gamma^2(A\alpha^2 + B\beta^2 + C) - A^2\alpha^2\gamma^2 + AB\gamma^4,$$

ou encore $\Theta = AB\gamma^2(\alpha^2 + \beta^2 + \gamma^2) + C(A + B)\gamma^2 = AB\gamma^2\left(\alpha^2 + \beta^2 + \gamma^2 + \dfrac{C}{A} + \dfrac{C}{B}\right);$

à cause de $A = \dfrac{-C}{a^2}, \qquad B = \dfrac{-C}{b^2},$ on a donc

$$\Delta = \frac{C^3\gamma^4}{a^2b^2}, \qquad \Theta = \frac{C^2\gamma^2}{a^2b^2}\,.\,P.$$

L'élimination de C donne

$$I = \frac{\Theta}{\sqrt[3]{\Delta^2}} = \frac{P\gamma^2}{a^2b^2\sqrt[3]{\dfrac{\gamma^8}{a^4b^4}}} = \frac{P}{\sqrt[3]{a^2b^2\gamma^2}}.$$

Pour passer au cas de la parabole, nous partirons par exemple du cas de l'ellipse. Si R est le rayon de la sphère orthoptique, on peut écrire

$$I = \frac{\dfrac{P}{R}}{\sqrt[3]{\dfrac{a^2b^2}{R^3}\cdot\gamma^2}};$$

en posant $\dfrac{b^2}{a} = p \ (p > 0),$ ce qui donne $R = \sqrt{a(a+p)},$ on a d'ailleurs

$$\frac{a^2b^2}{R^3} = \frac{a^3p}{\sqrt{a^3(a+p)^3}};$$

si l'on fait croître a indéfiniment, d'une part, la quantité $\dfrac{P}{R}$ a pour limite le double de la distance d du sommet du cône au plan orthoptique de la parabole, cette distance étant positive lorsque le sommet du cône est séparé de la parabole par le plan orthoptique, d'autre part, la constante ci-dessus tend vers p ; on a donc la formule (1').

On a cette conséquence :

4. *Le lieu des sommets des cônes de même paramètre tangentiel circonscrits à une conique à centre donnée est une surface de révolution dont l'axe est la perpendiculaire au plan de la conique menée par le centre de cette conique.* La puissance P d'un point de cette surface par rapport à la sphère orthoptique de la conique est proportionnelle à la racine cubique du carré de la distance γ de ce point au plan de la conique ; cette puissance a d'ailleurs le signe de I ou le signe contraire selon qu'il s'agit d'une ellipse ou d'une hyperbole.

Pour une parabole, le lieu en question est un cylindre dont les génératrices sont parallèles à la directrice de la courbe. On a d'ailleurs $d = \lambda.\gamma^{\frac{2}{3}},$ et λ a le signe de I.

5. Le fait énoncé au début de cette note résulte également de la formule (1), les cônes considérés ayant même paramètre tangentiel.

GÉOMÉTRIE ANALYTIQUE

911. — *On donne un angle droit xOy et sur Ox deux points A, A′ symétriques l'un de l'autre par rapport au point O. Trouver l'équation générale des coniques tangentes à Oy, traçant sur Ox une involution dont A et A′ sont les points doubles et ayant pour centre commun le point de la première bissectrice qui se projette sur Ox en A.*

Cela étant, on demande :

1° *De séparer les points du plan par lesquels passent deux coniques réelles du faisceau de ceux par lesquels il passe deux coniques imaginaires ;*

2° *De trouver le lieu des points de rencontre de la parallèle à Ox menée par le point de contact de l'une de ces coniques avec Oy et des deux droites qui joignent le centre aux points de rencontre de cette conique avec Ox ; en outre, de construire ce lieu ;*

3° *De trouver le lieu du point de rencontre ordinaire de chacune de ces coniques avec le cercle osculateur au point situé sur Oy, et de construire ce lieu.*

Si nous désignons OA par a, l'équation demandée sera évidemment de la forme

$$(x-a)^2+2\lambda(x-a)(y-a)+\mu(y-a)^2+\nu=0.$$

Nous aurons successivement les relations qui existent entre les paramètres λ, μ, ν en écrivant d'abord que les deux points de rencontre avec Ox divisent harmoniquement les points A et A′, c'est-à-dire que le produit des racines de l'équation en x obtenue en annulant y dans l'équation de la conique est égal à a^2 ; puis, que l'axe des y rencontre la conique en deux points confondus, c'est-à-dire que l'équation en $y-a$ obtenue en faisant $x=0$ dans l'équation de la conique a une racine double. Le premier calcul donne $\nu=-2\lambda a^2-\mu a^2$; la seconde donne, en tenant compte de cette valeur de ν, $(\lambda+\mu)^2=\mu$. Posons alors $\mu=\rho^2$, nous aurons $\lambda+\rho^2=\pm\rho$, et il suffit de prendre un signe dans cette relation, car, prendre ensuite le second signe revient à changer ρ en $-\rho$ et ceci n'altère pas les valeurs que prend le paramètre, puisque c'est une variable indépendante. Nous avons donc finalement $\mu=\rho^2$ et $\lambda=\rho-\rho^2$; de là nous déduisons sans peine, en développant et simplifiant, l'équation générale des coniques envisagées

$$x^2+2(\rho-\rho^2)xy+\rho^2y^2-2a(1+\rho-\rho^2)x-2a\rho y+a^2=0. \tag{1}$$

La signification géométrique de ρ est facile à apercevoir : en faisant $x=0$ dans l'équation, nous trouvons $(\rho y-a)^2=0$; $\dfrac{a}{\rho}$ est donc l'ordonnée du point de contact avec Oy.

1. Écrivons que la conique (1) passe par un point (x, y) donné dans le plan, nous aurons une équation du second degré en ρ qui nous donnera les paramètres des deux coniques du système qui passent au point choisi. Si ces paramètres sont imaginaires, les coniques (1) seront imaginaires ; sinon elles seront réelles, car chacune d'elles aura alors une équation réelle, un centre et un point réels distincts l'un de l'autre. Tout revient donc à étudier la réalité des racines de l'équation du second degré en ρ,

$$(y^2-2xy+2ax)\rho^2+2(xy-ax-ay)\rho+(x-a)^2=0 ;$$

la conique en deux points D, E, il y aura deux directions asymptotiques AD′ et AE′ isogonales de AD et AE.

L'ellipse n'ayant pas de points à l'infini, la quartique ne coupera point le cercle circonscrit au triangle.

Dans le cas d'une hyperbole, la courbe sera analogue, mais elle coupera le cercle circonscrit en deux points qu'on obtiendra en prenant les isogonales des directions asymptotiques de l'hyperbole. Le cercle ne pourra couper l'hyperbole qu'en deux points qui donneront naissance à deux directions asymptotiques.

Enfin, quand la conique sera une parabole, la quartique aura une forme analogue avec deux directions asymptotiques; mais comme la parabole n'a qu'une direction asymptotique la quartique sera tangente au cercle circonscrit au triangle ABC.

4. Pour avoir ce lieu, il faut éliminer λ, μ, ν entre les équations suivantes :

équation de AM $\mu y = \nu z$, équation de la conique $\sqrt{\lambda x} + \sqrt{\mu y} + \sqrt{\nu z} = 0$,

équation de condition $\sqrt{\lambda x_0} + \sqrt{\mu y_0} + \sqrt{\nu z_0} = 0$.

Des deux premières on tire $\dfrac{\lambda}{4yz} = \dfrac{\mu}{xz} = \dfrac{\nu}{xy}$ ou $\dfrac{\lambda}{\frac{4}{x}} = \dfrac{\mu}{\frac{1}{y}} = \dfrac{\nu}{\frac{1}{z}}$.

En portant les valeurs proportionnelles à λ, μ, ν, dans la troisième équation, on a pour le lieu

$$\sqrt{\frac{4x_0}{x}} + \sqrt{\frac{y_0}{y}} + \sqrt{\frac{z_0}{z}} = 0.$$

La courbe isogonale sera $\sqrt{4x_0X} + \sqrt{y_0Y} + \sqrt{z_0Z} = 0$, conique inscrite dans le triangle ABC.

La quartique sera analogue à la précédente, et tout ce qui a été dit s'applique de nouveau en remplaçant le point P par le point $2x_0$, y_0, z_0 qui est le point de concours des tangentes à la quartique aux sommets du triangle dans le problème précédent.

CANS.

Remarque. — Par une transformation homographique qui change les points B et C en les deux points cycliques, les coniques de l'énoncé deviennent des paraboles ayant un foyer commun, le point A (dans sa nouvelle position) et passant par un point donné P.

Nous laissons au lecteur le soin de développer cette méthode et d'édifier la solution correspondante.

Bonnes solutions : MM. J.-D. Dufaut, école primaire supérieure d'Aiguillon; C. Grolleau, répétiteur général au lycée de Marseille; Pelvoisin.

917. — *Etant données deux quadriques* C *et* C′ *qui se coupent suivant deux courbes planes.* P *et* Q, *il est possible de leur circonscrire une infinité de quadriques* S. *Deux de ces quadriques* S_1 *et* S_2 *se coupent suivant deux courbes planes.*

1° *Les plans de ces deux courbes se coupent sur l'intersection de* P, Q, *et forment avec ces dernières un faisceau harmonique.*

2° *Par ces deux courbes passe une quadrique contenant la conique* P *et une contenant la conique* Q.

3° *Par ces deux courbes passent deux cônes du second degré. Ces cônes ont leurs sommets sur une droite fixe et restent circonscrits à une quadrique fixe, tangente aux plans* P, Q *et inscrite dans les deux cônes circonscrits à la fois aux deux quadriques données* C *et* C′.

Faisons une transformation homographique de la figure de manière que la conique Q se transforme en le cercle de l'infini ; les deux quadriques C et C' se transforment alors en deux sphères Γ et Γ', et la conique P devient le cercle Π situé dans le plan radical des deux sphères.

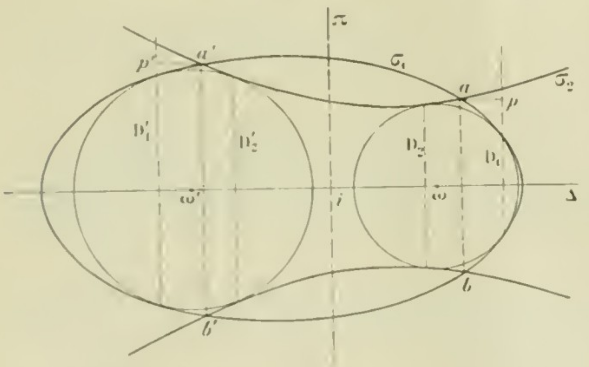
Il suffit alors de résoudre la question dans ce cas particulier, puisque les propriétés à démontrer se conservent dans une transformation homographique quelconque.

Toute quadrique Σ circonscrite à la fois aux deux sphères est de révolution autour de la droite Δ qui joint les centres ω et ω' des deux sphères ; deux de ces quadriques Σ_1 et Σ_2 se coupent suivant deux cercles C_1 et C_2 dont les centres sont sur la droite Δ et dont les plans sont perpendiculaires à Δ.

Coupons la figure par un plan passant par Δ ; les sphères Γ, Γ' sont coupées suivant deux grands cercles γ, γ' ; le plan radical Π suivant une droite π, axe radical des cercles γ, γ', qui rencontre Δ au point i ; les quadriques Σ_1 et Σ_2 sont coupées suivant des coniques σ_1, σ_2 bitangentes aux cercles γ, γ', les cordes de contact étant D_1, D'_1 pour σ_1, D_2, D'_2 pour σ_2. Les coniques σ_1, σ_2 se coupent en quatre points a, b, a', b' symétriques deux à deux par rapport à Δ. Les droites ab, $a'b'$ sont des diamètres des cercles C_1 et C_2.

La conique σ_1 étant bitangente aux cercles γ et γ', les cordes de contact D_1 et D'_1 forment un faisceau harmonique avec l'axe radical π et la droite de l'infini, donc D_1 et D'_1 sont équidistantes de l'axe radical, il en est de même pour D_2 et D'_2.

1. Le cercle γ étant bitangent aux coniques σ_1 et σ_2, les cordes de contact D_1 et D_2 sont conjuguées harmoniques par rapport à ab et $a'b'$: de même ab et $a'b'$ forment un faisceau harmonique avec D_1 et D_2. Comme D_1 et D'_1 d'une part, D_2 et D'_2 d'autre part sont équidistantes du point i, il en est de même de ab et $a'b'$. Par suite les plans des cercles C_1 et C_2 forment un faisceau harmonique avec le plan radical Π et le plan de l'infini.



2. Par les quatre points a, b, a', b' on peut faire passer un cercle ayant son centre sur Δ : ce cercle en tournant autour de Δ engendre une sphère contenant les deux cercles C_1 et C_2. Cette sphère est la transformée homographique de la quadrique qui contient les coniques communes aux quadriques S_1 et S_2 et qui passe par la conique Q.

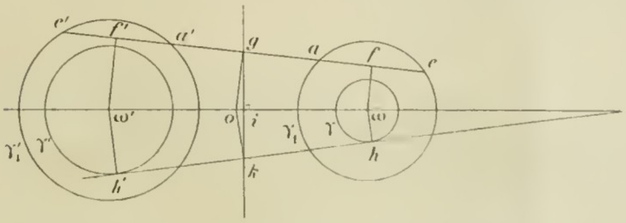
Soient c et d les points où l'axe radical πi rencontre les cercles γ et γ'. Par les six points a, b, a', b', c, d on peut faire passer une seule conique ayant pour axe Δ. En tournant autour de Δ, cette conique engendre une quadrique contenant les cercles C_1, C_2 et le cercle commun aux sphères Γ et Γ'.

3. Par les cercles C_1 et C_2 passent visiblement deux cônes de révolution ayant pour axe Δ et dont les sommets sont les points s_1 et s_2 où aa' et ab' rencontrent Δ.

Pour démontrer que ces cônes sont circonscrits à une quadrique fixe, il suffit d'établir que les droites aa' et ab' sont tangentes à une conique fixe ayant pour axe Δ.

Soient at, $a't'$ les tangentes menées des points a et a' respectivement aux cercles γ et γ', et ap, $a'p'$ les distances des mêmes points aux droites D_1 et D'_1. D'après une propriété bien connue des cercles focaux d'une conique, les rapports $\frac{at}{ap}$ et $\frac{a't'}{a'p'}$ sont égaux à l'excentricité de la conique. Comme $ap = a'p'$, on en conclut $at = a't'$. Donc les puissances des points a et a' par rapport aux cercles γ et γ' respectivement sont égales. Il en résulte immédiatement que les cercles γ_1 et γ_2 qui ont pour centres ω et ω' et qui passent par les points a et a' ont même axe radical que les cercles γ et γ'.

La droite aa' rencontre les cercles γ_1 et γ'_1 et l'axe radical πi aux points e, e', g. Comme on a $ga = ga'$ et $ga.ge = ga'.ge'$, on en conclut $ge = ge'$ et par suite $ae = a'e'$. Si on abaisse ωf et $\omega' f'$ perpendiculaires sur aa', on a $gf = g'f'$ et par suite la perpendiculaire menée par le point g à la droite aa' passe par le point o milieu de $\omega\omega'$.



Il en résulte que aa' est tangente à une parabole ayant pour foyer le point o et pour tangente au sommet ig. On verrait de même que ab' touche la même parabole. On en conclut que les deux cônes qui contiennent les cercles C et C' sont circonscrits à un paraboloïde de révolution ayant pour foyer le point o et pour plan tangent au sommet le plan II.

Il nous reste à démontrer que ce paraboloïde est également inscrit dans les cônes circonscrits aux deux sphères Γ et Γ'. Soit hh' une tangente commune aux deux cercles γ et γ', rencontrant ig au point k; comme ωh et $\omega' h'$ sont perpendiculaires à hh', ok l'est aussi, et par suite hh' touche la parabole de foyer o et de tangente au sommet ig.

Observons en terminant que si l'on revient à la première figure, le paraboloïde est la transformée d'une quadrique qui touche les plans P et Q.

On rapprochera avec intérêt cette solution de la solution géométrique de la question **898** (N° de juin 1900, p. 530).

---

918. — *Si un triangle varie en restant inscrit dans une conique* C *et circonscrit à une autre conique* C', *la polaire de tout point de* C *par rapport au système des trois côtés du triangle passe par un point fixe.*

Prenons pour triangle de référence l'un des triangles indiqués et représentons par

$$yz + zx + xy = 0, \qquad avw + bwu + cuv = 0,$$

les équations ponctuelle et tangentielle des deux coniques C et C'. La seconde équation peut s'écrire

$$\frac{a}{u} + \frac{b}{v} + \frac{c}{w} = 0,$$

et donne immédiatement, en fonction d'un paramètre λ,

$$\frac{a}{u} = \lambda, \qquad \frac{b}{v} = 1 - \lambda, \qquad \frac{c}{w} = -1;$$

par conséquent les coordonnées d'une tangente quelconque à la seconde conique s'expriment rationnellement en λ par les formules très simples

$$u = \frac{a}{\lambda}, \qquad v = \frac{b}{1-\lambda}, \qquad w = -c.$$

Nous pouvons démontrer en passant que le pôle de cette droite par rapport aux trois sommets du triangle choisi décrit une droite fixe liée à ce triangle ; en effet, appelons u_0, v_0, w_0 les trois nombres précédents ; le pôle de la droite correspondante par rapport à la courbe impropre de troisième classe $uvw = 0$ a pour équation

$$uv_0w_0 + vw_0u_0 + wu_0v_0 = 0, \qquad \text{ou} \qquad \frac{u}{u_0} + \frac{v}{v_0} + \frac{w}{w_0} = 0,$$

(b)

Substituting P atoms for Si atoms therefore creates a semiconducting compound with majority electron doping, which is said to be *n*-doped. Note that the electron and hole densities are always related by (3.54).

In the same way, some Si atoms could be replaced by atoms of a trivalent element like B, which is an electron acceptor, introducing an acceptor level E_a above the top of the valence band. One can thus obtain a *p*-doped compound, i.e., doped with holes, with the electronic structure illustrated in Fig. 4.12b.

Note that the presence of positive charges can be detected directly by electron transport experiments with a magnetic field $B = \mu_0 H_\mathrm{a}$ perpendicular to the current. In the plane perpendicular to the field, the Laplace force deflects the carrier trajectories in the same direction whether they be positively or negatively charged. It follows that charges accumulate in the direction perpendicular to the current, and in the steady-state regime, this produces an electric field transverse to the direction of the current. The associated potential difference has the sign of the majority carriers in the material. This effect, called the *Hall effect*, can be used to determine the density and sign of the carriers in a semiconductor.

The industrial applications of semiconductors stem from this ability to control the density and *n* or *p* type of the carriers by doping. This in turn led to the development of microelectronics, where diodes and transistors were constructed by making junctions between *n*- and *p*-doped semiconductors. Another important step was to make transistors by applying an electric field to a semiconducting layer in order to control the level of doping, as we shall see for the specific example of graphene.

4.6 Electrons, Holes, and Transport in Graphene

As we saw in Chap. 3, graphene has the band structure of a zero gap semiconductor. We shall see here how the particular shape of the dispersion curves $E(\mathbf{k})$ shown in Fig. 3.19 thus leads to rather novel properties.

a. Consequences of the Graphene Band Structure

To begin with, consider the dispersion relations (3.60), taking E_0 as the zero energy. The experimental value $t \simeq 3$ eV is high, and we may restrict to eigenstates of energy $|E| \ll t$ if we are interested in low energy properties at experimentally accessible temperatures. Indeed, for neutral graphene, the conduction electrons and holes appear for energies close to $E_\mathrm{F} = 0$. The corresponding momenta lie near the six vertices of the Brillouin zone, to be reduced to two points K^+ and K^- with wave vectors $\mathbf{K}^\varepsilon$ with $\varepsilon = \pm$, called Dirac points (see box below). The four others are obtained from K^+ and K^- by translations along a vector of the reciprocal lattice $(\mathbf{a}_1^*, \mathbf{a}_2^*)$, as shown in Fig. 4.13a. Setting

$$\mathbf{k} = \mathbf{K}^\varepsilon + \mathbf{q} \, ,$$

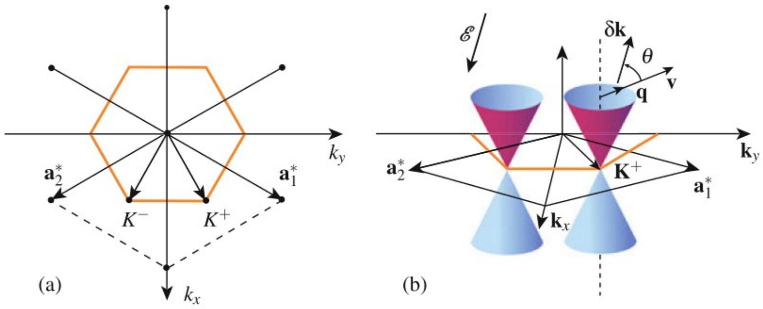

Fig. 4.13 (**a**) Hexagonal reciprocal lattice of graphene and its first Brillouin zone. The primitive cell $(\mathbf{a}_1^*, \mathbf{a}_2^*)$ is shown, as are the two Dirac points K^+ and K^- of this cell. (**b**) The conical dispersion relation $E(\mathbf{k})$ near the Dirac points is shown inside the same primitive cell. This is a zoom on Fig. 3.19 in the vicinity of the Dirac points. The real space velocity $\mathbf{v}$ of an electron with wave vector $\mathbf{K}^+ + \mathbf{q}$ is indicated

we may consider an expansion of (3.60) to first order in $\mathbf{q}$:

$$E_{\mathbf{k}} = \pm\frac{3}{2}at\,|\mathbf{q}| \ . \tag{4.74}$$

Figure 4.13b shows these dispersion relations, which are conical close to the Dirac points. The velocity of an electron in a state $E_{\mathbf{k}}$ is given by

$$\langle \mathbf{v}_{\mathbf{k}} \rangle = \frac{1}{\hbar}\nabla_{\mathbf{k}} E_{\mathbf{k}} = \pm\frac{3at}{2\hbar}\mathbf{n} = \pm v_{\mathrm{F}}\mathbf{n} \, , \tag{4.75}$$

where $\mathbf{n}$ is the unit vector normal to the constant energy circle at $\mathbf{K}^{\varepsilon} + \mathbf{q}$, which thus lies along $\mathbf{q}$ (see Fig. 4.13b). The electron velocity is aligned with its quasi-momentum $\mathbf{q}$ and has magnitude $v_{\mathrm{F}} = 3at/2\hbar$, which is independent of the electron state. Note that the zero curvature of the constant energy surface implies that *the effective mass vanishes*. Moreover, the dispersion relation (4.74) can be rewritten in the form

$$E_{\mathbf{K}^{\varepsilon}+\mathbf{q}} = \pm\hbar v_{\mathrm{F}}\,|\mathbf{q}| \ . \tag{4.76}$$

This dispersion relation provides a simple way of calculating the density of energy states $D_{\mathrm{S}}(E)$ per unit area and spin direction, when $|E| \ll t$. The number $D_{\mathrm{S}}(E)\mathrm{d}E$ of states with energies lying between E and $E + \mathrm{d}E$ is the number of electron states contained in the area $2\pi q\mathrm{d}q$ of reciprocal space, viz.,

$$D_{\mathrm{S}}(E)\mathrm{d}E = 2\pi q\mathrm{d}q \times (2\pi)^{-2} \times 2 \, ,$$

taking into account the existence of the two branches at points K^+ and K^-. We obtain

$$D_{\mathrm{S}}(E) = \frac{|E|}{\pi\hbar^2 v_{\mathrm{F}}^2} \ . \tag{4.77}$$

This density of states, which vanishes at $E = 0$, increases linearly with energy, a distinctly unusual behaviour compared with standard metals or semiconductors. A detailed calculation using the general form of the dispersion curves (3.60) gives Van Hove singularities for $D_S(E)$ when $E = \pm t$, energies at which the dispersion curves have saddle points, and a constant limiting value for the extrema of the energy $E = \pm 3t$, where a parabolic dispersion relation and finite effective mass are obtained (see Fig. 4.14).

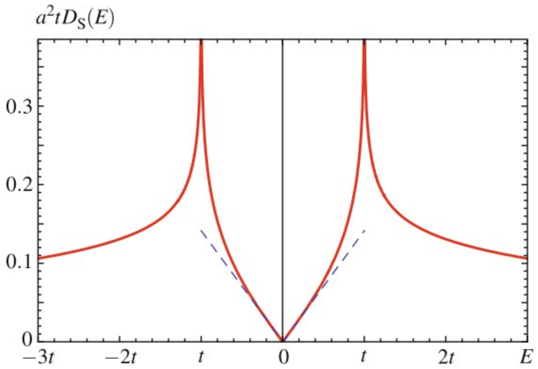

Fig. 4.14 Density of states per unit area for graphene, obtained numerically from the dispersion curves given in (3.60). For $|E| < t$, we recover the linear relation (4.77) close to the Dirac points. Figure courtesy of Montambaux, G.: Laboratoire de Physique des Solides, Orsay, France

Dirac Points and Relativistic Physics

The similarity between (4.76) and the dispersion relation for photons, together with the vanishing effective mass, has inspired an analogy between the equations of motion of the electrons in graphene around the points K^+ and K^- and those of massless quantum particles. The speed v_F given in (4.75), which is independent of the electron energy, plays the role of the speed of light. For this reason, the points K^+ and K^- are commonly referred to as Dirac points today. For the same reason, the surfaces representing the energy dispersion relation are called Dirac cones. The states in the conduction band then represent particles, while those of the valence band are identified with antiparticles.

Note that the degeneracy between the two conical valleys introduces a complication which we have hidden in (4.76), where the sign ± for the energy is obviously not related to the one used to characterise the Dirac points $\mathbf{K}^{\varepsilon}$.

This analogy with 2D relativistic quantum physics can be taken a long way. As in this last case, where the particle spin is represented by 2×2 Pauli matrices, in the case of graphene, these matrices take into account the sublattices A and B. In this representation, the Hamiltonian yielding the conical dispersion relations can then be written

$$\hat{H} = \hbar v_F \, |\mathbf{q}| \, \hat{\boldsymbol{\xi}} \ .$$

The operator $\hat{\boldsymbol{\xi}}$, with eigenvalues ± 1, describes the projection of the sublattice 'spin' in the direction of propagation of the electron in the graphene. It is analogous to helicity in particle physics. Helicity is the projection of the real spin of the particle onto its direction of propagation. This analogy leads us to consider massless charged particles, something unknown in particle physics, since the only known massless particles, photons or neutrinos, are electrically neutral.

b. Electron Transport

At $T = 0$, there are in principle no carriers, and one therefore expects zero conductivity for graphene. However, for $T \neq 0$, electrons with surface density n_{e} are excited in the conduction band, with a resulting hole surface density n_{h} in the valence band, and graphene becomes a conductor. Given the electron–hole symmetry of the band structure, charge conservation implies that $n_{\mathrm{e}} = n_{\mathrm{h}}$ and that the chemical potential remains fixed at $\mu = E_{\mathrm{F}} = 0$.

> **Question 4.5.** Show that the number of carriers thermally excited varies as T^2 and that the same is true of the electronic specific heat.

Insofar as the dispersion relation is not quadratic, and since the effective mass is zero, the Drude relation is not applicable, in contrast to the case of standard semiconductors. We must therefore consider a more general expression for the electrical conductivity, taking into account the total current of the occupied electron states, in the form

$$\mathbf{j} = -2\sum_{\mathbf{q}} e\mathbf{v}(\mathbf{q}) f\big(E(\mathbf{q})\big) , \tag{4.78}$$

where $f(E)$ is the Fermi function and the factor of 2 is due to spin degeneracy. This current is clearly zero when there is no electric field. If we assume, as discussed in this chapter, that the electrons are subjected to viscous friction, in the presence of a field $\mathscr{E}$, the stationary solution implies a shift $\boldsymbol{\delta}\mathbf{k}$ of the electronic states given by

$$\hbar\boldsymbol{\delta}\mathbf{k} = -\tau_{\mathrm{e}} e\mathscr{E} = \hbar\boldsymbol{\delta}\mathbf{q} , \tag{4.79}$$

where τ_{e} is the collision time, assumed to be the same for both electrons and holes, since the problem is symmetric. Taking into account the displacement $\boldsymbol{\delta}\mathbf{q}$ of the Fermi surface in (4.78), we obtain

$$\begin{aligned}\mathbf{j} &= -2e\sum_{\mathbf{q}} \mathbf{v}(\mathbf{q}+\boldsymbol{\delta}\mathbf{q}) f\big[E(\mathbf{q})\big] = -2e\sum_{\mathbf{q}} \mathbf{v}(\mathbf{q}) f\big[E(\mathbf{q}-\boldsymbol{\delta}\mathbf{q})\big] \\ &= 2e\sum_{\mathbf{q}} \mathbf{v}(\mathbf{q})\frac{\mathrm{d}f\big[E(\mathbf{q})\big]}{\mathrm{d}E}(\boldsymbol{\nabla}_{\mathbf{q}}E)\boldsymbol{\cdot}\boldsymbol{\delta}\mathbf{q} = 2e\hbar\boldsymbol{\delta}\mathbf{q}\sum_{\mathbf{q}} v_x^2(\mathbf{q})\frac{\mathrm{d}f\big[E(\mathbf{q})\big]}{\mathrm{d}E} .\end{aligned}$$

Equation (4.79) was used in the last equality, taking $\mathbf{x}$ to be a unit vector in the direction $\mathbf{j} \parallel \mathscr{E} \parallel \boldsymbol{\delta}\mathbf{q}$. For temperatures such that $k_{\mathrm{B}}T \ll t$, we can restrict the dispersion relations to their conical part given by (4.76). Setting $\theta = (\mathbf{q}, \boldsymbol{\delta}\mathbf{q})$ as shown in Fig. 4.13b, this leads to

$$\mathbf{j} = -2e^2\tau_{\mathrm{e}} v_{\mathrm{F}}^2 \mathscr{E} \sum_{\mathbf{q}} \cos^2\theta \,\frac{\mathrm{d}f\big[E(\mathbf{q})\big]}{\mathrm{d}E} . \tag{4.80}$$

The sum can be replaced by an integral over energy, after integrating over the angular orientation of $\mathbf{q}$ at given energy E, viz., $\int_{-\pi}^{\pi}\cos^2\theta(\mathrm{d}\theta/2\pi) = 1/2$. We thus obtain

$$\mathbf{j} = e^2\tau_e v_F^2 \mathscr{E}\int_{-\infty}^{\infty} -\frac{\mathrm{d}f}{\mathrm{d}E} D_S(E)\mathrm{d}E\,. \tag{4.81}$$

The 2D conductivity can then be written in the form

$$\sigma = \frac{2}{\pi\hbar^2}e^2\tau_e\int_0^{\infty} -\frac{\mathrm{d}f}{\mathrm{d}E}E\mathrm{d}E = \frac{2}{\pi\hbar^2}e^2\tau_e k_B T\int_0^{\infty} -\frac{\mathrm{d}f}{\mathrm{d}x}x\mathrm{d}x\,, \tag{4.82}$$

where $x = E/k_BT$. The integral has the form

$$\int_0^{\infty}\frac{x\mathrm{d}x}{\cosh^2 x} = \ln 2\,,$$

so

$$\boxed{\sigma = 2\frac{\ln 2}{\pi}\frac{e^2}{\hbar^2}\tau_e k_B T}\,. \tag{4.83}$$

We thus expect zero conductivity at $T = 0$, and *growing linearly with temperature*. Note that, in two dimensions, the resistivity $\rho = 1/\sigma$ corresponds to a current density $\mathbf{j}$ per unit width of material (not per unit area), so ρ has the dimensions of a resistance (and the symbol $\Omega/\square$ is sometimes used to express the units of ρ).

c. Doping by Field Effect

It is certainly an interesting fact that graphene is metallic at room temperature because carriers are thermally excited. However, for applications in electronics, it is essential to be able to construct active components producing some specific response to an applied voltage. One of the most widely used approaches with semiconductors is to make a metal oxide semiconductor capacitive structure, called a MOSFET (MOS field effect transistor), to control the doping of the semiconductor through an electric field obtained by applying a voltage to the metal gate.

This effect can be illustrated by the equivalent structure used for graphene, shown schematically in Fig. 4.15a. In this case, the gate is a doped Si substrate, oxidised at the surface to produce a film of SiO_2 with a thickness d of a few hundred nanometers. The graphene layer constitutes the second plate of the capacitor. When a voltage V_G is applied across the gate and the graphene, the charges appearing on the capacitor plates dope the graphene. If ε is the dielectric constant of the oxide layer, the capacitance $C = \varepsilon\varepsilon_0/d$ per unit area of the junction induces a charge

$$\boxed{n = \frac{\varepsilon\varepsilon_0}{ed}V_G}\,. \tag{4.84}$$

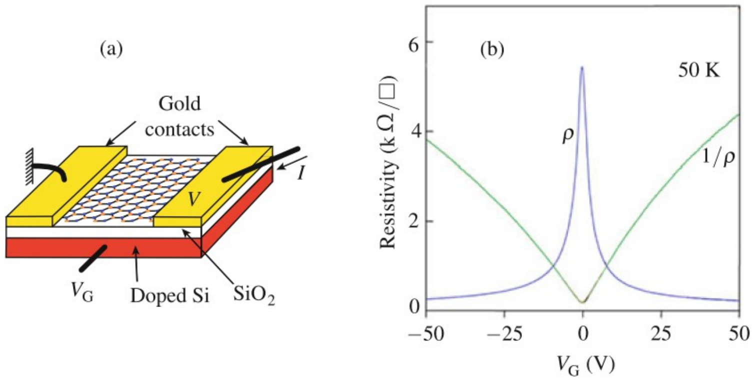

Fig. 4.15 (**a**) Semiconductor–oxide–graphene structure used to dope the graphene sheet by varying the voltage V_G applied to the semiconducting gate. (**b**) Dependence of the resistance and conductivity of graphene on V_G. Figure courtesy of A.K. Geim, from results published by Morozov, S.V., *et al*., Phys. Rev. Lett. **100**, 016602 (2008)

The surface density n of the carriers induced in graphene by an electric field thus varies linearly with the gate voltage V_G. We therefore observe, e.g., in Fig. 4.15b, that the resistivity of graphene falls off rapidly as a function of the gate voltage.

Question 4.6. 1. Which experimental observations in Fig. 4.15b can be explained by the approach discussed in Sects. 4.6b and c? Which cannot be explained? Compare the density of carriers induced experimentally by the field effect with the one obtained in Question 4.5 at thermodynamic equilibrium at 50 K ($\varepsilon = 4$, $d = 300$ nm).
2. What becomes of the chemical potential μ of the carriers in this experiment?

Note that the observations made with the atomic layer of graphene are similar to those carried out on silicon MOSFET transistors, which are made by depositing a metal film on a much thicker semiconducting layer whose carrier density is controlled by the voltage across the metal gate. In the case of graphene, the change in the resistance induced by a voltage $V_G = 10$ V is of the order of a factor of 10, which is a significant transistor effect. This type of structure has been used over the past few years to demonstrate many novel physical properties in graphene, suggesting applications for graphene or graphene multilayers in nanotechnology in the near future.

Question 4.7. What experiment could determine the sign of the injected carriers? How could one check experimentally whether the graphene energy spectrum does indeed correspond to that of the Dirac cones?

Light Deflection

One of the earliest calculations of the deflection of light from a distant source by a foreground gravitational field is due to Henry Cavendish around 1784. Unfortunately, the only evidence that he did such a calculation is on an "isolated scrap" of paper. Will [Wil] offers some details of this story and attempts to reproduce Cavendish's calculation of the bending angle of light passing near the surface of an attracting mass.

The next closest calculations seems to have been in an 1801 paper by Johann von Soldner: "Ueber die Ablenkung eines Lichtstrals von seiner geradlinigen Bewegung, durch die Attraktion eines Weltkörpers, an welchem er nahe vorbeigeht" ["On the Deviation of a Light Ray from its Motion along a Straight Line through the attraction of a Celestial Body which it Passes Closeby"]. This article appeared in "Berliner Astronomisches Jahrbuch für das Jahr 1804" [Sol]; see Jaki's English translation [Jak]. We note that initially von Soldner's paper calculates — using Newtonian mechanics — the bending angle formula for light emitted tangentially from the surface of a gravitating body and travels off to infinity. When applying his formula, however, he reverses the light ray's path, so it comes in from infinity and "grazes" the attracting body [Jak, pp. 945-947] (cf. [Wil, p. 414, Sec. III]). Von Soldner, who later became director of the Munich observatory and a foreign member of the Royal Astronomical Society, figured out: "Thus when a light ray passes by a celestial body, it will, instead of going on in a straight direction, be forced by its attraction to describe a hyperbola whose concave side is directed against the attracting body." He showed that a light ray grazing the sun would be deflected by 0.84 seconds of arc and concluded: "If one could observe the fixed stars very close to the sun, then one would have to take this very much into account." Von Soldner realized that he was far ahead of his time when he apologized at the end: "Hopefully, no one would find it objectionable that I treat a light ray as a heavy body." As a consequence, "Soldner's work on the deflection of light had no influence either on practice or on theory" [Jak].

Even earlier, John Michell in 1783 [Miche] and Pierre-Simon Laplace in 1796 [Lap] independently investigated light being subjected to gravity, but in the context of a body acting on the very light it emits. They both basically arrived at a notion resembling a "black hole," that is, a sufficiently massive star can capture its own light, leaving the star invisible. Laplace stated his result initially without proof, but provided the proof in 1798; see Hawking and Ellis [Haw-E, p. 365] for an English translation. It seems, however, that Michell and Laplace did not write about the situation of light coming from a distant source and undergoing deflection as it passes near a gravitating body. We note, though, that it was Michell and Laplace who inspired the works of Cavendish and von Soldner, respectively (e.g., [Wil, p. 413] and [Jak, pp. 935–936]).

In hindsight, it is slightly surprising that Newton himself did not seem to have studied light deflection by gravity. All the ingredients were there with his gravitational dynamics and the corpuscular theory of light, and the mathematics involved was straightforward compared to other problems he solved successfully. His famous Query 1 of the *Opticks* (1704):

"Do not Bodies act upon Light at a distance, and by their action bend its Rays; and is not this action strongest at the least distance?" [New] is phrased in such a general way that today we tend to assume that it includes gravitational bending as well. This is not the case, though, according to Jaki, who comments [Jak]: "He [Newton], of course, had reflection, refraction and diffraction in mind."

Maybe it is equally surprising that it seems to have taken more than 100 years after von Soldner until somebody else dealt again quantitatively with the problem of light deflection. Even more so, when one learns that a famous contemporary of von Soldner, the physicist-philosopher Georg Christoph Lichtenberg wrote in the year 1796, "Wenn das Licht trotz seiner Geschwindigkeit noch eine Schwere hat, so würde doch so etwas wie Refraktion am Horizonte erscheinen müssen, weil es von der Erde stark gezogen wird" ["If light despite its velocity also had gravity, then something like refraction would have to occur at the horizon, because it would be attracted heavily by the earth"] [Lic].

We know today that the value of the deflection angle that Cavendish and von Soldner calculated is too small by a factor of two.[1] About a century after von Soldner's work, Albert Einstein arrived at a similar numerical value in his first attempt to determine the deflection angle — based on the equivalence principle. Einstein directly addressed the influence of gravity on light in a letter entitled: "Über den Einfluß der Schwerkraft auf die Ausbreitung des Lichtes" ["On the Influence of Gravitation on the Propagation of Light"] [Ein11]; see [Lor-EMW, p. 99] for an English translation of [Ein11]. He predicted that a light ray passing close to a "celestial body" might suffer a deflection towards the side of decreasing gravitational potential. Einstein found a numerical value of 0.83 seconds of arc for the deflection angle of light grazing the sun. In this paper, Einstein also stated that he wished astronomers to investigate this question: "Es wäre dringend zu wünschen, daß sich Astronomen der hier aufgerollten Frage annähmen, auch wenn die im vorigen gegebenen Überlegungen ungenügend fundiert oder gar abenteuerlich erscheinen sollten" ["It would be highly desirable that astronomers take up the question raised here, even if the considerations should seem to be insufficiently founded or entirely speculative"].

By 1915 Einstein succeeded in deriving the correct expression for the light deflection angle with the presentation of the General Theory of Relativity [Ein16, Ein22]. For a light ray passing at a distance R from an object of mass M he found the following deflection angle[2] — see Figure 1.1:

$$\hat{\alpha} = \frac{4GM}{c^2 R}, \tag{1.1}$$

where G is the constant of gravity and c is the speed of light. With the solar values for

---

[1] Will [Wil] compares Cavendish and von Soldner's determinations of the light deflection angle, and includes Einstein's correction to twice the value.

[2] Notice that the bending angle $\hat{\alpha}$ is independent of the light's wavelength and depends on the impact distance and deflector's mass. See Section 3.1.5.

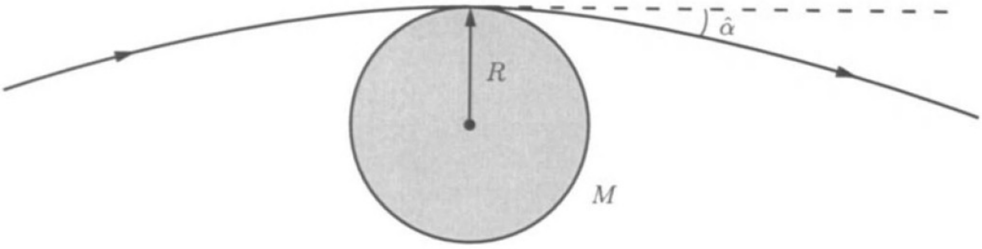

Figure 1.1. Light from a distant source experiences a deflection through angle $\hat{\alpha}$ by a mass M. The angle $\hat{\alpha}$ was calculated incorrectly by Cavendish (1784) and von Soldner (1801) since they used Newton's theory of gravity (see [Wil] for details). It was not until the formulation of General Relativity in 1915 that the correct formula for the bending angle was established by Einstein — see equation (1.1).

radius and mass he obtained

$$\hat{\alpha} = \frac{4GM_\odot}{c^2 R_\odot} \simeq 1.''74.$$

Note that since the light ray grazes the sun, we assume $R \simeq R_\odot$. In Einstein's own words: "Ein an der Sonne vorbeigehender Lichtstrahl erfährt demnach eine Biegung von 1.7 Bogensekunden" ["A light ray grazing the sun therefore experiences a deflection of 1.7 arcseconds"]. We refer readers to [Ray-BB, pp. 59–60] for a derivation of (1.1).

In the following years there were several papers dealing theoretically with light deflection, among them a short letter by Oliver Lodge about the "Einstein deflection" in which he made the point that "it is not permissible to say that the solar gravitational field acts as a lens, for it has no focal length" [Lod]. He pointed out that one would get a focal line starting at "a place seventeen times the distance of Neptune."

Multiple Imaging

While investigating the birth of general relativity, Renn, Sauer and Stachel [Ren-SS] discovered that in notes dated to the spring of 1912 Einstein explored gravitational lensing by a star. He showed that a distant star lying close to the line of sight to a foreground star will be imaged twice, with a faint secondary image increasing the total measurable intensity of the background star [Ren-SS, pp. 185, 186].[3] Einstein did not publish these results until 1936 [Ein36]. The possibility of double images was also mentioned in 1923 by Sir Arthur Eddington in his book *Space, Time and Gravitation* [Edd, p. 133–134]. This effect was also quantitatively studied by Chwolson[Chw] in 1924. Chwolson's article, "Über eine mögliche Form fiktiver Doppelsterne" ["On a possible form of fictitious double stars"], even mentions the "reversed mirror image" (i.e., the negative parity of the second image) and cautioned at the end: "Ob der hier angegebene Fall eines fiktiven Doppelsterns auch wirklich vorkommt, kann ich nicht beurteilen" ["Whether the here mentioned case of a fictitious double star really exists I cannot judge"].

---

[3] In the same notes, Einstein also determined the 'lens equation' for the system, that is, the equation whose solutions give the image positions [Ren-SS, p. 185].

Einstein Rings

In 1936 a Czech engineer named Rudi Mandl approached various scientists (including Einstein) with his idea that a foreground star may act as a "gravitational lens" for light coming from a background star. After Mandl's urging, Einstein wrote a short article for *Science* on the matter, which was published in 1936 [Ein36]. This article was clearly based on Einstein's 1912 notes on the subject [Ren-SS, p. 186]. The paper included the new result that at perfect alignment a background star undergoing lensing by a foreground one will appear as a very bright ring (hence the name "Einstein ring"). However, Einstein concluded that the size of the ring would be far too small to be resolvable, and that the probability of such a configuration was extremely small. He was pessimistic about a possible detection: "Of course, there is not much hope of observing this phenomenon directly." According to [Ren-SS, p. 186], Einstein was so skeptical that in his letter to the editor of *Science* he wrote: "Let me also thank you for your cooperation with the little publication, which Mister Mandl squeezed out of me. It is of little value, but it makes the poor guy happy." Fortunately, history would favor Mandl.

Giant Luminous Arcs, Microlensing, and Blending of Light

Einstein's article inspired (prior to its publication) his Princeton colleague Henry Norris Russell to write the first popular article on gravitational lenses: In *Scientific American*, he presents lensing as a perfect test of general relativity. Russell invented a hypothetical observer on a planet around the White Dwarf companion of the bright star Sirius to illustrate the relativistic effect of bending of light and to make it "conspicuous to the immediate gaze" [Rus]. In this scenario, Russell seems to be the first to study the lensing effect of extended sources, and his figures even show the typical and now well-known images of giant arcs — magnified and tangentially extended images of a background source that look like crescents.

Russell also noticed that star-star lensing (today we call this galactic microlensing) would produce a change of the observable brightness of the background star due to the relative motion between source, lens and observer, and that such an event would typically last for about a day. He mentioned the problem of blending of light due to the brightness of the lensing star[4] as well as the desirability of an early warning system[5] — all basic issues that today's observers have to face (see Section 5.5 on galactic microlensing). In the following year, Tikhov [Tik] determined the intensities of the two images of a star lensed by another star (cf. [Ein36]).

---

[4] "Blending" here relates to the fact that we do not measure the light of the lensed star alone; but that there is additional light, in this case from the lensing star itself. As a consequence, the "baseline" of the light curve is higher than in the case in which we see the background star alone; thus some properties in a "blended" system may be different from those in an isolated one, e.g., the magnification as a function of time is changed (the amplitude is smaller), and the light curve can be chromatic if the stars involved have different colors.

[5] The idea is to observe a star very often in order to be able to notice a possible change due to gravita-

Galaxies as Lenses

Fritz Zwicky — indirectly influenced by Mandl as well — point out in 1937 that "extragalactic *nebulae* offer a much better chance than *stars* for the observation of gravitational lens effects" [Zwi37a]. So he was the first to recognize the potential of galaxies as gravitational lenses. Zwicky reiterated and emphasized these points about lensing in his 1957 book *Morphological Astronomy* [Zwi57]. Aside from this book, there seems to be a 25-year silence in the field of gravitational lensing following the short, productive period in the mid-1930s.

Lens Renaissance in the 1960s

It was not until the early 1960s when there was another sudden outburst of papers that considered the theoretical aspects of gravitational lensing. In particular, Liebes and Refsdal derived in detail some of the basic equations of gravitational lensing with suggestions for applications.

Liebes. In 1964, Liebes [Lie] gave many applications, including discussions of galactic star-star lensing, lensing of stars in the Andromeda galaxy, lensing by "unobservable bodies," and lensing of galaxies. Liebes critically discussed the probability of detecting these effects, and he even showed figures of "Giant Luminous Arcs."

Refsdal's Method: Time Delay and Hubble's Constant. Refsdal derived in 1964 the relations among the distances between observer, lens, and source, and the angles involved [Ref64a]. He showed how one can determine the mass of the lensing object, and he pointed out that "from theory it is reasonable to believe that the deflection of light is independent of frequency." He cautions though that this "... has not been tested by experiment with any accuracy."

In Refsdal's second lensing paper [Ref64b], he analyzed the lens effect by a galaxy on a light source lying far behind. He mainly had supernovae in mind as distant point-like sources. But he even notes that "star-like objects with intense emission ... have recently been discovered" — today we call them quasars. Refsdal realized the potential usefulness of quasars immediately, and he noted that with these objects "observations at greater distances than with supernova will be possible."

Refsdal found that for a double image there is a difference in arrival time between the two paths connecting source and observer. And since this time delay is inversely propor-

---

tional lens magnification early enough so that one is able to notify other observers and make more frequent observations possible.

tional to the Hubble constant, he was the first to note that measuring time delay in a lensed system is a way to determine the Hubble constant.

In two more papers, Refsdal suggested the use of gravitational lensing as a test for cosmological theories [Ref66]. A few years later with one of the first "numerical" projects on lensing [Ref70], he employed the ray-tracing technique to study the propagation of light in universes with inhomogeneous mass distributions. He investigated the influence of lensing on "standard candles" and emphasized the importance of magnification bias.[6]

Lensing, Cosmology, and Quasars

Two consequences of lensing with possible cosmological interest were investigated in the late sixties to early seventies: statistical effects of a lens population on background sources, and the possibility that the newly discovered quasars were just active galaxies, strongly magnified by lenses.

Statistical lensing due to local matter inhomogeneities can change the position, shape, and brightness of background sources, compared to a corresponding homogeneous universe [Gun67a, Gun67b, Noo]. If the universe is filled with a population of compact objects, identifying and counting "double images" on different angular scales could help us detect these objects. Press and Gunn showed that this method can work on mass scales from 10^4 to about 10^{17} solar masses [Pre-G].

The once popular hypothesis that quasars are highly magnified Seyfert galaxies was looked at by different authors. The basic conclusion was that although moderate magnification could be involved, lensing alone could not explain the whole quasar phenomenon. The Barnothys proposed a variety of lensing ideas and scenarios. Although some of their ideas are quite bizarre, they are often not given credit for pursuing the idea of gravitational lensing during a period in which the majority of astrophysicists were rather skeptical about this phenomenon [deS, San, Barn, Barn-B].

Specific Lens Models

The uniform transparent lens was explored in 1972 by Clark [Cla]. He gave an elementary discussion of the gravitational deflection of light due to radially and cylindrically symmetric masses.

Bourassa and colleagues developed a complex formalism to describe lensing situations and investigated a spheroidal gravitational lens, calculating bending angles and determining formulae for intensification, distortion and orientation of the images [Bou-KN]. Using this formalism, the theory of transparent gravitational lenses was fully developed. General expressions for the bending angle of a light ray around a bounded elliptical mass distribution were given, and the locations, magnifications, distortions and orientations of images could be calculated [Bou-K]. Cooke and Kantowski calculated time delays for multiple-imaged quasars. These delays are due to the differences in geometrical path lengths and gravitational potential along the light rays [Cook-K].

---

[6] Magnification bias is the effect whereby a fraction of all light sources are highly magnified due to gravitational lensing. Although the absolute fraction of them is small, there is usually a large reservoir of faint sources which can be magnified. So, in any sample of sources with a certain cut-off in apparent brightness, the fraction of sources that are affected by lensing is higher than in a "volume-limited" sample.

1.2 Detecting Gravitational Lens Effects

Here we list a number of first observations on various aspects of light deflection. Discoveries as well as failures in the search for certain lensing signatures are described, starting in the early years of the twentieth century. Observational phenomena are described in more detail in Chapter 5.

Measuring Light Deflection at Solar Limb

There were various plans to test Einstein's (wrong!) 1911 prediction for the deflection angle at the solar limb. In 1912 an Argentinian expedition was to observe the solar eclipse in Brazil, but was rained out. Another attempt was made in 1914, when Erwin Freundlich led a group to measure the positions of stars near the sun during the solar eclipse on the Russian Crimea. However, when the observers were in Russia, World War I broke out and they were captured by the Russian soldiers and released only after the eclipse (see, e.g., [Bre, Pai]). So, fortunately for Einstein, the measurement of the light deflection by the sun was not made before the correct value was published.

With the full theory of general relativity [Ein16], the correct value for the light deflection was published. In 1917 the then Astronomer Royal Frank Dyson suggested using the solar eclipse in May 1919 for the observational confirmation. This eclipse was particularly well suited, since it occurred in the Hyades constellation with many bright stars in the field. In two famous expeditions to Sobral (Brazil) and Principe Island (Gulf of Guinea, Africa), Eddington measured the displacement of stars close to the sun during the solar eclipse of May 29, 1919 to within 30% of the value predicted by Einstein (the deflection angle has been confirmed very recently with an accuracy of better than 0.02% [Leb] !) .

This experiment became the first and most famous test of general relativity. The confirmation of the result of general relativity — announced by Dyson and Eddington at a joint meeting of the Royal Society and the Royal Astronomical Society in London on November 6, 1919 — was the basis of Einstein's huge popularity starting in the 1920s.

Vain Attempts for other Lensing Effects

As early as 1923 there were attempts to measure the effect of star-star lensing. According to a footnote in [Zwi37b], E.B. Frost, then director of Yerkes Observatory, outlined a program to look for the lensing effect. The lack of any subsequent paper on this project leads us to

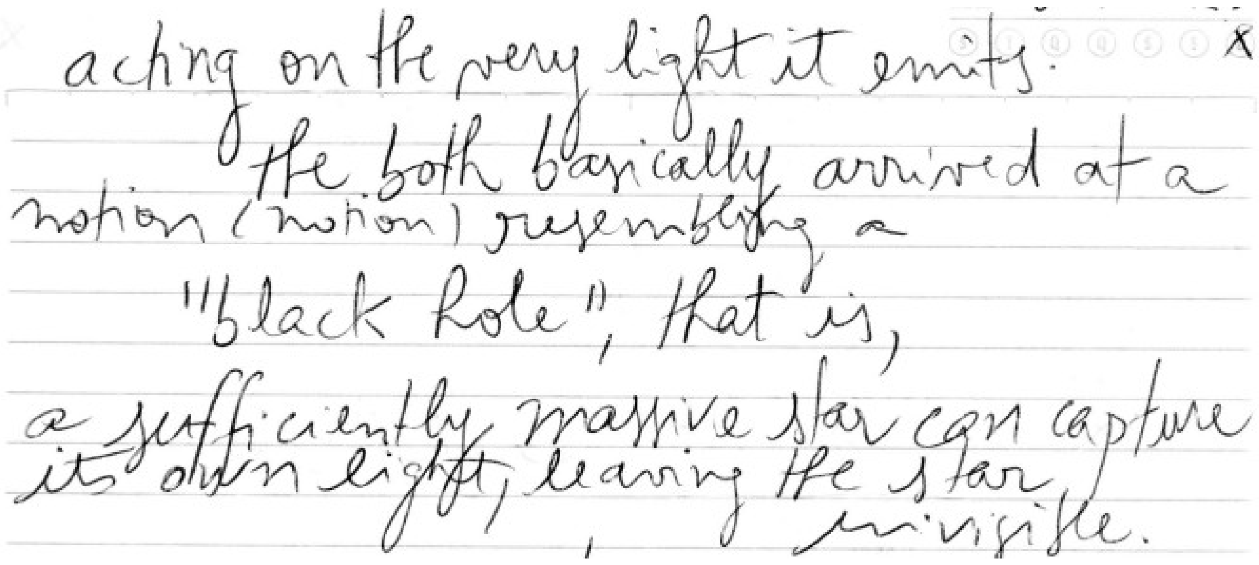
Light Deflection (cont.)

Even earlier:

c) John Michell (1783)

d) Pierre-Simon Laplace (1796)

independently investigated light being subjected to gravity, but in the context of a body



acting on the very light it emits.

He both basically arrived at a notion (notion) resembling a "black hole", that is, a sufficiently massive star can capture its own light, leaving the star invisible.

Michell and Laplace did not write about the situation of light coming from a distant source and undergoing deflection as it passes near a gravitating body.

They are who inspired the works of Cavendish and von Soldner

Soldner:

"Thus when a light ray passes by a celestial body, it will, instead of a going on in a straight direction, be forced by its attraction to describe a hyperbola whose concave side is directed against the attracting body."

He showed that a light grazing the sun would be deflected by 0.84 seconds of arc.

Light Deflection

One of the earliest calculations of the deflection of light from a distant source by a foreground gravitational field is due to Henry Cavendish around 1784. Unfortunately, the only evidence that he did such a calculation is on an "isolated scrap" of paper. Will [Wil] offers some details of this story and attempts to reproduce Cavendish's calculation of the bending angle of light passing near the surface of an attracting mass.

The next closest calculations seems to have been in an 1801 paper by Johann von Soldner: "Ueber die Ablenkung eines Lichtstrals von seiner geradlinigen Bewegung, durch die Attraktion eines Weltkörpers, an welchem er nahe vorbeigeht" ["On the Deviation of a Light Ray from its Motion along a Straight Line through the attraction of a Celestial Body which it Passes Closeby"]. This article appeared in "Berliner Astronomisches Jahrbuch für das Jahr 1804" [Sol]; see Jaki's English translation [Jak]. We note that initially von Soldner's paper calculates — using Newtonian mechanics — the bending angle formula for light emitted tangentially from the surface of a gravitating body and travels off to infinity. When applying his formula, however, he reverses the light ray's path, so it comes in from infinity and "grazes" the attracting body [Jak, pp. 945-947] (cf. [Wil, p. 414, Sec. III]). Von Soldner, who later became director of the Munich observatory and a foreign member of the Royal Astronomical Society, figured out: "Thus when a light ray passes by a celestial body, it will, instead of going on in a straight direction, be forced by its attraction to describe a hyperbola whose concave side is directed against the attracting body." He showed that a light ray grazing the sun would be deflected by 0.84 seconds of arc and concluded: "If one could observe the fixed stars very close to the sun, then one would have to take this very much into account." Von Soldner realized that he was far ahead of his time when he apologized at the end: "Hopefully, no one would find it objectionable that I treat a light ray as a heavy body." As a consequence, "Soldner's work on the deflection of light had no influence either on practice or on theory" [Jak].

Even earlier, John Michell in 1783 [Miche] and Pierre-Simon Laplace in 1796 [Lap] independently investigated light being subjected to gravity, but in the context of a body acting on the very light it emits. They both basically arrived at a notion resembling a "black hole," that is, a sufficiently massive star can capture its own light, leaving the star invisible. Laplace stated his result initially without proof, but provided the proof in 1798; see Hawking and Ellis [Haw-E, p. 365] for an English translation. It seems, however, that Michell and Laplace did not write about the situation of light coming from a distant source and undergoing deflection as it passes near a gravitating body. We note, though, that it was Michell and Laplace who inspired the works of Cavendish and von Soldner, respectively (e.g., [Wil, p. 413] and [Jak, pp. 935–936]).

In hindsight, it is slightly surprising that Newton himself did not seem to have studied light deflection by gravity. All the ingredients were there with his gravitational dynamics and the corpuscular theory of light, and the mathematics involved was straightforward compared to other problems he solved successfully. His famous Query 1 of the *Opticks* (1704):

"Do not Bodies act upon Light at a distance, and by their action bend its Rays; and is not this action strongest at the least distance?" [New] is phrased in such a general way that today we tend to assume that it includes gravitational bending as well. This is not the case, though, according to Jaki, who comments [Jak]: "He [Newton], of course, had reflection, refraction and diffraction in mind."

Maybe it is equally surprising that it seems to have taken more than 100 years after von Soldner until somebody else dealt again quantitatively with the problem of light deflection. Even more so, when one learns that a famous contemporary of von Soldner, the physicist-philosopher Georg Christoph Lichtenberg wrote in the year 1796, "Wenn das Licht trotz seiner Geschwindigkeit noch eine Schwere hat, so würde doch so etwas wie Refraktion am Horizonte erscheinen müssen, weil es von der Erde stark gezogen wird" ["If light despite its velocity also had gravity, then something like refraction would have to occur at the horizon, because it would be attracted heavily by the earth"] [Lic].

We know today that the value of the deflection angle that Cavendish and von Soldner calculated is too small by a factor of two.[1] About a century after von Soldner's work, Albert Einstein arrived at a similar numerical value in his first attempt to determine the deflection angle — based on the equivalence principle. Einstein directly addressed the influence of gravity on light in a letter entitled: "Über den Einfluß der Schwerkraft auf die Ausbreitung des Lichtes" ["On the Influence of Gravitation on the Propagation of Light"] [Ein11]; see [Lor-EMW, p. 99] for an English translation of [Ein11]. He predicted that a light ray passing close to a "celestial body" might suffer a deflection towards the side of decreasing gravitational potential. Einstein found a numerical value of 0.83 seconds of arc for the deflection angle of light grazing the sun. In this paper, Einstein also stated that he wished astronomers to investigate this question: "Es wäre dringend zu wünschen, daß sich Astronomen der hier aufgerollten Frage annähmen, auch wenn die im vorigen gegebenen Überlegungen ungenügend fundiert oder gar abenteuerlich erscheinen sollten" ["It would be highly desirable that astronomers take up the question raised here, even if the considerations should seem to be insufficiently founded or entirely speculative"].

By 1915 Einstein succeeded in deriving the correct expression for the light deflection angle with the presentation of the General Theory of Relativity [Ein16, Ein22]. For a light ray passing at a distance R from an object of mass M he found the following deflection angle[2] — see Figure 1.1:

$$\hat{\alpha} = \frac{4GM}{c^2 R}, \tag{1.1}$$

where G is the constant of gravity and c is the speed of light. With the solar values for

---

[1] Will [Wil] compares Cavendish and von Soldner's determinations of the light deflection angle, and includes Einstein's correction to twice the value.

[2] Notice that the bending angle $\hat{\alpha}$ is independent of the light's wavelength and depends on the impact distance and deflector's mass. See Section 3.1.5.

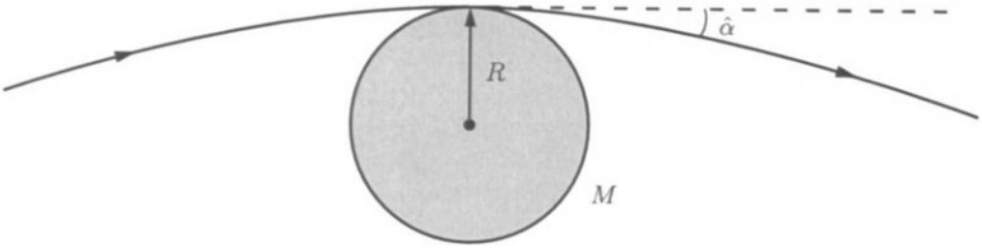

Figure 1.1. Light from a distant source experiences a deflection through angle $\hat{\alpha}$ by a mass M. The angle $\hat{\alpha}$ was calculated incorrectly by Cavendish (1784) and von Soldner (1801) since they used Newton's theory of gravity (see [Wil] for details). It was not until the formulation of General Relativity in 1915 that the correct formula for the bending angle was established by Einstein — see equation (1.1).

radius and mass he obtained

$$\hat{\alpha} = \frac{4GM_\odot}{c^2 R_\odot} \simeq 1.''74.$$

Note that since the light ray grazes the sun, we assume $R \simeq R_\odot$. In Einstein's own words: "Ein an der Sonne vorbeigehender Lichtstrahl erfährt demnach eine Biegung von 1.7 Bogensekunden" ["A light ray grazing the sun therefore experiences a deflection of 1.7 arcseconds"]. We refer readers to [Ray-BB, pp. 59–60] for a derivation of (1.1).

In the following years there were several papers dealing theoretically with light deflection, among them a short letter by Oliver Lodge about the "Einstein deflection" in which he made the point that "it is not permissible to say that the solar gravitational field acts as a lens, for it has no focal length" [Lod]. He pointed out that one would get a focal line starting at "a place seventeen times the distance of Neptune."

Multiple Imaging

While investigating the birth of general relativity, Renn, Sauer and Stachel [Ren-SS] discovered that in notes dated to the spring of 1912 Einstein explored gravitational lensing by a star. He showed that a distant star lying close to the line of sight to a foreground star will be imaged twice, with a faint secondary image increasing the total measurable intensity of the background star [Ren-SS, pp. 185, 186].[3] Einstein did not publish these results until 1936 [Ein36]. The possibility of double images was also mentioned in 1923 by Sir Arthur Eddington in his book *Space, Time and Gravitation* [Edd, p. 133–134]. This effect was also quantitatively studied by Chwolson[Chw] in 1924. Chwolson's article, "Über eine mögliche Form fiktiver Doppelsterne" ["On a possible form of fictitious double stars"], even mentions the "reversed mirror image" (i.e., the negative parity of the second image)

---

[3] In the same notes, Einstein also determined the 'lens equation' for the system, that is, the equation whose solutions give the image positions [Ren-SS, p. 185].

4.2 Fundamental Relations

In this chapter, we will consider a simple thermodynamic system described by the following state variables: entropy S, volume V and number of moles $N_1, \ldots, N_r$ of the r constituents. From now on, we shall denote by $\{N_A\}$ the set of numbers of moles of the r chemical constituents ($A = 1, \ldots, r$).

4.2.1 Gibbs Relation

According to the definitions (2.9), (2.10) and (2.11) of temperature T, pressure p and chemical potentials μ_A, the differential of $U(S, V, \{N_A\})$ is obtained by applying relation (1.7),

4 Thermodynamic Potentials

Hermann Ludwig Ferdinand von Helmholtz, 1821–1894

H. L. F. von Helmoltz was professor of physiology, first in Königsberg, then in Bonn, Heidelberg and Berlin. He saw friction and inelastic collisions as processes of energy redistribution, which he explained in his first book on thermodynamics : 'Über die Erhaltung der Kraft'. In addition to the vast research that made him famous, he was interested in the sensory perception of colours and music.

4.1 Historical Introduction

The nineteenth century witnessed many developments in thermodynamics, most notably the introduction of the ***thermodynamic potentials*** that will be presented in this chapter.

The study of chemical equilibria raised the question of knowing whether it was possible to define a potential that would play in thermodynamics an analogous role to that of the potential in mechanics. Then, equilibrium would be obtained by minimising the potential [32].

In 1869, François-Jacques-Dominique Massieu, general inspector of "Ecole des Mines" and professor at the Science Faculty of the University of Rennes, presented to the "Académie des sciences" his work on what he called the *characteristic functions of fluids*. He considered entropy as a function of internal energy, volume and number of moles of each constituent. He then defined transformations of this function according to a method developed by the French mathematician Adrien-Marie Legendre [33].

In the 1870s, the American physico-chemist and mathematician Josiah Williard Gibbs published a series of articles on the equilibrium of heterogeneous fluids. While his analysis was based on the condition of entropy maximisation, he used the functions denoted nowadays by F, G and H in order to clarify the equilibrium conditions he had found. He acknowledged the contribution of Massieu in his work. Gibbs considered how much energy changed when the mass of one of the constituents changed. Thus, he introduced the notion of chemical potential, but did not use this term. He insisted on avoiding the adjective 'chemical', as he wished to emphasise that his equilibrium conditions pertained not only to chemical substances, but also to phase transitions, electrical effects or elastic media [34].

In 1882, Hermann von Helmholtz determined the potential that defined the equilibrium state of a system when its temperature is kept constant [35]. Thus, he defined the ***free energy***, denoted by the letter F, that is still used nowadays. Another potential, designated today by the letter H, was named ***enthalpy*** by Kammerling Onnes [36].

In 1884, the Frenchman Pierre Duhem presented a thesis on the application of thermodynamic potentials in chemistry. Purportedly, he had to withdraw it under the pressure of Marcelin Berthelot. Later, he published his works in the form of three books, in which he described what he called *chemical mechanics*, which in effect was a description of chemical reactions based on thermodynamics.

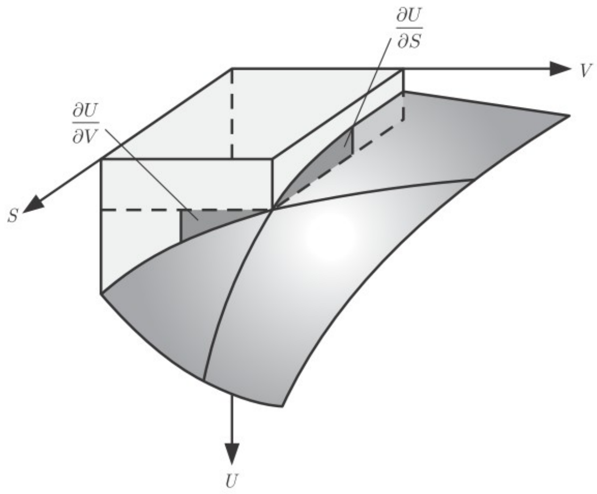
In this chapter, we introduce the free energy also called the "Helmholtz free energy", denoted F, and the "Gibbs free energy" denoted G. The international organisation IUPAC recommends using the expressions "***Helmholtz free energy***" A and "***Gibbs free energy***" G. We will discuss the meaning of the adjective "free" in these designations. Although the IUPAC convention denotes Helmholtz free energy by the letter A, the physics community perseveres in the usage of F and we will follow this convention.

4.2 Fundamental Relations

In this chapter, we will consider a simple thermodynamic system described by the following state variables: entropy S, volume V and number of moles $N_1, \ldots, N_r$ of the r constituents. From now on, we shall denote by $\{N_A\}$ the set of numbers of moles of the r chemical constituents ($A = 1, \ldots, r$).

4.2.1 Gibbs Relation

According to the definitions (2.9), (2.10) and (2.11) of temperature T, pressure p and chemical potentials μ_A, the differential of $U(S, V, \{N_A\})$ is obtained by applying relation (1.7),



$\frac{\partial U}{\partial S}$
V
$\frac{\partial U}{\partial V}$
S
U

Figure 4.1 Convex surface corresponding to the internal energy $U(S, V)$ as a function of entropy S and volume V in state space (S, U, V). The vertical planes at fixed S or fixed V define curves on the surface $U(S, V)$. The slopes of these curves correspond to the partial derivatives.

$$dU = T\,dS - p\,dV + \sum_{A=1}^{r} \mu_A\,dN_A \tag{4.1}$$

Equation (4.1) is called the ***Gibbs relation***. This equation can also be obtained by multiplying (2.12) by the infinitesimal time interval dt. The Gibbs relation (4.1) expresses the fact that the internal energy U is a state function, i.e. $U = U(S, V, \{N_A\})$, and that the intensive quantities T, p and μ_A are also state functions, i.e.

$$\begin{aligned} T &= T(S, V, \{N_A\}) \\ p &= p(S, V, \{N_A\}) \\ \mu_A &= \mu_A(S, V, \{N_A\}) \end{aligned} \tag{4.2}$$

The relations that appear in (4.2) are called ***equations of state***, because they constitute relationships between the state variables S, V and $\{N_A\}$.

As an ilustration, the internal energy $U(S, V)$ is graphically represented as a state function of the variables entropy S and volume V (Fig. 4.1). This allows a geometric interpretation of the temperature $T(S, V)$ and pressure $p(S, V)$. In general, the internal energy $U(S, V)$ is represented as a surface in the abstract 3-dimensional space (S, U, V), called ***state space***. The temperature $T(S, V)$ and pressure $p(S, V)$ are state functions evaluated at a point on the surface $U(S, V)$. The temperature, defined by $T = \partial U(S, V)/\partial S$, is the derivative with respect to S of the curve located at the intersection of the surface $U(S, V)$ and the plane $V = \text{const}$. The pressure $p = -\,\partial U(S, V)/\partial V$ is the opposite of the derivative with respect to V of the curve located at the intersection of the surface $U(S, V)$ and the plane $S = \text{const}$. The curvature of the surface $U(S, V)$ is such that $T > 0$ and

$p > 0$. Notice that the equations of state $U(S, V)$ and $S(U, V)$ are represented by the same surface in state space.

4.2.2 Euler Relation

Let us consider now a system consisting of λ identical subsystems, each characterised by its entropy S, volume V and number of moles N_A for substances $A = 1, ..., r$. Since the state variables are extensive, the system has a total entropy λS, a total volume λV and λN_A moles of substance A. Since the internal energy of the system is an extensive state function, it is the sum of the internal energies of the subsystems, i.e.

$$U(\lambda S, \lambda V, \{\lambda N_A\}) = \lambda U(S, V, \{N_A\}) \tag{4.3}$$

The derivative of the relation (4.3) with respect to λ can be written as,

$$\frac{\partial U}{\partial(\lambda S)} \frac{d(\lambda S)}{d\lambda} + \frac{\partial U}{\partial(\lambda V)} \frac{d(\lambda V)}{d\lambda} + \sum_{A=1}^{r} \frac{\partial U}{\partial(\lambda N_A)} \frac{d(\lambda N_A)}{d\lambda} = U \tag{4.4}$$

Since S, V and N_A are independent of λ, equation (4.4) reduces to,

$$\frac{\partial U}{\partial(\lambda S)} S + \frac{\partial U}{\partial(\lambda V)} V + \sum_{A=1}^{r} \frac{\partial U}{\partial(\lambda N_A)} N_A = U \tag{4.5}$$

Equation (4.5) has to be satisfied for every value of λ. Thus, choosing $\lambda = 1$,

$$U = \frac{\partial U}{\partial S} S + \frac{\partial U}{\partial V} V + \sum_{A=1}^{r} \frac{\partial U}{\partial N_A} N_A \tag{4.6}$$

Using the definitions (2.9)–(2.11), relation (4.6) yields,

$$U = TS - pV + \sum_{A=1}^{r} \mu_A N_A \tag{4.7}$$

which is called the ***Euler relation***.

4.2.3 Gibbs–Duhem Relation

The infinitesimal variation of internal energy dU is obtained by differentiating the Euler equation (4.7),

$$dU = T\,dS + S\,dT - p\,dV - V\,dp + \sum_{A=1}^{r} \left(\mu_A\,dN_A + N_A\,d\mu_A\right) \tag{4.8}$$

Then, according to the Gibbs relation (4.1), the expression (4.8) requires that,

$$S\,dT - V\,dp + \sum_{A=1}^{r} N_A\,d\mu_A = 0 \tag{4.9}$$

which is called the ***Gibbs–Duhem relation***.

4.3 Legendre Transformation

So far, we have considered the state function internal energy, which is a function of extensive state variables. The conjugated quantities obtained from internal energy by partial derivation are intensive quantities. Often in practical situations, it is these intensive quantities that are measured or controlled. The most obvious case is entropy and its conjugated variable temperature. In a measurement, temperature is more likely to be controlled than entropy.

This raises the question whether it is possible to reformulate our mathematical description in order to use intensive quantities as state variables. The extensive variables will appear then as conjugated quantities. We will now see that such a mathematical operation is possible [37]. This approach will lead us to introduce the thermodynamic potentials called free energy, enthalpy and Gibbs free energy. The simplest case is a state function $F(X_0, X_1, \ldots, X_n)$. Our goal is to use one or more partial derivatives $Y_i(X_0, X_1, \ldots, X_n) = \partial F/\partial X_i$ as independent state variables without loosing the information contained in the function $F(X_0, X_1, \ldots, X_n)$.

Let us consider first the state function $F(X)$ of a single extensive variable X. The slope of the tangent to the state function $F(X)$ at X is given by,

$$Y(X) = \frac{dF(X)}{dX} \tag{4.10}$$

The state function $F(X)$ is a curve determined by a set of points (X, F) corresponding to values of the variable X and the associated function F. The tangent of slope $Y(X)$ to this curve at a fixed point (X, F) intersects the vertical axis at point $(0, G)$ (Fig. 4.2).

Thus, the tangent is determined by a couple of values (Y, G) that correspond to the slope Y and to the coordinate of the intersect on the vertical axis G. Graphically (Fig. 4.2), the slope Y of the tangent is given by

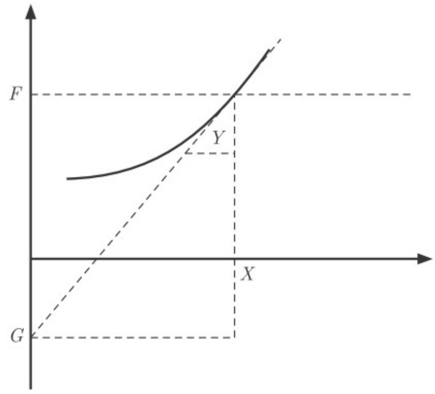


Figure 4.2 $Y(X)$ is the slope of the tangent to the state function $F(X)$ at point X. The tangent intersects the vertical axis at point G.

$$Y = \frac{F - G}{X - 0} \tag{4.11}$$

When inverting the equation of state $Y = Y(X)$, we obtain $X = X(Y)$. Thus, the state function F can be expressed as $F(X(Y))$ and equation (4.11) becomes

$$G(Y) = F(X(Y)) - YX(Y) \tag{4.12}$$

The expression (4.12) is called the ***Legendre transform*** of the state function F with respect to the state variable X. The Legendre transform $G(Y)$ is a state function of Y. The Legendre transformation of $G(Y)$ with respect Y yields again the function $F(X)$. Thus, the state functions $F(X)$ and $G(Y)$ contain the same information.

The Legendre transformation can be generalised from one to several variables. The partial derivative of the state function $F(X_0, X_1, \dots, X_n)$ with respect to X_i, where $i = 0, 1, \dots, n$, evaluated in the state $(X_0, X_1, \dots, X_n)$ is given by,

$$Y_i(X_0, X_1, \dots, X_n) = \frac{\partial F(X_0, X_1, \dots, X_n)}{\partial X_i} \tag{4.13}$$

By analogy with the Legendre transformation with respect to a single state variable, we can write,

$$Y_i = \frac{F - G}{X_i - 0} \tag{4.14}$$

When inverting the equation of state $Y_i = Y_i(X_0, X_1, \dots, X_n)$, we obtain $X_i = X_i(X_0, X_1, \dots, Y_i, \dots, X_n)$. Thus, the state function F can be expressed as $F\Big(X_0, X_1, \dots, X_i(X_0, X_1, \dots, Y_i, \dots, X_n), \dots, X_n\Big)$ and equation (4.11) becomes,

$$\begin{aligned} G(X_0, X_1, \dots, Y_i, \dots, X_n) = {} & F\Big(X_0, X_1, \dots, X_i(X_0, X_1, \dots, Y_i, \dots, X_n), \dots, X_n\Big) \\ & - Y_i X_i(X_0, X_1, \dots, Y_i, \dots, X_n) \end{aligned} \tag{4.15}$$

According to the definition (4.13), the partial derivative of equation (4.15) with respect to Y_i yields,

$$\frac{\partial G}{\partial Y_i} = \frac{\partial F}{\partial X_i}\frac{\partial X_i}{\partial Y_i} - X_i - Y_i\frac{\partial X_i}{\partial Y_i} = -X_i \tag{4.16}$$

There is a simple relationship between the curvatures of the functions $G(Y)$ and $F(X)$ that we can demonstrate as follows. We obtain the second order partial derivative of F with respect to X_i and of G with respect to Y_i, by differentiating relations (4.13) and (4.16),

$$\frac{\partial^2 F}{\partial X_i^2} = \frac{\partial Y_i}{\partial X_i} \quad \text{and} \quad \frac{\partial^2 G}{\partial Y_i^2} = -\frac{\partial X_i}{\partial Y_i} \tag{4.17}$$

This implies that,

$$\frac{\partial^2 G}{\partial Y_i^2} = -\left(\frac{\partial^2 F}{\partial X_i^2}\right)^{-1} \tag{4.18}$$

Hence, we find that the sign of the curvature of the state function G with respect to the variable Y_i is the opposite of the sign of the curvature of the state function F with respect to the variable X_i.

Equation (4.12) defines the Legendre transform of the state function F with respect to the state variable X_i. To simplify the notation, we simply write,

$$G = F - \; Y_i \, X_i \tag{4.19}$$

We obtain the state function $H\,(Y_0, Y_1, \ldots, Y_n)$ by performing successive Legendre transformations on the state function $F\,(X_0, X_1, \ldots, X_n)$, i.e.

$$H = F - \sum_{i=0}^{n} Y_i \, X_i \tag{4.20}$$

It is also possible to perform Legendre transformations on a few variables only, which is often the case in thermodynamics. In the following section, we will obtain the thermodynamic potentials by performing several Legendre transformations of the internal energy with respect to various extensive state variables.

4.3.1 Link between Thermodynamics and Mechanics

In analytical mechanics, a Legendre transformation defined with the opposite sign relates the Lagrangian $L\,(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_n, \boldsymbol{v}_1, \ldots, \boldsymbol{v}_n)$ of a system containing n material points to the Hamiltonian $H\,(\boldsymbol{r}_1, \ldots, \boldsymbol{r}_n, \boldsymbol{P}_1, \ldots, \boldsymbol{P}_n)$ of this system [9], i.e.

$$H = \sum_{i=1}^{n} \boldsymbol{P}_i \cdot \boldsymbol{v}_i - \; L \tag{4.21}$$

Since the Legendre transform of a state function is a state function, its opposite is also a state function and contains the same information.

4.4 Thermodynamic Potentials

The extensive state function that plays a central role in thermodynamics is the internal energy $U\,(S, V, \{N_A\})$. We call ***thermodynamic potential*** every state function obtained by a Legendre transformation of $U\,(S, V, \{N_A\})$. By extension, the internal energy itself can also be called a thermodynamic potential since it can be obtained by two successive Legendre transformations starting from itself. The three other thermodynamic potentials that we will define in this section are the free energy, the enthalpy and the Gibbs free energy.

4.4.1 Free Energy

The ***free energy*** $F\,(T, V, \{N_A\})$, also called ***Helmholtz free energy***, is defined as the Legendre transform (4.19) of the internal energy $U\,(S, V, \{N_A\})$ with respect to the entropy S, i.e.

$$F = U - \; T S \tag{4.22}$$

According to the Euler relation (4.7), the free energy can be written as,

$$F = -\,p\,V + \sum_{A=1}^{r} \mu_A\,N_A \tag{4.23}$$

The differentiation of expression (4.22) is written,

$$dF = dU - \,T\,dS - \,S\,dT \tag{4.24}$$

Substituting for dU its value given by the Gibbs relation (4.1), expression (4.24) becomes,

$$dF = -\,S\,dT - \,p\,dV + \sum_{A=1}^{r} \mu_A\,dN_A \tag{4.25}$$

In conformity with the mathematical description of Legendre transformations, the differential (4.25) shows that the free energy is a state function of the variables T, V and N_A. Moreover, the variables that are conjugates of these state variables are defined as,

$$S\,(T,V,\{N_A\}) = -\,\frac{\partial F\,(T,V,\{N_A\})}{\partial T} \tag{4.26}$$

$$p\,(T,V,\{N_A\}) = -\,\frac{\partial F\,(T,V,\{N_A\})}{\partial V} \tag{4.27}$$

$$\mu_A\,(T,V,\{N_A\}) = \frac{\partial F\,(T,V,\{N_A\})}{\partial N_A} \tag{4.28}$$

4.4.2 Enthalpy

The ***enthalpy*** $H\,(S,p,\{N_A\})$ is defined as the Legendre transform (4.19) of the internal energy $U\,(S,V,\{N_A\})$ with respect to the volume V, i.e.

$$H = U + p\,V \tag{4.29}$$

According to the Euler relation (4.7), the enthalpy H can be written as,

$$H = T\,S + \sum_{A=1}^{r} \mu_A\,N_A \tag{4.30}$$

The differentiation of expression (4.29) yields,

$$dH = dU + p\,dV + V\,dp \tag{4.31}$$

Substituting for dU its value given by the relation (4.1), expression (4.31) becomes,

$$dH = T\,dS + V\,dp + \sum_{A=1}^{r} \mu_A\,dN_A \tag{4.32}$$

The differential (4.32) shows that the enthalpy is a state function of the variables S, p and N_A. Moreover, the conjugates of these state variables are,

$$T(S,p,\{N_A\}) = \frac{\partial H(S,p,\{N_A\})}{\partial S} \tag{4.33}$$

$$V(S,p,\{N_A\}) = \frac{\partial H(S,p,\{N_A\})}{\partial p} \tag{4.34}$$

$$\mu_A(S,p,\{N_A\}) = \frac{\partial H(S,p,\{N_A\})}{\partial N_A} \tag{4.35}$$

4.4.3 Gibbs Free Energy

The ***Gibbs free energy*** $G(T,p,\{N_A\})$ also called ***free enthalpy*** is defined as the Legendre transform (4.19) of the internal energy $U(S,V,\{N_A\})$ with respect to entropy S and volume V or, equivalently, as the Legendre transform of the enthalpy $H(S,p,\{N_A\})$ with respect to entropy S, i.e.

$$G = U + pV - TS = H - TS \tag{4.36}$$

Taking into account the Euler relation (4.7), the Gibbs free energy reads,

$$G = \sum_{A=1}^{r} \mu_A N_A \tag{4.37}$$

The differentiation of (4.36) yields,

$$dG = dU - T\,dS - S\,dT + p\,dV + V\,dp \tag{4.38}$$

Substituting for dU its value given by the Gibbs relation (4.1), the expression (4.38) for dG becomes,

$$dG = -S\,dT + V\,dp + \sum_{A=1}^{r} \mu_A\,dN_A \tag{4.39}$$

The differential (4.39) shows that the Gibbs free energy is a state function of the variables T, p and N_A. Moreover, the conjugates of these state variables are defined as,

$$S(T,p,\{N_A\}) = -\frac{\partial G(T,p,\{N_A\})}{\partial T} \tag{4.40}$$

$$V(T,p,\{N_A\}) = \frac{\partial G(T,p,\{N_A\})}{\partial p} \tag{4.41}$$

$$\mu_A(T,p,\{N_A\}) = \frac{\partial G(T,p,\{N_A\})}{\partial N_A} \tag{4.42}$$

In the following sections of this chapter, we shall see that these thermodynamic potentials enable the characterisation of equilibrium states of systems subjected to constraints imposed by their interaction with an environment that we shall define as reservoirs or baths.

Chapter 7

Angular Momentum

In our discussion of the Schrödinger equation in three dimensions we will need to deal with the kinetic energy in three dimensions, which has the form

$$K = \frac{\mathbf{p}^2}{2\mu} \tag{7-1}$$

for problems in which the effective mass of the particle is μ. Just as in classical mechanics, there is a close connection between $\mathbf{p}^2$ and the square of the angular momentum $\mathbf{L} = \mathbf{r} \times \mathbf{p}$. We shall take over this expression for the angular momentum into quantum mechanics, with the recognition that $\mathbf{r}$ and $\mathbf{p}$ are to be treated as operators. We will also see (Supplement 7-A **[www.wiley.com/college/gasiorowicz]**) that when the potential in a three-dimensional Schrödinger equation

$$H\psi(\mathbf{r}) = \left(\frac{\mathbf{p}^2}{2\mu} + V(\mathbf{r})\right)\psi(\mathbf{r}) = E\psi(\mathbf{r}) \tag{7-2}$$

is central, so that

$$V(\mathbf{r}) = V(r) \tag{7-3}$$

then angular momentum is conserved.

The conservation of angular momentum implies the operator equation

$$\frac{d\mathbf{L}}{dt} = 0 \tag{7-4}$$

This, as seen in Chapter 6, is equivalent to

$$[H, \mathbf{L}] = 0 \tag{7-5}$$

Our discussion of the details of the eigenvalues and eigenfunctions of the angular momentum operators is presented in two ways. We may proceed from $\mathbf{p}^2$ and obtain the angular momentum eigenvalue equation directly as a differential equation, which can be solved in a standard way. The other way proceeds from the definition of the angular momentum operator, and deals with the angular momentum commutation relations. This approach is patterned after the way we dealt with the harmonic oscillator in Chapter 6, and is more directly "quantum mechanical." We therefore relegate the direct approach to Supplement 7-B **[www.wiley.com/college/gasiorowicz]**, and turn directly to the algebraic, operator approach.

7-1 THE ANGULAR MOMENTUM COMMUTATION RELATIONS

We might be tempted to look for simultaneous eigenfunctions of H and all three components of $\mathbf{L}$. This, as we have seen in Chapter 5, is only possible if all four operators commute with each other. To proceed we must check whether *all* of the operators L_x, L_y, and L_z commute with each other, as well as with H. In fact, different components of the angular momentum *do not* commute with each other. For example, paying particular attention to the ordering of the operators, we get, using $\mathbf{L} = \mathbf{r} \times \mathbf{p}$,

$$\begin{aligned}[L_x, L_y] &= [yp_z - zp_y, zp_x - xp_z] \\ &= y[p_z, z]p_x + x[z, p_z]p_y \\ &= \frac{\hbar}{i}(yp_x - xp_y) = i\hbar L_z\end{aligned} \tag{7-6a}$$

Similarly we can show that

$$[L_y, L_z] = i\hbar L_x \tag{7-6b}$$

and

$$[L_z, L_x] = i\hbar L_y \tag{7-6c}$$

It is true that each of the components of angular momentum commutes with $\mathbf{L}^2$. For example,

$$\begin{aligned}[L_z, L_x^2 + L_y^2 + L_z^2] &= L_y[L_z, L_y] + [L_z, L_y]L_y + L_x[L_z, L_x] + [L_z, L_x]L_x \\ &= -i\hbar L_yL_x - i\hbar L_xL_y + i\hbar L_xL_y + i\hbar L_yL_x = 0\end{aligned} \tag{7-7}$$

We can see that as a consequence of these commutation relations, only one component of $\mathbf{L}$ may be chosen with H and $\mathbf{L}^2$ to form a simultaneously commuting set. To show this let us assume that we have a set of eigenfunctions that are simultaneous eigenfunctions of all three components of $\mathbf{L}$. Let us assume that

$$L_x|u\rangle = l_1|u\rangle$$

and

$$L_y|u\rangle = l_2|u\rangle$$

which implies that $L_xL_y|u\rangle = l_1l_2|u\rangle$ and $L_yL_x|u\rangle = l_2l_1|u\rangle$. As a consequence of (7-6a) this means that $L_z|u\rangle = 0$. This, however implies that

$$l_2|u\rangle = L_y|u\rangle = \frac{1}{i\hbar}[L_z, L_x]|u\rangle = \frac{1}{i\hbar}L_zl_1|u\rangle = 0$$

Similarly, we can show that $l_1|u\rangle = 0$. This means that only for $\mathbf{L} = 0$ can we have simultaneous eigenfunction for all three components of the angular momentum.

There is nothing to keep us from picking just one component of $\mathbf{L}$ as part of the commuting set. Conventionally the choice is L_z, but there is nothing special about this choice. We thus will deal with simultaneous eigenfunctions of $\mathbf{L}^2$ and L_z. We will denote the eigenkets by $|l, m\rangle$. Our starting point is thus the set of equations

$$\begin{aligned}\mathbf{L}^2|l, m\rangle &= \hbar^2 l(l+1)|l, m\rangle \\ L_z|l, m\rangle &= \hbar m|l, m\rangle\end{aligned} \tag{7-8}$$

At this point we make no statements about what the values of l and m are. They must be real since the operators $\mathbf{L}$ are hermitian. The factors of $\hbar$ are there purely for dimensional reasons, since the product $\mathbf{r} \times \mathbf{p}$ has the dimensions of $\hbar$.

7-2 RAISING AND LOWERING OPERATORS FOR ANGULAR MOMENTUM

Our starting point is (7-8), together with the angular momentum commutation relations (7-6) and the orthonormality relation

$$\langle l', m' | l, m \rangle = \delta_{ll'} \delta_{mm'} \tag{7-9}$$

It will prove convenient to introduce the operators

$$L_\pm = L_x \pm iL_y \tag{7-10}$$

These obey the commutation relations

$$\begin{aligned} [L_+, L_-] &= [L_x + iL_y, L_x - iL_v] = (-2i)[L_x, L_v] \\ &= 2\hbar L_z \end{aligned} \tag{7-11}$$

and

$$\begin{aligned} [L_z, L_\pm] &= [L_z, L_x \pm iL_y] = i\hbar L_y \mp i(i\hbar L_x) = \pm\hbar(L_x \pm iL_y) \\ &= \pm\hbar L_\pm \end{aligned} \tag{7-12}$$

It is also obvious that

$$[\mathbf{L}^2, L_\pm] = 0 \tag{7-13}$$

Furthermore, we have

$$\begin{aligned} L_+L_- &= (L_x + iL_y)(L_x - iL_y) = L_x^2 + L_y^2 - i[L_x, L_y] \\ &= \mathbf{L}^2 - L_z^2 + \hbar L_z \end{aligned} \tag{7-14}$$

and similarly,

$$L_-L_+ = \mathbf{L}^2 - L_z^2 - \hbar L_z \tag{7-15}$$

Thus

$$L_+L_- + L_z^2 - \hbar L_z = L_-L_+ + L_z^2 + \hbar L_z = \mathbf{L}^2 \tag{7-16}$$

We now note that $\langle l, m | L_x^2 | l, m \rangle = \langle L_x(l, m) | L_x(l, m) \rangle \geq 0$ and by extension $\langle l, m | \mathbf{L}^2 | l, m \rangle \geq 0$. This implies that $l(l + 1) \geq 0$. From this it follows that $l \geq 0$. (The alternative that $l \leq -1$ we reject, since we would then call $l + 1 = -l'$ and get $l' \geq 0$.) First, we note that

$$\mathbf{L}^2 L_\pm | l, m \rangle = L_\pm \mathbf{L}^2 | l, m \rangle = \hbar^2 l(l + 1) L_\pm | l, m \rangle \tag{7-17}$$

This means that $L_\pm | l, m \rangle$ is an eigenstate of $\mathbf{L}^2$ with the eigenvalue characterized by l. On the other hand,

$$L_z L_+ | l, m \rangle = (L_+ L_z + \hbar L_+) | l, m \rangle = \hbar(m + 1) L_+ | l, m \rangle \tag{7-18}$$

and similarly

$$L_z L_- | l, m \rangle = \hbar(m - 1) L_- | l, m \rangle \tag{7-19}$$

These equations imply that $L_+ | l, m \rangle$ is an eigenstate of L_z with the m value raised by unity, and $L_- | l, m \rangle$ is an eigenstate of L_z with m value lowered by unity. We therefore call $L_\pm$ *raising* and *lowering* operators, respectively. We may write

$$\begin{aligned} L_+ | l, m \rangle &= C_+(l, m) | l, m + 1 \rangle \\ L_- | l, m \rangle &= C_-(l, m) | l, m - 1 \rangle \end{aligned} \tag{7-20}$$

The conjugate relation of the first of the above is

$$\langle l, m|L_- = \langle l, m+1|C_+^*(l, m) \tag{7-21}$$

Multiplying this with the first of (7-20) yields

$$\begin{aligned} |C_+(l, m)|^2\langle l, m+1|l, m+1\rangle = \langle l, m|L_-L_+|l, m\rangle &= \langle l, m|\mathbf{L}^2 - L_z^2 - \hbar L_z|l, m\rangle \\ &= \hbar^2[l(l+1) - m^2 - m] \\ &= \hbar^2[(l-m)(l+m+1)] \end{aligned} \tag{7-22}$$

Thus

$$C_+(l, m) = \hbar\sqrt{(l-m)(l+m+1)} \tag{7-23}$$

and, similarly

$$C_-(l, m) = \hbar\sqrt{l(l+1) - m(m-1)} = \hbar\sqrt{(l+m)(l-m+1)} \tag{7-24}$$

It follows from

$$\langle L_\pm(l, m)|L_\pm(l, m)\rangle \geq 0$$

that

$$\begin{aligned} \langle L_\pm(l, m)|L_\pm(l, m)\rangle &= \langle l, m|L_\mp L_\pm|l, m\rangle \\ &= \langle l, m|\mathbf{L}^2 - L_z^2 \pm \hbar L_z|l, m\rangle \\ &= \hbar^2[l(l+1) - m(m \mp 1)] \geq 0 \end{aligned} \tag{7-25}$$

This implies that both

$$\begin{aligned} l(l+1) &\geq m(m+1) \\ l(l+1) &\geq m(m-1) \end{aligned} \tag{7-26}$$

are true. Since $l \geq 0$, it follows from the above that

$$-l \leq m \leq l \tag{7-27}$$

Let us assume that the minimum value of m is $m_{\min}$. This means that we cannot lower the m-value any further, and thus

$$L_-|l, m_{\min}\rangle = 0 \tag{7-28}$$

We can see, in a number of ways (by looking at $C_-(l, m)$ for example), that

$$m_{\min} = -l \tag{7-29}$$

Similarly, the maximum value of m, denoted by $m_{\max}$ is such that

$$L_+|l, m_{\max}\rangle = 0 \tag{7-30}$$

and

$$m_{\max} = l \tag{7-31}$$

Since the maximum value is to be reached from the minimum value by unit steps (repeated application of L_+), we find, as seen in Fig. 7-1, that there are $(2l + 1)$ steps. This implies that $(2l + 1)$ is an integer, and m can take on the values

$$m = -l, -l+1, -l+2, \ldots, l-1, l \tag{7-32}$$

The possibility that l is half-integral, $l = 1/2, 3/2, 5/2, \ldots$, will be discussed in Chapter 10, when we discuss *spin*. Until then, we restrict ourselves to *integer values of l*.

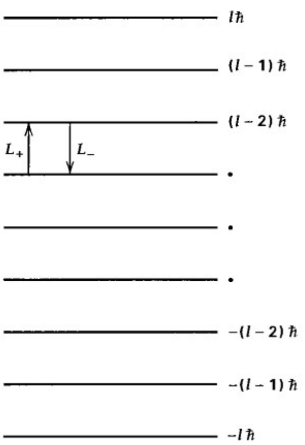

Figure 7-1 Spectrum of the operator L_z for a given value of l.

7-3 REPRESENTATION OF $|l, m\rangle$ STATES IN SPHERICAL COORDINATES

Our next task is to work out the general form of $Y_{lm}(\theta, \varphi)$, defined by

$$Y_{lm}(\theta, \varphi) = \langle \theta, \varphi | l, m \rangle \tag{7-33}$$

The angles (θ, φ) are the coordinates on the surface of a unit sphere (Fig. 7-2). The analog of

$$\int_{-\infty}^{\infty} dx |x\rangle\langle x| = \mathbf{1}$$

is

$$\int d\Omega |\theta, \varphi\rangle\langle \theta, \varphi| \equiv \int_0^{2\pi} d\varphi \int_0^{\pi} \sin\,\theta\, d\theta |\theta, \varphi\rangle\langle \theta, \varphi| = \mathbf{1} \tag{7-34}$$

It follows that the application of $\langle \theta', \varphi'|$ to (7-34) leads to

$$\langle \theta', \varphi' | \theta, \varphi \rangle = \frac{1}{\sin\,\theta} \delta(\theta - \theta')\, \delta(\varphi - \varphi') \tag{7-35}$$

To find an explicit form of the spherical harmonics as defined in (7-33) we make use of the polar coordinate representations

$$\begin{aligned} L_z &= \frac{\hbar}{i} \frac{\partial}{\partial \varphi} \\ L_\pm &= \hbar e^{\pm i\varphi}\left(\pm \frac{\partial}{\partial \theta} + i\, \cot\,\theta \frac{\partial}{\partial \varphi} \right) \end{aligned} \tag{7-36}$$

which are easily obtained from the material in Supplement 7-B.

Consider now $\langle \theta, \varphi | L_z | l, m \rangle$. This can be written in two ways. In one of them we have

$$\langle \theta, \varphi | L_z | l, m \rangle = \hbar m \langle \theta, \varphi | l, m \rangle \tag{7-37}$$

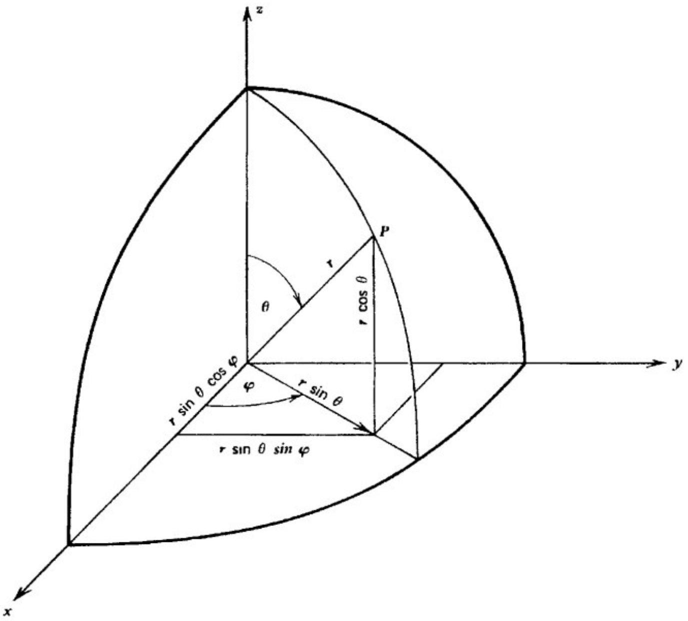

Figure 7-2 The definition of the spherical coordinates used in the text and the relation between the cartesian coordinates (x, y, z) and the spherical coordinates (r, θ, φ).

In the other we use (7-36) to write

$$\begin{aligned}\frac{i}{\hbar}\langle\theta, \varphi|L_z|l, m\rangle &= \lim_{\delta\varphi\to 0}[\langle\theta, \varphi + \delta\varphi|l, m\rangle - \langle\theta, \varphi|l, m\rangle]/\delta\varphi \\ &= \frac{\partial}{\partial\varphi}\langle\theta, \varphi|l, m\rangle\end{aligned} \tag{7-38}$$

Combining (7-37) and (7-38) we get the differential equation

$$\frac{\partial}{\partial\varphi}\langle\theta, \varphi|l, m\rangle = im\langle\theta, \varphi|l, m\rangle \tag{7-39}$$

whose solution is

$$\langle\theta, \varphi|l, m\rangle = F(\theta)e^{im\varphi} \tag{7-40}$$

We next consider the maximum m-state $|l, l\rangle$ for which $L_+|l, l\rangle = 0$. This implies that

$$\begin{aligned}0 = \langle\theta, \varphi|L_+|l, l\rangle &= \hbar e^{i\varphi}\left(\frac{\partial}{\partial\theta} + i\cot\theta\frac{\partial}{\partial\varphi}\right)\langle\theta, \varphi|l, l\rangle \\ = \hbar e^{i\varphi}\left(\frac{\partial}{\partial\theta} - l\cot\theta\right)\langle\theta, \varphi|l, l\rangle &= \hbar e^{i(l+1)\varphi}\left(\frac{\partial}{\partial\theta} - l\cot\theta\right)F(\theta)\end{aligned} \tag{7-41}$$

or

$$\left(\frac{\partial}{\partial\theta} - l \cot \theta\right)F(\theta) = 0$$

The solution of this equation is easily seen to be

$$F(\theta) = (\sin \theta)^l \tag{7-42}$$

States with values of m lower than l can be obtained by repeated application of the *lowering operator* L_- to the state $|l, l\rangle$.[1] This amounts to

$$\begin{aligned} Y_{lm}(\theta, \varphi) &= C(L_-)^{l-m}(\sin \theta)^l e^{il\varphi} \\ &= C\left(-\frac{\partial}{\partial\theta} + i \cot \theta \frac{\partial}{\partial\varphi}\right)^{l-m}[(\sin \theta)^l e^{il\varphi}] \end{aligned} \tag{7-43}$$

The coefficient C is there so that the eigenstates are normalized according to

$$\int d\Omega\, |Y_{lm}(\theta, \varphi)|^2 = 1 \tag{7-44}$$

The details of working out the Y_{lm} can be found in Supplement 7-B. **[www.wiley.com/college/gasiorowicz]** Here we restrict ourselves to writing down the appropriately normalized Y_{lm} with the phases that are conventionally used. We have

$$Y_{lm}(\theta, \varphi) = (-1)^m\left[\frac{2l+1}{4\pi}\frac{(l-m)!}{(l+m)!}\right]^{1/2} P_l^m(\cos \theta)e^{im\varphi} \tag{7-45}$$

for $m \geq 0$, with

$$Y_{l,-m} = (-1)^m Y_{lm}^* \tag{7-46}$$

The *associated Legendre polynomials* are given by

$$P_l^m(u) = (-1)^{l+m}\frac{(l+m)!}{(l-m)!}\frac{(1-u^2)^{-m/2}}{2^l l!}\left(\frac{d}{du}\right)^{l-m}(1-u^2)^l \tag{7-47}$$

for $m \geq 0$. The values for negative m are obtained from

$$P_l^{-m}(u) = (-1)^m\frac{(l-m)!}{(l-m)!}P_l^m(u) \tag{7-48}$$

We list some of the spherical harmonics in the following table.

---

[1] We may relate our results here to our discussion of *degeneracy* in Chapter 5. There are $(2l + 1)$ eigenfunctions of $\mathbf{L}^2$. In other words, the eigenfunctions are $(2l + 1)$-fold degenerate We found another operator L_z that commutes with $\mathbf{L}^2$, and we were able to arrange things so that the eigenfunctions are *simultaneous* eigenfunctions of the *mutually commuting operators* $\mathbf{L}^2$ and L_z. They are *not* eigenfunctions of L_x or L_y.

Table of Spherical Harmonics

$$Y_{0,0} = \frac{1}{\sqrt{4\pi}}$$

$$Y_{1,1} = -\sqrt{\frac{3}{8\pi}}\, e^{i\varphi} \sin\theta$$

$$Y_{1,0} = \sqrt{\frac{3}{4\pi}} \cos\theta$$

$$Y_{2,2} = \sqrt{\frac{15}{32\pi}}\, e^{2i\varphi} \sin^2\theta$$

$$Y_{2,1} = -\sqrt{\frac{15}{8\pi}}\, e^{i\varphi} \sin\theta \cos\theta$$

$$Y_{2,0} = \sqrt{\frac{5}{16\pi}} (3\cos^2\theta - 1)$$

$$Y_{3,3} = -\sqrt{\frac{35}{64\pi}}\, e^{3i\varphi} \sin^3\theta$$

$$Y_{3,2} = \sqrt{\frac{105}{64\pi}}\, e^{2i\varphi} \sin^2\theta \cos\theta$$

$$Y_{3,1} = -\sqrt{\frac{21}{64\pi}}\, e^{i\varphi} \sin\theta (5\cos^2\theta - 1)$$

$$Y_{3,0} = \sqrt{\frac{7}{16\pi}} (5\cos^3\theta - 3\cos\theta)$$

EXAMPLE 7-1

Use the raising/lowering operators to obtain the (unnormalized) eigenfunctions $Y_{lm}(\theta, \varphi)$ for $l = 2$ for $m = 2, 1, 0$.

SOLUTION We start with

$$Y_{22}(\theta, \varphi) = A \sin^2\theta e^{2i\varphi}$$

To get $Y_{21}(\theta, \varphi)$ we apply the L_- operator once. From (7-36) we find that

$$Y_{21}(\theta, \varphi) \propto L_- Y_{22}(\theta, \varphi) = \hbar e^{-i\varphi}\left(-\frac{\partial}{\partial\theta} + i \cot\theta \frac{\partial}{\partial\varphi}\right)(\sin^2\theta e^{2i\varphi})$$

A little algebra yields

$$Y_{21}(\theta, \varphi) = B e^{i\varphi} \sin\theta \cos\theta$$

Repeating the application of L_-, we get

$$\begin{aligned} Y_{20}(\theta, \varphi) \propto L_- Y_{21}(\theta, \varphi) &= \hbar e^{-i\varphi}\left(-\frac{\partial}{\partial\theta} + i \cot\theta \frac{\partial}{\partial\varphi}\right) B e^{i\varphi} \sin\theta \cos\theta \\ &= B\hbar(-\cos^2\theta + \sin^2\theta - \cos^2\theta) = C(3\cos^2\theta - 1) \end{aligned}$$

so that

$$Y_{20}(\theta, \varphi) = C(3 \cos^2\theta - 1)$$

We conclude with a comment on the connection with classical angular momentum. We expect that for large l the correspondence principle will lead us to the classical limit—that is, we will find something that we can associate with an angular momentum *vector*. We note that when $m = l$ (or $m = -l$) then

$$|Y_{l,\pm l}(\theta, \varphi)|^2 \propto (\sin\theta)^{2l} \tag{7-49}$$

This implies that for large l the probability distribution is strongly confined to the equatorial region around $\theta = \pi/2$. This is as expected: For $m = l$, L_z has its largest value so that $\mathbf{L}^2$ is as close as it can get to L_z^2. In the limit of large l, the classical limit,

$$\frac{\mathbf{L}^2 - L_z^2}{\mathbf{L}^2} = \frac{l}{l(l+1)} = \frac{1}{l+1} \to 0 \tag{7-50}$$

This means that it is possible to line up the angular momentum in a particular direction, here the z-axis. Such an alignment would require

$$\langle L_x^2 \rangle = \langle L_y^2 \rangle = 0$$

which is not possible when quantum mechanical effects become important, and commutation relations cannot be ignored.

7-4 COMMENTS ON THE EXPANSION THEOREM

The general statement of the expansion theorem allows us to expand a state vector in terms of a complete set of states. Consider

$$|\psi\rangle = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} C_{lm} |l, m\rangle \tag{7-51}$$

With the help of the orthonormality relation

$$\langle l', m' | l, m \rangle = \delta_{ll'} \delta_{mm'} \tag{7-52}$$

we get $C_{lm} = \langle l, m | \psi \rangle$, so that

$$|\psi\rangle = \sum_{l=0}^{\infty} \sum_{m=-l}^{l} |l, m\rangle\langle l, m|\psi\rangle \tag{7-53}$$

Since this is true for every $|\psi\rangle$, we get the expected completeness relation

$$\sum_{l=0}^{\infty} \sum_{m=-l}^{l} |l, m\rangle\langle l, m| = \mathbf{1} \tag{7-54}$$

where $\mathbf{1}$ is the unit operator.

If we multiply this on the left by $\langle \theta', \varphi' |$ and on the right by $|\theta, \varphi\rangle$, we get

$$\sum_{l=0}^{\infty} \sum_{m=-l}^{l} \langle \theta', \varphi' | l, m\rangle\langle l, m|\theta, \varphi\rangle = \langle \theta', \varphi' | \theta, \varphi\rangle$$

which can be written as

$$\sum_{l=0}^{\infty} \sum_{m=-l}^{l} Y_{lm}^*(\theta', \varphi') Y_{lm}(\theta, \varphi) = \frac{1}{\sin\theta} \delta(\theta - \theta')\, \delta(\varphi - \varphi') \tag{7-55}$$

We can use the expansion theorem to answer the question often raised by students. What is so special about the z-direction? Cannot we align the angular momentum (as far as possible) with the x-axis? The answer is that this is indeed possible. Such a state, which would be confined near the equatorial plane about the x-axis (in the vicinity of $\varphi = \pi/2$) will be a particular linear combination of the $Y_{lm}(\theta, \varphi)$. Its physical properties will be exactly the same as the Y_{ll} state.

PROBLEMS

1. Consider the molecule CN, which may be described by a dumbbell consisting of two masses M_1 and M_2 attached by a rigid rod of length a. The dumbbell rotates *in a plane* about an axis going through the center of mass and perpendicular to it.

   (a) Write down a Hamiltonian that describes the motion.

   (b) What is the energy spectrum?

   (c) Write down an expression for the difference in energy between the ground state and the first excited state in terms of the masses and a.

2. Express the spherical harmonics for $l = 0, 1, 2$ in terms of x, y, z.

3. Calculate $\langle l, m_1|L_x|l, m_2\rangle$ and $\langle l, m_1|L_y|l, m_2\rangle$.

4. Calculate $\langle l, m_1|L_x^2|l, m_2\rangle$ and $\langle l, m_1|L_y^2|l, m_2\rangle$. (*Hint:* Things will be easier with the use of $L_\pm$, $L_\pm^2$, and so on.)

5. The Hamiltonian for an axially symmetric rotator is

   $$H = \frac{L_x^2 + L_y^2}{2I_1} + \frac{L_z^2}{2I_3}$$

   (a) What are the eigenvalues of H?

   (b) Sketch the spectrum, assuming that $I_1 > I_3$.

   (c) What is the spectrum in the limit that I_1 is much larger than I_3?

6. Use lowering operators to calculate the angular dependence (without worrying about normalization) of $Y_{4m}(\theta. \varphi)$ for $m = 3, 2, 1, 0$. You are given $Y_{44}(\theta, \varphi) = Ae^{4i\varphi} \sin^4 \theta$.

7. A system is described by the Hamiltonian

   $$H = \frac{\mathbf{L}^2}{2I} + \alpha L_z$$

   What is the energy spectrum of the system?

8. Calculate the commutators $[x, L_x]$, $[y, L_x]$, $[z, L_x]$, $[x, L_y]$, $[y, L_y]$, $[z, L_y]$. Do you detect a pattern that will allow you to state the commutators of x, y, z with L_z?

9. Repeat the calculation with $x, \ldots$ replaced by $p_x, \ldots$. in problem 8.

10. Consider a state of total angular momentum $l = 2$. What are the eigenvalues of the operators **(a)** L_z, **(b)** $\frac{3}{5}L_x - \frac{4}{5}L_y$, and **(c)** $2L_x - 6L_y + 3L_z$?

11. A particle in a spherically symmetric potential is in a state described by the wave packet

    $$\psi(x, y, z) = C(xy + yz + zx)e^{-\alpha r^2}$$

    What is the probability that a measurement of the square of the angular momentum yields 0? What is the probability that it yields $6\hbar^2$? If the value of l is found to be 2, what are the relative probabilities for $m = 2, 1, 0, -1, -2$?

12. Consider the following model of a perfectly smooth cylinder. It is a ring of equally spaced, identical particles, with mass M/N so that the mass of the ring is M and its moment of inertia is MR^2, with R

. 9(:69 9 92 9 ,% 3! 3 .- ! 3 ; " !

and the other in the spaceship. The observer at rest on Earth (and also assumed to be at rest with respect to the two stars) measures the distance between the stars to be L_p, where L_p is the proper length. According to this observer, the time it takes the spaceship to complete the voyage is $\Delta t = L_p/v$. What does an observer in the moving spaceship measure for the distance between the stars? Because of time dilation, the space traveler measures a smaller time of travel: $\Delta t' = \Delta t/\gamma$. The space traveler claims to be at rest and sees the destination star as moving toward the spaceship with speed v. Because the space traveler reaches the star in the shorter time $\Delta t'$, he or she concludes that the distance, L, between the stars is shorter than L_p. This distance measured by the space traveler is given by

$$L = v\Delta t' = v\frac{\Delta t}{\gamma}$$

Because $L_p = v\Delta t$, we see that $L = L_p/\gamma$ or

$$L = L_p\left(1 - \frac{v^2}{c^2}\right)^{1/2} \tag{1.10}$$

Length contraction

where $(1 - v^2/c^2)^{1/2}$ is a factor less than 1. This result may be interpreted as follows:

> If an object has a proper length L_p when it is measured by an observer at rest with respect to the object, when it moves with speed v in a direction parallel to its length, its length L is measured to be shorter according to $L = L_p\left(1 - \frac{v^2}{c^2}\right)^{1/2}$.

Note that the length contraction takes place only along the direction of motion. For example, suppose a stick moves past a stationary Earth observer with a speed v, as in Figure 1.13b. The length of the stick as measured by an observer in the frame attached to it is the proper length L_p, as illustrated in Figure 1.13a. The length of the stick, L, as measured by the Earth observer is shorter than L_p by the factor $(1 - v^2/c^2)^{1/2}$. Note that length contraction is a symmetric effect: If the stick were at rest on Earth, an observer in a frame moving past the earth at speed v would also measure its length to be shorter by the same factor $(1 - v^2/c^2)^{1/2}$.

As we mentioned earlier, one of the basic tenets of relativity is that all inertial frames are equivalent for analyzing an experiment. Let us return to the example of the decaying muons moving at speeds close to the speed of light to see an example of this. An observer in the muon's reference frame would measure the proper lifetime, whereas an Earth-based observer measures the proper height of the mountain in Figure 1.11. In the muon's reference frame, there is no time dilation, but the distance of travel is observed to be shorter when measured from this frame. Likewise, in the Earth observer's reference frame, there is time dilation, but the distance of travel is measured to be the proper height of the mountain. Thus, when calculations on the muon are performed in both frames, one sees the effect of "offsetting penalties," and the outcome of the experiment is the same!

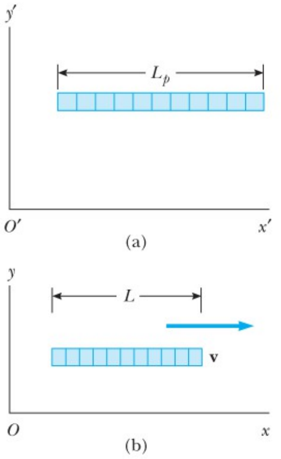

Figure 1.13 A stick moves to the right with a speed v. (a) The stick as viewed in a frame attached to it. (b) The stick as seen by an observer who sees it move past her at v. Any inertial observer finds that the length of a meter stick moving past her with speed v is less than the length of a stationary stick by a factor of $(1 - v^2/c^2)^{1/2}$.

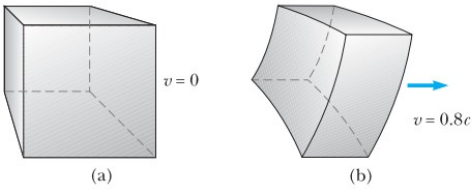

Figure 1.14 Computer-simulated photographs of a box (a) at rest relative to the camera and (b) moving at a speed $v = 0.8c$ relative to the camera.

Note that proper length and proper time are measured in *different* reference frames.

If an object in the shape of a box passing by could be photographed, its image would show length contraction, but its shape would also be distorted. This is illustrated in the computer-simulated drawings shown in Figure 1.14 for a box moving past an observer with a speed $v = 0.8c$. When the shutter of the camera is opened, it records the shape of the object at a given instant of time. Because light from different parts of the object must arrive at the shutter at the same time (when the photograph is taken), light from more distant parts of the object must start its journey earlier than light from closer parts. Hence, the photograph records different parts of the object at different times. This results in a highly distorted image, which shows horizontal length contraction, vertical curvature, and image rotation.

EXAMPLE 1.3 The Contraction of a Spaceship

A spaceship is measured to be 100 m long while it is at rest with respect to an observer. If this spaceship now flies by the observer with a speed of $0.99c$, what length will the observer find for the spaceship?

Solution The proper length of the ship is 100 m. From Equation 1.10, the length measured as the spaceship flies by is

$$L = L_p\sqrt{1 - \frac{v^2}{c^2}} = (100\text{ m})\sqrt{1 - \frac{(0.99c)^2}{c^2}} = 14\text{ m}$$

Exercise 4 If the ship moves past the observer at $0.01000c$, what length will the observer measure?

Answer 99.99 m.

EXAMPLE 1.4 How High Is the Spaceship?

An observer on Earth sees a spaceship at an altitude of 435 m moving downward toward the Earth at $0.970c$. What is the altitude of the spaceship as measured by an observer in the spaceship?

Solution The proper length here is the Earth–ship separation as seen by the Earth-based observer, or 435 m. The moving observer in the ship finds this separation (the altitude) to be

$$L = L_p\sqrt{1 - \frac{v^2}{c^2}} = (435\text{ m})\sqrt{1 - \frac{(0.970c)^2}{c^2}}$$
$$= 106\text{ m}$$

EXAMPLE 1.5 The Triangular Spaceship

A spaceship in the form of a triangle flies by an observer at $0.950c$. When the ship is measured by an observer at rest with respect to the ship (Fig. 1.15a), the distances x and y are found to be 50.0 m and 25.0 m, respectively. What is the shape of the ship as seen by an observer who sees the ship in motion along the direction shown in Figure 1.15b?

Solution The observer sees the horizontal length of the ship to be contracted to a length of

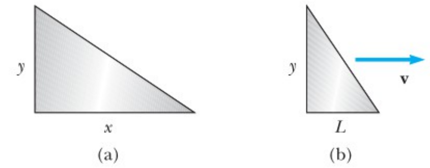

Figure 1.15 (Example 1.5) (a) When the spaceship is at rest, its shape is as shown. (b) The spaceship appears to look like this when it moves to the right with a speed v. Note that only its x dimension is contracted in this case.

$$L = L_p\sqrt{1-\frac{v^2}{c^2}}$$

$$= (50.0\text{ m})\sqrt{1-\frac{(0.950c)^2}{c^2}} = 15.6\text{ m}$$

The 25-m vertical height is unchanged because it is perpendicular to the direction of relative motion between the observer and the spaceship. Figure 1.15b represents the shape of the spaceship as seen by the observer who sees the ship in motion.

THE TWINS PARADOX

OPTIONAL

If we placed a living organism in a box . . . one could arrange that the organism, after an arbitrary lengthy flight, could be returned to its original spot in a scarcely altered condition, while corresponding organisms which had remained in their original positions had long since given way to new generations. **(Einstein's original statement of the twins paradox in 1911)**

An intriguing consequence of time dilation is the so-called clock or twins paradox. Consider an experiment involving a set of identical 20-year-old twins named Speedo and Goslo. The twins carry with them identical clocks that have been synchronized. Speedo, the more adventuresome of the two, sets out on an epic journey to planet X, 10 lightyears from Earth. (Note that 1 lightyear (ly) is the distance light travels through free space in 1 year.) Furthermore, his spaceship is capable of a speed of $0.500c$ relative to the inertial frame of his twin brother. After reaching planet X, Speedo becomes homesick and impetuously sets out on a return trip to Earth at the same high speed of the outbound journey. On his return, Speedo is shocked to discover that many things have changed during his absence. To Speedo, the most significant change is that his twin brother Goslo *has aged more than he* and is now 60 years of age. Speedo, on the other hand, has aged by only 34.6 years.

At this point, it is fair to raise the following question—Which twin is the traveler and which twin would really be the younger of the two? If motion is relative, the twins are in a symmetric situation and either's point of view is equally valid. From Speedo's perspective, it is he who is at rest while Goslo is on a high-speed space journey. To Speedo, it is Goslo and the Earth that have raced away on a 17.3-year journey and then headed back for another 17.3 years. This leads to the paradox: Which twin will have developed the signs of excess aging?

To resolve this apparent paradox, recall that special relativity deals with inertial frames of reference moving with respect to one another at *uniform speed*. However, the trip situation is not symmetric. Speedo, the space traveler, must experience acceleration during his journey. As a result, his state of motion is not always uniform, and consequently Speedo is not in an inertial frame. He cannot regard himself to always be at rest and Goslo to be in uniform motion. Hence Speedo cannot apply simple time dilation to Goslo's motion, because to do so would be an incorrect application of special relativity. Therefore there is no paradox and Speedo will really be the younger twin at the end of the trip.

The conclusion that Speedo is not in a *single* inertial frame is inescapable. We may diminish the length of time needed to accelerate and decelerate Speedo's spaceship to an insignificant interval by using very large and expensive rockets and claim that he spends all but a negligible amount of time coasting to planet X at $0.500c$ in an inertial frame. However, to return to Earth, Speedo must slow down, reverse his motion, and return in a different inertial frame, one which is moving uniformly toward the Earth. At the very best, Speedo is in *two* different inertial frames. The important point is that even when we idealize Speedo's trip, it consists of motion in two different inertial frames and a very real lurch as he hops from the outbound ship to the returning Earth shuttle. Only Goslo remains in a single inertial frame, and so only he can correctly apply the simple time dilation formula of special relativity to Speedo's trip. Thus, Goslo finds that instead of aging 40 years (20 ly/$0.500c$), Speedo actually ages only $(\sqrt{1 - v^2/c^2})(40 \text{ yr})$, or 34.6 yr. Clearly, Speedo spends 17.3 years going to planet X and 17.3 years returning in agreement with our earlier statement.

The result that Speedo ages 34.6 yr while Goslo ages 40 yr can be confirmed in a very direct experimental way from Speedo's frame if we use the special theory of relativity but take into account the fact that *Speedo's idealized trip takes place in two different inertial frames.* In yet another flight of fancy, suppose that Goslo celebrates his birthday each year in a flashy way, sending a powerful laser pulse to inform his twin that Goslo is another year older and wiser. Because Speedo is in an inertial frame on the outbound trip in which the Earth appears to be receding at $0.500c$, the flashes occur at a rate of one every

$$\frac{1}{\sqrt{1 - (v^2/c^2)}}\text{ yr} = \frac{1}{\sqrt{1 - [(0.500c)^2/c^2]}}\text{ yr} = 1.15 \text{ yr}$$

This occurs because moving clocks run slower. Also, because the Earth is receding, each successive flash must travel an additional distance of $(0.500c)(1.15 \text{ yr})$ between flashes. Consequently, Speedo observes flashes to arrive with a total time between flashes of $1.15 \text{ yr} + (0.500c)(1.15 \text{ yr})/c = 1.73$ yr. The total number of flashes seen by Speedo on his outbound voyage is therefore $(1 \text{ flash}/1.73 \text{ yr})(17.3 \text{ yr}) =$ 10 flashes. This means that Speedo views the Earth clocks to run more slowly than his own on the outbound trip because he observes 17.3 years to have passed for him while only 10 years have passed on Earth.

On the return voyage, because the Earth is racing toward Speedo with speed $0.500c$, successive flashes have less distance to travel, and the total time Speedo sees between the arrival of flashes is drastically shortened: $1.15 \text{ yr} - (0.500)(1.15 \text{ yr}) = 0.577$ yr/flash. Thus, during the return trip, Speedo sees $(1 \text{ flash}/0.577 \text{ yr})(17.3 \text{ yr}) = 30$ flashes in total. In sum, during his 34.6 years of travel, Speedo receives $(10 + 30)$ flashes, indicating that his twin has aged 40 years. Notice that there has been no failure of special relativity for Speedo as long as we take his *two* inertial frames into account and assume negligible acceleration and deceleration times. On both the outbound and inbound trips Speedo correctly judges the Earth clocks to run slower than his own, but on the return trip his rapid movement toward the light flashes more than compensates for the slower rate of flashing.

Figure 1.16 "I love hearing that lonesome wail of the train whistle as the frequency of the wave changes due to the Doppler effect."

The Relativistic Doppler Shift

Another important consequence of time dilation is the shift in frequency found for light emitted by atoms in motion as opposed to light emitted by atoms at rest. A similar phenomenon, the mournful drop in pitch of the sound of a passing train's whistle, known as the Doppler effect, is quite familiar to most cowboys (Fig. 1.16). The Doppler shift for sound is usually

1 THE MICHELSON INTERFEROMETER

The Michelson interferometer, first introduced by Albert Michelson in 1881, has played a vital role in the development of modern physics. This simple and versatile instrument was used, for example, to establish experimental evidence for the validity of the special theory of relativity, to detect and measure hyperfine structure in line spectra, to measure the tidal effect of the moon on the earth, and to provide a substitute standard for the meter in terms of wavelengths of light. Michelson himself pioneered much of this work.

A schematic of the Michelson interferometer is shown in Figure 1a. From an extended source of light *S*, beam 1 of light is split by a beam splitter (BS) by means of a thin, semitransparent front surface metallic or dielectric film, deposited on glass. The interferometer is therefore of the amplitude-splitting type. Reflected beam 2 and transmitted beam 3, of roughly equal amplitudes, continue to fully-reflecting mirrors *M*2 and *M*1, respectively, where their directions are reversed. On returning to the beam splitter, beam 2 is now transmitted and beam 3 is reflected by the semitransparent film so that they come together again and leave the interferometer as beam 4. The useful aperture of this double-beam interferometer is such that all rays striking *M*1 and *M*2 will be normal, or nearly so. Thus, beam 4 includes rays that have traveled different optical paths and will demonstrate interference. At least one of the mirrors is equipped with tilting adjustment screws that allow the surface of *M*1 to be made perpendicular to that of *M*2. One of the mirrors is also movable along the direction of the beam by means of an accurate track and micrometer screw. In this way, the difference between the optical paths of

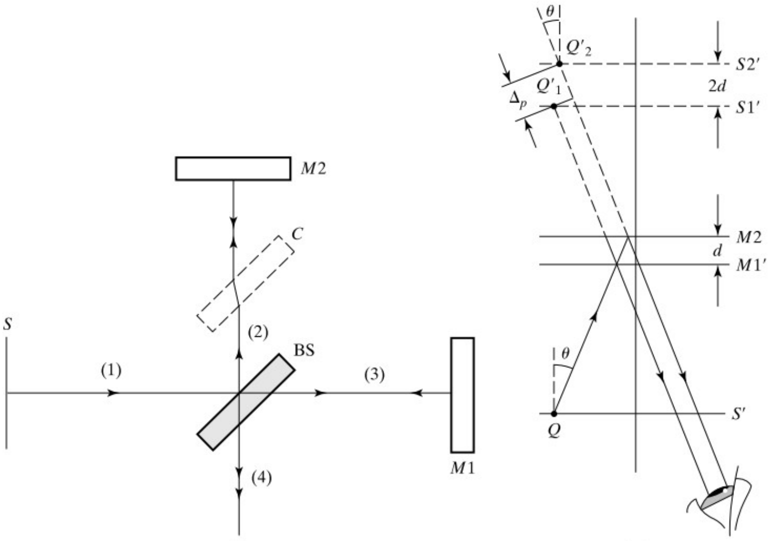

Figure 1 (a) The Michelson interferometer. (b) Equivalent optics for the Michelson interferometer.

beams 2 and 3 can be gradually varied. Notice that beam 3 traverses the beam splitter three times, whereas beam 2 traverses it only once. In some applications, where white light is used, it is essential that the optical paths of the two beams be made precisely equal. Although this can be accomplished at one wavelength by appropriately increasing the distance of $M2$ from BS, the correction would not suffice at another wavelength because of the dispersion of the glass. To compensate for all wavelengths at once, a compensator plate C made of the same material and dimensions as BS is inserted parallel to BS in the path of beam 2. Any small, remaining inequalities in optical paths can be removed by allowing the compensator to rotate, thus varying the optical path through the thickness of its glass plate.

The actual interferometer in Figure 1a possesses two optical axes at right angles to one another. A simpler but equivalent optical system, having a single optical axis, can be drawn by working with virtual images of source S and mirror $M1$ via reflection in the BS mirror. These positions are most simply found by regarding the assembly including S, $M1$, and beams 1 and 3 of Figure 1a as rotated counterclockwise by 90° about the point of intersection of the beams with the BS mirror. The resulting geometry is shown in Figure 1b. The new position of the source plane is S', and the new position of the mirror $M1$ is $M1'$. Light from a point Q on the source plane S' then effectively reflects from both mirrors $M2$ and $M1'$, shown parallel and with an optical path difference of d. The two reflected beams appear to come from the two virtual images, Q_1' and Q_2', of object point Q. Since the images $S1'$ and $S2'$ of the source plane in the mirrors must be separated by twice the mirror separation, the distance between Q_1' and Q_2' is $2d$, and the optical-path difference Δ_p between the two beams emerging from the interferometer is

$$\Delta_p = 2d \cos\theta \tag{1}$$

where the angle θ measures the inclination of the beams relative to the optical axis. For a normal beam, $\theta = 0$ and $\Delta_p = 2d$. We expect this result, since, if one mirror is farther from BS than the other by a distance d, the extra distance traversed by the beam taking the longer route includes distance d twice, once before and once after reflection. If, in addition, $\Delta = m\lambda$, so that the two beams interfere constructively, it follows that they will do so repeatedly for every $\lambda/2$ translation of one of the mirrors so long as the separation Δ_p does not exceed the so-called *coherence length*, l_t, of the source. The coherence length is the length along a wave train over which the phase of the wave remains correlated. The coherence length of the light emitted by a particular source is the ratio of the speed of light c to the spread of frequencies $\Delta\nu$ present in the source. The coherence length of typical laser sources ranges from tens of centimeters to tens of kilometers. Throughout this chapter, we will assume that all effective path-length differences between interfering beams that originate from the same source are much less than the coherence length of the source.

The optical system of Figure 1b is now equivalent to the case of interference due to a plane, parallel air film, illuminated by an extended source. Virtual fringes of equal inclination may be seen by looking into the beam splitter along ray 4, with the eye or a telescope focused at infinity. Assuming that the two interfering beams are of equal amplitude, the irradiance of the fringe system of circles concentric with the optical axis is given by

$$I = 4I_0 \cos^2\left(\frac{\delta}{2}\right) \tag{2}$$

where the phase difference is

$$\delta = k\Delta = \left(\frac{2\pi}{\lambda}\right)\Delta \tag{3}$$

The net optical path difference is $\Delta = \Delta_p + \Delta_r$, as usual. A relative π phase shift between the two beams occurs because the reflection coefficients from opposite sides of a beam splitter differ by $-1 = e^{i\pi}$.[1] For dark fringes, then,

$$\Delta_p + \Delta_r = 2d\cos\theta + \frac{\lambda}{2} = \left(m + \frac{1}{2}\right)\lambda$$

or, more simply,

$$2d\cos\theta = m\lambda \qquad m = 0, 1, 2, \ldots \text{ dark fringes} \tag{4}$$

If d is of such magnitude that the normal rays forming the center of the fringe system satisfy Eq. (4), that is, the center fringe is dark, then its order, given by

$$m_{\max} = \frac{2d}{\lambda} \tag{5}$$

is a large integer. Neighboring dark fringes decrease in order outwards from the center of the pattern, as $\cos\theta$ decreases from its maximum value of 1. This ordering of fringes may be inverted for convenience by associating another integer p with each fringe of order m, where

$$p = m_{\max} - m = \frac{2d}{\lambda} - m \tag{6}$$

Using Eq. (6) to replace m in Eq. (4), we arrive at

$$p\lambda = 2d(1 - \cos\theta) \qquad p = 0, 1, 2, \ldots \text{ dark fringes} \tag{7}$$

where now the central fringe is of order zero and the neighboring fringes increase in order, outward from the center. Figure 2 illustrates the relationship between orders m and p for the arbitrary case where $m_{\max} = 100$. Equation (4) or (7) indicates that, as d is varied, a particular point in the fringe pattern (θ = constant) will correspond to gradually changing values of order m or p.

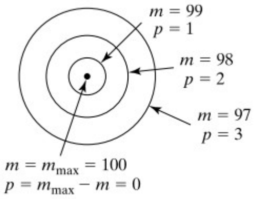

Figure 2 Alternate orderings of fringes.

Integral values occur whenever the point coincides with a dark fringe. Equivalently, this means that as d is varied, fringes of the pattern appear to move inward toward the center, where they disappear, or else move outward from the center, where they seem to originate, depending on whether the optical-path difference is decreasing or increasing. The motion of the fringe pattern thus reverses as one of the mirrors is moved continually through the point of zero path difference. Viewed in another way, Eq. (4) requires an increase in the angular separation $\Delta\theta$ of a given small fringe interval Δm as the mirror spacing d becomes smaller, since taking the differential of Eq. (4) leads to

$$|\Delta\theta| = \frac{\lambda\Delta m}{2d\sin\theta}$$

---

[1] This conclusion assumes real beam-splitter transmission coefficients. The assumption is made to allow discussion of the fringe pattern in a concrete (and common) situation. It does not affect the validity of results like Eq. (8), for example, because measurements depend on the net *motion* of the fringe pattern, not on precisely where it is dark and where it is bright.

This means that the fringes are more widely separated when optical-path differences are small. In fact, if $d = \lambda/2$, then from Eq. (4), $m = \cos\theta$, and the entire field of view encompasses no more than one fringe! For a mirror translation Δd, the number Δm of fringes passing a point at or near the center of the pattern is, according to Eq. (4),

$$\Delta m = \frac{2\Delta d}{\lambda} \tag{8}$$

Equation (8) suggests an experimental way of either measuring λ when Δd is known or calibrating the micrometer translation screw when λ is known.

Example 1

Fringes are observed due to monochromatic light in a Michelson interferometer. When the movable mirror is translated by 0.073 mm, a shift of 300 fringes is observed. What is the wavelength of the light? What displacement of the fringe system takes place when a flake of glass of index 1.51 and 0.005 mm thickness is placed in one arm of the interferometer? (Assume that the light beam is normal to the glass surface.)

Solution

Using Eq. (8),

$$\lambda = \frac{2\Delta d}{\Delta m} = \frac{(2)(0.073)}{300} = 4.87 \times 10^{-4}\text{ mm} = 487\text{ nm}$$

With the glass inserted, one arm is effectively lengthened by a path difference of $\Delta d = n_g t - n_{\text{air}} t$, so that

$$\Delta m = \frac{2\Delta d}{\lambda} = \frac{2(n_g - 1)t}{\lambda} = \frac{2(0.51)(0.005 \times 10^{-3})}{487 \times 10^{-9}} = 10.5\text{ fringes}$$

2 APPLICATIONS OF THE MICHELSON INTERFEROMETER

The Michelson interferometer is easily adaptable to the measurement of thin films, a technique essentially the same as that described in the preceding chapter. It can also be adapted to measure the index of refraction of a gas. An evacuable cell with plane, parallel windows is interposed in the path of beam 3 (Figure 1a) and is filled with a gas at a pressure and temperature for which its index of refraction is desired. The fringe system established under these conditions is monitored as the gas is gradually pumped out of the cell. A count Δm of the net fringe shift is related to the change in optical path during the decrease of the gas pressure. If the actual length of the cell is accurately known to be L, the change in optical path is given by

$$\Delta d = nL - L = L(n - 1) \tag{9}$$

and using Eq. (8), it follows that the index can be determined from

$$n - 1 = \left(\frac{\lambda}{2L}\right)\Delta m \tag{10}$$

Consider another direct application of the Michelson interferometer, the determination of wavelength difference between two closely spaced components of a spectral "line," λ and λ'. Each wavelength forms its own system of circular fringes according to Eq. (4). Suppose we view the circular systems near their center, so that $\cos\theta \cong 1$. Then for a given path difference d of the interferometer, the product $m\lambda$ is fixed, that is, $m\lambda = m'\lambda'$. When the fringe systems coincide, the pattern appears sharp, whereas when the fringes of one system in the region of observation lie midway between the fringes of the second system, the pattern appears rather uniform in brightness, or "washed out." The mirror movement Δd required between consecutive coincidences is related to the wavelength difference $\Delta\lambda$ as follows. At one coincidence, when fringes are "in step," the orders of the two systems corresponding to λ and λ' must be related by

$$m = m' + N$$

where N is an integer. If the optical-path difference at this time is d_1, then from Eq. (4),

$$\frac{2d_1}{\lambda} = \frac{2d_1}{\lambda'} + N \tag{11}$$

Let the optical-path difference be increased to d_2, when the next coincidence is found. Then,

$$m = m' + (N + 1)$$

or

$$\frac{2d_2}{\lambda} = \frac{2d_2}{\lambda'} + N + 1 \tag{12}$$

By subtracting Eq. (11) from Eq. (12) and by writing the mirror movement $\Delta d = d_2 - d_1$, we find

$$\lambda' - \lambda = \frac{\lambda\lambda'}{2\Delta d} \tag{13}$$

Now since λ and λ' are very close, the wavelength difference of the two unresolved components can be approximated by

$$\Delta\lambda = \frac{\lambda^2}{2\Delta d} \tag{14}$$

This technique is often employed in an optics laboratory course to measure the wavelength difference of 6 Å between the two components of the yellow "line" of sodium.

All the preceding discussion of the fringes from a Michelson interferometer has been in terms of virtual fringes of equal inclination. We have assumed that mirrors $M1$ and $M2$ are precisely perpendicular as shown in Figure 1a, or, what amounts to the same thing, precisely parallel in the equivalent optical system of Figure 1b. If the alignment is such that the air space between $M1'$ and $M2$ in Figure 1b is a wedge, fringes of equal thickness may be seen localized at the mirrors. These fringes will be straight, oriented parallel to the line that represents the intersection of $M1'$ and $M2$. If the wedge is of large angle, they will be curved in a way that can be shown to be hyperbolic arcs. Again, if the source is small, then real, nonlocalized fringes appear in the light emerging from the interferometer, as if formed by the two virtual images of the source in $M1'$ and $M2$. These fringes appear without effort when the intense, coherent light of a laser is used. These possibilities have already been discussed in the previous chapter, where we treated the various interference fringes that can be formed by illumination of a film. Figure 3 is a photograph showing the distortion of fringes of equal thickness produced by a candle flame when situated in one arm of a Michelson interferometer. Variations in temperature produce variations in optical-path length by changing the refractive index of the air.

> Fritz Haber is known for developing the means for synthesizing ammonia and developing fertilizers. He won the Nobel Prize in chemistry in 1918. He is also known for the Born–Haber cycle for finding he lattice energy of ionic solids. However, he was prominent as the father of chemical warfare for developing and directing the use of chorine and other poison gases in war. His first wife committed suicide. Some say that was because the involvement of Haber with the use of poison gases, others say it was because of his alleged infidelity.

1.1.3 Metals and Wigner–Seitz Theory (B)

Examples of metals are sodium (Na) and copper (Cu). A metal such as Na is viewed as being composed of positive ion cores (Na^+) immersed in a "sea" of free conduction electrons that come from the removal of the 3s electron from atomic Na. Metallic binding can be partly understood within the context of the Wigner–Seitz theory. In a full treatment, it would be necessary to confront the problem of electrons in a periodic lattice. (A discussion of the Wigner–Seitz theory will be deferred until Chap. 3.) One reason for the binding is the lowering of the kinetic energy of the "free" electrons relative to their kinetic energy in the atomic 3s state [41]. In a metallic crystal, the valence electrons are free (within the constraints of the Pauli principle) to wander throughout the crystal, causing them to have a smoother wave function and hence less $\nabla^2\psi$. Generally speaking this spreading of the electrons wave function also allows the electrons to make better use of the attractive potential. Lowering of the kinetic and/or potential energy implies binding. However, the electron–electron Coulomb repulsions cannot be neglected (see, e.g., Sect. 3.1.4), and the whole subject of binding in metals is not on so good a quantitative basis as it is in crystals involving the interactions of atoms or molecules which do not have free electrons. One reason why the metallic crystal is prevented from collapsing is the kinetic energy of the electrons. Compressing the solid causes the wave functions of the electrons to "wiggle" more and hence raises their kinetic energy.

A very simple picture[6] suffices to give part of the idea of metallic binding. The ground-state energy of an electron of mass M in a box of volume V is [19]

$$E = \frac{\hbar^2\pi^2}{2M}V^{-2/3}.$$

---

[6] A much more sophisticated approach to the binding of metals is contained in the pedagogical article by Tran and Perdew [1.26]. This article shows how exchange and correlation effects are important and discusses modern density functional methods (see Chap. 3).

Thus the energy of N electrons in N separate boxes is

$$E_A = N\frac{\hbar^2\pi^2}{2M}V^{-2/3}. \tag{1.21}$$

The energy of N electrons in a box of volume NV is (neglecting electron–electron interaction that would tend to increase the energy)

$$E_M = N\frac{\hbar^2\pi^2}{2M}V^{-2/3}N^{-2/3}. \tag{1.22}$$

Therefore $E_M/E_A = N^{-2/3} \ll 1$ for large N and hence the total energy is lowered considerably by letting the electrons spread out. This model of binding is, of course, not adequate for a real metal, since the model neglects not only electron–electron interactions but also the potential energy of interaction between electrons and ions and between ions and other ions. It also ignores the fact that electrons fill up states by satisfying the Pauli principle. That is, they fill up in increasing energy. But it does clearly show how the energy can be lowered by allowing the electronic wave functions to spread out.

In modern times, considerable progress has been made in understanding the cohesion of metals by the density functional method, see Chap. 3. We mention in particular, Daw [1.6].

Due to the important role of the free electrons in binding, metals are good electrical and thermal conductors. They have moderate to fairly strong binding. We do not think of the binding forces in metals as being two-body, central, or short-range.

1.1.4 Valence Crystals and Heitler–London Theory (B)

An example of a valence crystal is carbon in diamond form. One can think of the whole valence crystal as being a huge chemically saturated molecule. As in the case of metals, it is not possible to understand completely the binding of valence crystals without considerable quantum-mechanical calculations, and even then the results are likely to be only qualitative. The quantum-mechanical considerations (Heitler–London theory) will be deferred until Chap. 3.

Some insight into covalent bonds (also called homopolar bonds) of valence crystals can be gained by considering them as being caused by sharing electrons between atoms with unfilled shells. Sharing of electrons can lower the energy because the electrons can get into lower energy states without violating the Pauli principle. In carbon, each atom has four electrons that participate in the valence

Chapter 2

VECTOR SPACES AND COORDINATE SYSTEMS

In this chapter, the concept of an inner product vector space will be developed. Coordinate maps will be introduced, and common orthogonal curvilinear coordinate systems will be defined. Curves and surfaces will be treated as manifolds embedded in Euclidean space. This chapter provides a basic overview of the elements of vector calculus. Detail properties of the rotational group will be discussed later in Chapter 7.

2.1 POINTS AND VECTORS

Space and time define a continuous differentiable arena or manifold in which particles and fields interact. In nonrelativistic mechanics, space is considered to form a three-dimensional continuum, while time forms a separate one-dimensional continuum. In relativistic mechanics, *spacetime* forms a single four-dimensional continuum of indefinite metric signature. The nonrelativistic picture will be used for now.

A physical particle is a point-like object with a well-defined position and velocity, to which additional physical attributes, such as mass and charge, can be assigned. A point is an entity with a location but no extent. The motion of a particle is given by the trajectory of its point. *Points* are fundamental to the language of mathematics. In mathematics, any form of space can be constructed from elemental points.

Newton's fiction of absolute space, existing independent of matter, is perhaps the easiest way to introduce the concept of a geometric vector space.

Consider a point **P** in an absolute three-dimensional Euclidean space, parameterized by three, independent, continuous Cartesian coordinates $(x^1, x^2, x^3) = (x, y, z)$ with respect to a constant, orthogonal Euclidean basis $(\mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3)$. The origin $\mathbf{O} = (0, 0, 0)$ is embedded in the space. The location of a point defined on E^3 with respect to a Cartesian basis is given by[1]

$$\mathbf{P}(x, y, z) = x^i \mathbf{e}_i = x\,\mathbf{e}_1 + y\,\mathbf{e}_2 + z\,\mathbf{e}_3. \tag{2.1}$$

2.1.1 Displacement

The *displacement* of a point from the origin is given by

$$\mathbf{r} = \mathbf{P} - \mathbf{O}. \tag{2.2}$$

Infinitesimal displacements between points are vectors. With respect to a fixed origin, one gets

$$d\mathbf{r} = dx^i \mathbf{e}_i. \tag{2.3}$$

The Euclidean basis of absolute space is constant in time and position independent; therefore, all of their partial derivatives vanish

$$\partial \mathbf{e}_i / \partial x^j = 0 \quad \partial \mathbf{e}_i / \partial t = 0. \tag{2.4}$$

Euclidean space is translationally and rotationally invariant. Euclidean space is an example of a flat metric space. It has no intrinsic curvature. The length of a relative displacement between two points in this space is given by the *Pythagorean theorem*:

$$(d\mathbf{r})^2 = \delta_{ij} dx^i dx^j = (dx)^2 + (dy)^2 + (dz)^2. \tag{2.5}$$

Infinitesimal displacements $d\mathbf{r}$ are the prototypes for all vectors. A point on a general manifold is not a vector, since a point has a fixed origin of reference, while a vector quantity, like the velocity, only has a magnitude and direction. This distinction becomes important when discussing curved spaces. A common example of a vector is a force—force has a magnitude and an orientation. Multiple forces acting on an object point are summed according to the parallelogram law of vector addition.

The chain rule for partial derivates can be used to map infinitesimal displacements into multiple coordinate systems

$$\begin{gathered} d\mathbf{r}(\xi(x, y, z)) = d\xi^i \frac{\partial \mathbf{r}}{\partial \xi^i}, \\ d\mathbf{r} = dx^i \mathbf{e}_i = d\xi^i \boldsymbol{\lambda}_i. \end{gathered} \tag{2.6}$$

---

[1] Please note that the *Einstein summation convention* will be used throughout this book: the sum (contraction) over repeated raised and lowered tensor indices is implied in an equation unless otherwise noted by use of the acronym (nsc) denoting "No Summation Convention."

A coordinate map or *patch* is allowable in any region of space where it is differentiable and invertible (non-singular). The chain rule yields a *form invariant* expression for generalized *contravariant* elements of displacement $d\xi^i$ with respect to a *covariant* vector basis $\boldsymbol{\lambda}_i$ defined by

$$\boldsymbol{\lambda}_i = \frac{\partial \mathbf{r}}{\partial \xi^i}. \tag{2.7}$$

A space point can be located by specifying its generalized coordinates ξ^i. The motion of the point is a parameterized curve called its *trajectory*

$$\mathbf{r}(t) = \mathbf{r}(\xi^i(t)), \tag{2.8}$$

where the function $\mathbf{r}(t)$ is twice differentiable with respect to the time. Since a particle has a well-defined location at any instance of time, the equation of a particle trajectory must be a *single-valued function* of the time.

2.1.2 Velocity

The velocity of a particle is the vector tangent to the trajectory obtained by taking the total time derivative of its position

$$\mathbf{v} = \frac{d\mathbf{r}}{dt} = \dot{\xi}^i \boldsymbol{\lambda}_i. \tag{2.9}$$

A *vector* is a special case of a *tensor*, or a form-invariant object. The components of velocity $\dot{\xi}^i$ with respect to a general tensor basis $\boldsymbol{\lambda}_i$ are its *generalized velocities*. The tensor itself is an invariant object, but its components transform by covariance under a coordinate transformation. Vectors are rank-1 tensors and can be used to create tensors of greater rank. Vectors form the foundation for vector fields and vector analysis. Tensors of arbitrary rank can be expressed as multidimensional arrays with respect to some tensor basis, although as objects, in and of themselves, they are invariants, independent of any choice of coordinates. They conform to Einstein's principle of relativity, which asserts that the inherent properties of physical objects should not depend on choice of reference frame used to represent them.

2.2 INNER PRODUCT SPACES

Geometric vector spaces are inner product spaces with a metric, which provide a measure of separation. They are defined over the field of real numbers. If the space has a mixed metric signature, such as Minkowski Space, the

sideración sólo a las formas mecánicas de la energía. La conservación de la energía se trata en la sección 5-6

5-2 ▪ CONSERVACIÓN DE LA MASA

El principio de conservación de la masa es uno de los principios más fundamentales de la naturaleza. Todos estamos familiarizados con este principio y es fácil entenderlo. Una persona no tiene que ser un científico para imaginarse cuánto aderezo de vinagre y aceite se obtendrá cuando se mezclan 100 g de aceite con 25 g de vinagre. Inclusive las ecuaciones químicas se balancean con base en el principio de conservación de la masa. Cuando 16 kg de oxígeno reaccionan con 2 kg de hidrógeno, se forman 18 kg de agua (Fig. 5-2). En un proceso electrolítico, el agua se separará de vuelta a 2 kg de hidrógeno y 16 kg de oxígeno.

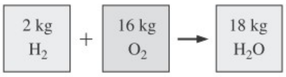

FIGURA 5-2
La masa se conserva, inclusive, durante las reacciones químicas.

Realmente, no es exacto confirmar que la masa se conserva. Ocurre que la masa m y la energía E pueden convertirse una en otra, según la conocida fórmula propuesta por Albert Einstein (1879-1955):

$$E = mc^2 \tag{5-3}$$

donde c es la velocidad de la luz en el vacío, la cual es $c = 2.9979 \times 10^8$ m/s. Esta ecuación sugiere que hay equivalencia entre masa y energía. Todos los sistemas físicos y químicos muestran interacciones de energía con su alrededor; pero la cantidad de energía que participa es equivalente a una masa extremadamente pequeña en comparación con la masa total del sistema. Por ejemplo, cuando se forma 1 kg de agua a partir de oxígeno e hidrógeno, a las condiciones atmosféricas comunes la cantidad de energía liberada es de 15.8 MJ, lo cual corresponde a una masa de 1.76×10^{-10} kg. Sin embargo, en las reacciones nucleares, la equivalencia en masa de la cantidad de energía que interactúa es una fracción importante de la masa total que participa. Por lo tanto, en la mayoría de los análisis de ingeniería, consideramos tanto la masa como la energía como cantidades conservadas.

Para los *sistemas cerrados*, el principio de conservación de la masa se usa de manera implícita cuando se establece que la masa del sistema permanezca constante durante el proceso. Sin embargo, para los *volúmenes de control*, la masa puede cruzar las fronteras y, por consiguiente, se debe considerar la razón de la masa que entra y que sale del volumen de control.

Gastos de masa y de volumen

La cantidad de masa que fluye a través de una sección transversal por unidad de tiempo se llama **razón de flujo de masa**, o simplemente flujo o gasto másico, se denota por $\dot{m}$. Se pone un punto sobre el símbolo para indicar *razón de cambio respecto al tiempo*.

Un fluido fluye hacia dentro o hacia fuera de un volumen de control normalmente por tubos o ductos. El gasto diferencial de masa de fluido que fluye a través de un pequeño elemento de área, dA_c (el subíndice corresponde a la primera letra de la palabra inglesa *cross-section*), en una sección transversal de tubo, es proporcional al propio dA_c, a la densidad ρ del fluido y a la componente de la velocidad del flujo normal a dA_c, la cual se denota como V_n, (Fig. 5-3) y se expresa de la siguiente manera:

$$\delta\dot{m} = \rho V_n \, dA_c \tag{5-4}$$

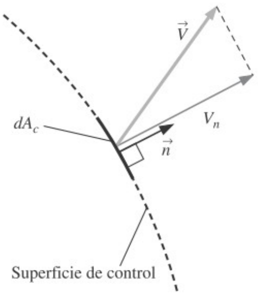

FIGURA 5-3
La velocidad normal V_n para una superficie es la componente de la velocidad perpendicular a esa superficie.

Note que se usan tanto δ como d para indicar las cantidades diferenciales, pero, por lo general, δ se usa para cantidades (como calor, trabajo y transferencia de masa) que son *funciones de trayectoria* y tienen *diferenciales inexactas*, en tanto que d se usa para cantidades (como las propiedades) que son *funciones de punto* y tienen *diferenciales exactas*. Por ejemplo, para el flujo en el tubo exterior de un ducto que consta de dos tubos concéntricos de radio interior r_1 y radio exterior r_2, se tiene $\int_1^2 dA_c = A_{c2} - A_{c1} = \pi(r_2^2 - r_1^2)$, pero $\int_1^2 \delta\dot{m} = \dot{m}_{\text{total}}$ (razón total de flujo de masa total en el tubo exterior), no $\dot{m}_2 - \dot{m}_1$. Para valores especificados de r_1 y r_2, el valor de la integral de dA_c es fijo (de allí provienen los nombres de función de punto y diferencial exacta), pero éste no es el caso para la integral de $\delta\dot{m}$ (de ahí provienen los nombres de función de trayectoria y diferencial inexacta).

La razón de flujo de masa que cruza toda el área de la sección transversal de un tubo o de un ducto se obtiene por integración:

$$\dot{m} = \int_{A_c} \delta\dot{m} = \int_{A_c} \rho V_n \, dA_c \qquad \text{(kg/s)} \tag{5-5}$$

No obstante que la ecuación 5-5 siempre es válida (de hecho, es *exacta*), no siempre es práctica porque implica integración. En lugar de ello, resultaría conveniente expresar el flujo másico en términos de valores promediados sobre la sección transversal del tubo. En un flujo compresible, ρ y V_n varían a lo largo de la sección transversal. Sin embargo, en muchas aplicaciones prácticas, la densidad es esencialmente uniforme sobre la sección transversal del tubo y se puede extraer ρ afuera de la integral de la ecuación 5-5. Pero la velocidad *nunca* es uniforme sobre una sección transversal de un tubo debido a la condición de no deslizamiento en las paredes. Más bien, la velocidad varía desde cero en las paredes hasta algún valor máximo en la línea central del tubo o cerca de éste. Se define la **velocidad promedio** V_{prom} como el valor de V_n promediado a lo largo de toda la sección transversal del tubo (Fig. 5-4):

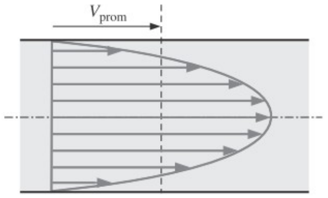

FIGURA 5-4
La velocidad promedio V_{prom} se define como la magnitud de la velocidad promediada a lo largo de la sección transversal.

Velocidad promedio:

$$V_{\text{prom}} = \frac{1}{A_c}\int_{A_c} V_n \, dA_c \tag{5-6}$$

donde A_c es el área de la sección transversal normal a la dirección del flujo. Note que si la magnitud de la velocidad fuera V_{prom} en toda la sección transversal, el gasto de masa sería idéntico al que se obtiene cuando se integra el perfil real de velocidad. De donde, para el flujo incompresible o inclusive para el flujo compresible para el cual ρ sea uniforme a lo largo de A_c, la ecuación 5-5 queda:

$$\dot{m} = \rho V_{\text{prom}} A_c \qquad \text{(kg/s)} \tag{5-7}$$

Para el flujo compresible se puede concebir ρ como la densidad promedio sobre la sección transversal y entonces, no obstante, se usa la ecuación 5-7 como una aproximación razonable. Por sencillez, se elimina el subíndice de la velocidad promedio. A menos que se indique lo contrario, V denota la velocidad promedio en la dirección del flujo. Asimismo, A_c denota el área de la sección transversal normal a la dirección del flujo.

El volumen del fluido que fluye a través de una sección transversal por unidad de tiempo se llama **razón de flujo volumétrico**, o gasto volumétrico, o simplemente flujo volumétrico, $\dot{V}$ (Fig. 5-5), y se da por:

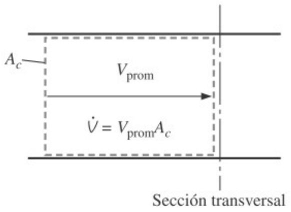

FIGURA 5-5
El gasto volumétrico es el volumen de fluido que fluye a través de una sección transversal por unidad de tiempo.

$$\dot{V} = \int_{A_c} V_n \, dA_c = V_{\text{prom}} A_c = V A_c \qquad (\text{m}^3/\text{s}) \tag{5-8}$$

En 1628, el monje italiano Benedetto Castelli (1577-1644) publicó una primera forma de la ecuación 5-8. Note que en muchos textos de mecánica de fluidos se usa Q en lugar de $\dot{V}$ para el gasto volumétrico. Aquí se usa $\dot{V}$ para evitar confusión con la transferencia de calor.

Las razones de flujo de masa y de volumen están relacionadas por:

$$\dot{m} = \rho \dot{V} = \frac{\dot{V}}{v} \tag{5-9}$$

donde v es el volumen específico. Esta relación es análoga a $m = m = \rho V = V/v$, la cual es la relación entre la masa y el volumen de un fluido en un recipiente.

Principio de conservación de la masa

Este **principio para un volumen de control** se puede expresar como: *la transferencia neta de masa hacia dentro un volumen de control, o hacia fuera de éste, durante un intervalo* Δt*, es igual al cambio neto (aumento o disminución) en la masa total que está dentro de ese volumen en el transcurso de* Δt; es decir:

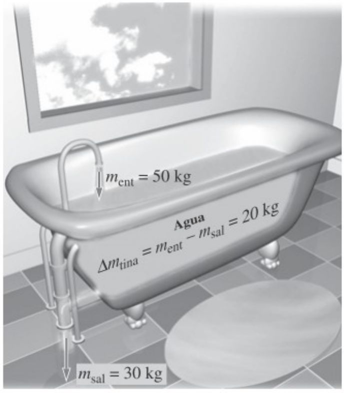
$$\begin{pmatrix}\text{Masa total que entra}\\ \text{al VC durante } \Delta t\end{pmatrix} - \begin{pmatrix}\text{Masa total que sale}\\ \text{del VC durante } \Delta t\end{pmatrix} = \begin{pmatrix}\text{Cambio neto durante } \Delta t \text{ en la}\\ \text{masa que está dentro del VC}\end{pmatrix}$$

o

$$m_{\text{ent}} - m_{\text{sal}} = \Delta m_{\text{VC}} \qquad \text{(kg)} \tag{5-10}$$

donde $\Delta m_{\text{VC}} = m_{\text{final}} - m_{\text{inicial}}$ es el cambio en la masa del volumen de control durante el proceso (Fig. 5-6). Esto también se puede expresar en la *forma de razones*:

$$\dot{m}_{\text{ent}} - \dot{m}_{\text{sal}} = dm_{\text{VC}}/dt \qquad \text{(kg/s)} \tag{5-11}$$



$m_{\text{ent}} = 50$ kg
Agua
$\Delta m_{\text{tina}} = m_{\text{ent}} - m_{\text{sal}} = 20$ kg
$m_{\text{sal}} = 30$ kg

FIGURA 5-6
Principio de conservación de la masa para una tina común de baño.

donde $\dot{m}_{\text{ent}}$ y $\dot{m}_{\text{sal}}$ son las razones totales de flujo de masa hacia dentro y hacia fuera del volumen de control, y dm_{CV}/dt es la razón de cambio de la masa que está dentro de las fronteras de ese volumen. Con frecuencia, se hace mención de las ecuaciones 5-10 y 5-11 como el **balance de masa** y son aplicables a cualquier volumen de control que pase por alguna clase de proceso.

Considere un volumen de control de forma arbitraria, como se muestra en la figura 5-7. La masa de un volumen diferencial dV que esté dentro del volumen de control es $dm = \rho\, dV$. Por integración se determina que la masa total dentro del volumen de control en cualquier instante t es:

Masa total dentro del VC:

$$m_{\text{VC}} = \int_{\text{VC}} \rho\, dV \tag{5-12}$$

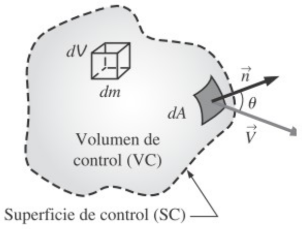


FIGURA 5-7
Volumen diferencial de control, dV, y superficie diferencial de control, dA, usados en la deducción de la relación de conservación de la masa.

Entonces la razón de cambio de la cantidad de masa dentro del volumen de control se puede expresar de la siguiente maneraa:

Razón de cambio de la masa dentro del VC:

$$\frac{dm_{\text{VC}}}{dt} = \frac{d}{dt}\int_{\text{VC}} \rho\, dV \tag{5-13}$$

Para el caso especial en el que nada de masa cruza la superficie de control (es decir, el volumen de control es un sistema cerrado), el principio de conservación de la masa se reduce al de un sistema que se puede expresar como $dm_{\text{VC}}/dt = 0$. Esta relación es válida si el volumen de control está fijo, en movimiento o deformándose.

Considérese ahora el flujo de masa hacia fuera o hacia dentro del volumen de control a través de un área diferencial dA sobre la superficie de control de un volumen fijo. Sea $\vec{n}$ el vector unitario, normal a la suprficie dA y dirigido hacia fuera de volumen de control, normal a ésta y $\vec{V}$ la velocidad del flujo dA en relación con un sistema fijo de coordenadas, como se muestra en la figura 5-7. En general, la velocidad cruza la superficie dA y forma un ángulo θ con la normal exterior de ésta, y la razón de flujo másico es proporcional a la componente normal de la velocidad $\vec{V}_n = \vec{V}\cos\theta$ cambiándose desde un valor de flujo hacia fuera cuando $\theta = 0$ (el flujo es normal a dA), pasando por cero, cuando $\theta = 90°$ (el flujo es tangente a dA), hasta llegar a un *flujo* máximo *hacia dentro* cuando $\theta = 180°$ (el flujo es normal a dA, pero en dirección opuesta). Al aplicar el concepto del producto punto de dos vectores, la magnitud de la componente normal de la velocidad se puede expresar de la siguiente manera:

Componente normal de la velocidad: $$V_n = V\cos\theta = \vec{V}\cdot\vec{n} \qquad \textbf{(5-14)}$$

El flujo másico a través de dA es proporcional a la densidad del fluido ρ, a la velocidad normal V_n y al área de flujo dA, y se puede expresar como:

Razón diferencial de flujo de masa:

$$\delta\dot{m} = \rho V_n\,dA = \rho(V\cos\theta)\,dA = \rho(\vec{V}\cdot\vec{n})\,dA \qquad \textbf{(5-15)}$$

El flujo másico neto hacia adentro o hacia afuera del volumen de control a través de toda la superficie de control se obtiene cuando se integra $\delta\dot{m}$ sobre esa superficie:

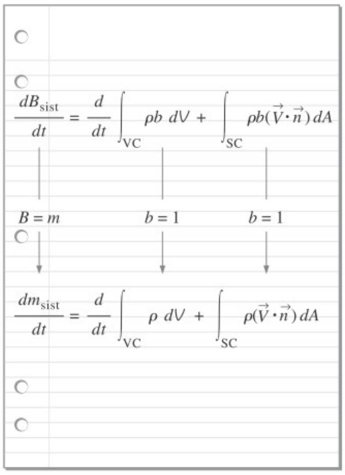
La razón neta de flujo de masa: $$\dot{m}_{\text{neto}} = \int_{\text{SC}} \delta\dot{m} = \int_{\text{CS}} \rho V_n\,dA = \int_{\text{SC}} \rho(\vec{V}\cdot\vec{n})\,dA \qquad \textbf{(5-16)}$$

Note que $\vec{V}\cdot\vec{n} = V\cos\theta$ es positiva para $\theta < 90°$ (flujo hacia fuera) y negativa para $\theta > 90°$ (flujo hacia dentro). Por lo tanto, se toma en cuenta de manera automática la dirección del flujo y la integral de la ecuación 5-16 da directamente la razón *neta* de flujo de masa. Un valor positivo para $\dot{m}_{\text{neto}}$ indica flujo neto hacia fuera y uno negativo indica flujo de masa neto hacia dentro.

Si se reordena la ecuación 5-11 como $dm_{\text{CV}}/dt + \dot{m}_{\text{sal}} - \dot{m}_{\text{ent}} = 0$, entonces se puede expresar la relación de conservación de la masa para un volumen fijo de control como:

Conservación de la masa, caso general: $$\frac{d}{dt}\int_{\text{VC}} \rho\,dV + \int_{\text{SC}} \rho(\vec{V}\cdot\vec{n})\,dA = 0 \qquad \textbf{(5-17)}$$

Ésta expresa que *la razón de cambio respecto al tiempo de la masa que está dentro del volumen de control más la razón neta de flujo de masa a través de la superficie de control es igual a cero.*



$\frac{dB_{\text{sist}}}{dt} = \frac{d}{dt}\int_{\text{VC}} \rho b\,dV + \int_{\text{SC}} \rho b(\vec{V}\cdot\vec{n})\,dA$
$B = m$
$b = 1$
$b = 1$
$\frac{dm_{\text{sist}}}{dt} = \frac{d}{dt}\int_{\text{VC}} \rho\,dV + \int_{\text{SC}} \rho(\vec{V}\cdot\vec{n})\,dA$

FIGURA 5-8
La ecuación de conservación de masa se obtiene cuando se reemplaza B en el teorema del transporte de Reynolds por la masa m y b por 1 (m por unidad de masa $= m/m = 1$).

También se puede deducir la relación general de conservación de la masa para un volumen de control con la aplicación del teorema del transporte de Reynolds (RTT, por sus siglas en inglés) cuando se toma la propiedad B como la masa m (capítulo 4). Entonces se tiene $b = 1$, ya que cuando se divide la masa, entre la masa, para obtener la propiedad por unidad de masa, da la unidad. Asimismo, la masa de un sistema es constante y su derivada respecto al tiempo es cero. Es decir $dm_{\text{sist}}/dt = 0$. Entonces el teorema del transporte de Reynolds se reduce de inmediato a la ecuación 5-17, como se muestra en la figura 5-8, y de este modo se ilustra que el teorema del transporte de Reynolds en verdad es un recurso muy poderoso.

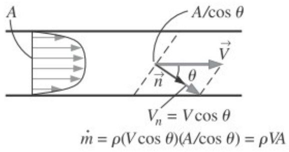
Cuando se divide la integral de superficie de la ecuación 5-17 en dos partes —una para las corrientes salientes (término positivo) y otra para las entrantes (término negativo)— la relación general de conservación de la masa también se puede expresar como:

$$\frac{d}{dt}\int_{\text{CV}} \rho\,dV + \sum_{\text{sal}} \rho|V_n|A - \sum_{\text{ent}} \rho|V_n|A = 0 \qquad \textbf{(5-18)}$$

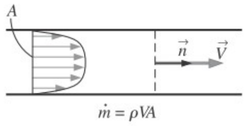
donde A representa el área para una entrada o una salida, y se usa el signo de sumatoria para subrayar que deben considerarse *todas* las entradas y salidas. Si se usa la definición de flujo másico, la ecuación 5-18 también se puede expresar como:

$$\frac{d}{dt}\int_{\text{VC}} \rho\,dV = \sum_{\text{ent}} \dot{m} - \sum_{\text{sal}} \dot{m} \quad \text{o} \quad \frac{dm_{\text{VC}}}{dt} = \sum_{\text{ent}} \dot{m} - \sum_{\text{sal}} \dot{m} \qquad \textbf{(5-19)}$$

Se tiene una flexibilidad considerable en la selección de un volumen de control cuando se resuelve un problema. Varias elecciones de este volumen son disponibles, pero algunas son más convenientes que otras. La selección de un volumen de control no debe llevar a las complicaciones innecesarias. La elección apropiada de un volumen de control puede hacer que la resolución de un problema aparentemente complicado sea más bien fácil. Una regla sencilla al elegir un volumen de control es hacer que la superficie de control sea *normal al flujo* en todos los lugares donde se se crucen la superficie y el flujo, siempre que sea posible. De esta manera, el producto punto $\vec{V} \cdot \vec{n}$ se convierte, simplemente, en la magnitud de la velocidad, y la integral $\int_A \rho(\vec{V} \cdot \vec{n})\, dA$ se vuelve ρVA (Fig. 5-9).



a) Superficie de control *formando un ángulo* con el flujo



b) Superficie de control *normal* al flujo

FIGURA 5-9
Siempre debe seleccionarse una superficie de control *normal al flujo* en todos los lugares donde se cruce con ese flujo del fluido, para evitar complicaciones, aun cuando el resultado sea el mismo.

Volúmenes de control en movimiento o en deformación

Las ecuaciones 5-17 y 5-19 también son válidas para volúmenes de control en movimiento y en deformación, siempre que se reemplace la *velocidad absoluta* $\vec{V}$ por la *velocidad relativa* $\vec{V}_r$, la cual es la velocidad del fluido con relación a la superficie de control (capítulo 4). En el caso de un volumen de control que está moviéndose pero no esté deformando, la velocidad relativa es la velocidad del fluido que observa una persona en movimiento con el volumen de control y se expresa como $\vec{V}_r = \vec{V} - \vec{V}_{\text{SC}}$, en donde $\vec{V}$ es la velocidad del fluido y $\vec{V}_{\text{SC}}$ es la velocidad de la superficie de control, ambas en relación con un punto fijo en el exterior. Note que ésta es una sustracción *vectorial.*

En algunos problemas prácticos (como la inyección de un medicamento a través de la aguja de una jeringa por el movimiento forzado del émbolo) intervienen volúmenes de control en deformación. Todavía se pueden usar las relaciones de conservación de la masa desarrolladas para esos volúmenes siempre que la velocidad del fluido que cruza una parte en deformación de la superficie de control se exprese en relación con ésta (es decir, la velocidad del fluido se debe expresar en relación con un marco de referencia sujeto a la parte en deformación de la superficie de control). En este caso, una vez más, la velocidad relativa en cualquier punto sobre la superficie de control se expresa como $\vec{V}_r = \vec{V} - \vec{V}_{\text{SC}}$, en donde $\vec{V}_{\text{SC}}$ es la velocidad local de esa superficie de control en ese punto en relación con un punto fijo en el exterior del volumen de control.

Balance de masa para procesos de flujo estacionario

En el transcurso de un proceso de flujo estacionario, la cantidad total de masa contenida dentro de un volumen de control no cambia con el tiempo (m_{VC} = constante). Entonces el principio de conservación de la masa exige que la cantidad total de masa que entra en un volumen de control sea igual a la cantidad total de masa que sale de él. Por ejemplo, para la boquilla de una manguera de jardín en operación estacionaria, la cantidad de agua que entra a la boquilla por unidad de tiempo es igual a la cantidad de agua que sale de ella por unidad de tiempo.

Cuando se trata con procesos de flujo estacionario no se tiene interés en la cantidad de masa que fluye hacia fuera o hacia dentro de un dispositivo en un transcurso de tiempo; en lugar de ello, se tiene interés en la cantidad de masa que fluye por unidad de tiempo; es decir, *la razón de flujo de masa* $\dot{m}$. *El principio de conservación de la masa* para un sistema general de flujo estacionario con entradas y salidas múltiples se puede expresar en la forma de razón como (Fig. 5-10):

Flujo estacionario:
$$\sum_{\text{ent}} \dot{m} = \sum_{\text{sal}} \dot{m} \qquad \text{(kg/s)} \tag{5-20}$$

Ésta expresa que *la razón total de masa que entra en un volumen de control es igual a la razón total de masa que sale de él.*

Numerosos dispositivos de ingeniería, como toberas, difusores, turbinas, compresores y bombas, forman una sola corriente (sólo una entrada y una salida).

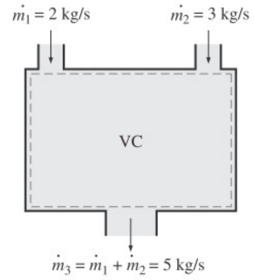


FIGURA 5-10
Principio de conservación de la masa para un sistema de flujo estacionario con dos entradas y una salida.

Para estos casos se denota el estado de entrada por el subíndice 1 y el de salida por el subíndice 2, y se eliminan los signos de suma. Entonces la ecuación 5-20 se reduce, para *sistemas de flujo estacionario con una sola corriente*, a:

$$\text{Flujo estacionario (una sola corriente):} \quad \dot{m}_1 = \dot{m}_2 \quad \rightarrow \quad \rho_1 V_1 A_1 = \rho_2 V_2 A_2 \qquad \textbf{(5-21)}$$

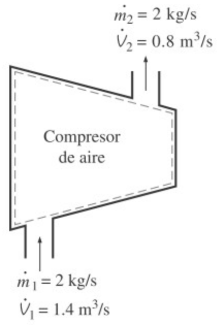

FIGURA 5-11
Cuando transcurre un proceso de flujo estacionario, los gastos volumétricos no se conservan necesariamente, aun cuando sí se conserven los flujos de masa.

Caso especial: flujo incompresible

Las relaciones de conservación de la masa se pueden simplificar todavía más cuando el fluido es incompresible, el cual suele ser el caso para los líquidos. Cuando se cancela la densidad en ambos miembros de la relación general del flujo estacionario da:

$$\text{Flujo estacionario e incompresible:} \quad \sum_{\text{ent}} \dot{V} = \sum_{\text{sal}} \dot{V} \qquad (\text{m}^3/\text{s}) \qquad \textbf{(5-22)}$$

Para sistemas de una sola corriente de flujo uniforme, la ecuación 5-22 se convierte en

$$\text{Flujo estacionario e incompresible (una sola corriente):} \quad \dot{V}_1 = \dot{V}_2 \rightarrow V_1 A_1 = V_2 A_2 \qquad \textbf{(5-23)}$$

Siempre se debe tener presente que no existen cosas como principio de "conservación del volumen". Por lo tanto, los gastos volumétricos hacia dentro y hacia fuera de un aparato pueden ser diferentes. El gasto volumétrico a la salida de un compresor de aire es mucho menor que el que se tiene en la admisión, aun cuando la razón de flujo de masa de aire a través del compresor es constante (Fig. 5-11). Esto se debe a la densidad más alta del aire a la salida del compresor. Sin embargo, para el flujo estacionario de líquidos, los gastos volumétricos, así como los de masa, permanecen constantes, ya que los líquidos son esencialmente sustancias incompresibles (de densidad constante). El flujo de agua por la boquilla de una manguera de jardín es un ejemplo de este último caso.

El principio de conservación de la masa exige tomar en cuenta toda pequeña porción de masa que participe en un proceso. Si el lector puede verificar el saldo de su chequera (mantener al día los depósitos y disposiciones o, sencillamente, si observa el principio de "conservación del dinero"), no debe tener dificultades en aplicar el principio de conservación de la masa a los sistemas de ingeniería.

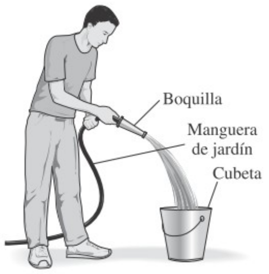

FIGURA 5-12
Esquema para el ejemplo 5-1.

EJEMPLO 5-1 Flujo de agua por la boquilla de una manguera de jardín

Se usa una manguera de jardín que tiene una boquilla de riego para llenar una cubeta de 10 gal. El diámetro de la manguera es de 2 cm y se reduce hasta 0.8 cm en la salida de la boquilla (Fig. 5-12). Si transcurren 50 s para llenar la cubeta con agua, determine *a*) las razones de flujo volumétrico y de masa del agua que pasa por la manguera y *b*) la velocidad promedio del agua a la salida de la boquilla.

SOLUCIÓN Se usa una manguera de jardín para llenar una cubeta con agua. Se deben determinar las razones de flujo volumétrico y de masa y la velocidad a la salida.

Suposiciones **1** El agua es una sustancia incompresible. **2** El flujo por la manguera es estacionario. **3** No hay desperdicio de agua por salpicadura.

Propiedades Se toma la densidad del agua como 1 000 kg/m³ = 1 kg/L.

Análisis *a*) Note que se descargan 10 gal de agua en 50 s, las razones de flujo volumétrico y de masa son:

$$\dot{V} = \frac{V}{\Delta t} = \frac{10 \text{ gal}}{50 \text{ s}} \left(\frac{3.7854 \text{ L}}{1 \text{ gal}} \right) = \mathbf{0.757\ L/s}$$

$$\dot{m} = \rho \dot{V} = (1 \text{ kg/L})(0.757 \text{ L/s}) = \mathbf{0.757\ kg/s}$$

Chapter 2
An Introduction to Differential Forms

In this chapter we introduce one of the fundamental ideas of this book, the differential one-form. Later chapters will discuss differential k-forms for $k > 1$. We slowly and systematically build up to the concept of a one-forms by first considering a variety of necessary ingredients. We begin in section one by introducing the Cartesian coordinate functions, which play a surprisingly important role in understanding exactly what a one-form is, as well as playing a role in the notation used for one-forms.

In section two we discuss manifolds, tangent spaces, and vector fields in enough detail to give you a good intuitive idea of what they are, leaving a more mathematically rigorous treatment for Chap. 10. In section three we return to the concept of directional derivatives that you are familiar with from vector calculus. The way directional derivatives are usually defined in vector calculus needs to be tweaked just a little for our purposes. Once this is done a rather surprising identification between the standard Euclidian unit vectors and differential operators can be made. This equivalence plays a central role going forward.

Finally in section four differential one-forms are defined. Thoroughly understanding differential one-forms requires pulling together a variety of concepts; vector spaces and dual spaces, the equivalence between Euclidian vectors and differential operators, directional derivatives and the Cartesian coordinate functions. The convergence of all of these mathematical ideas in the definition of the one-form is the goal of the chapter.

2.1 Coordinate Functions

Now that we have reviewed the necessary background we are ready to start getting into the real meat of the course, differential forms. For the first part of this course, until we understand the basics, we will deal with differential forms on $\mathbb{R}^n$, with $\mathbb{R}^2$ and $\mathbb{R}^3$ being our primary examples. Only after we have developed some intuitive feeling for differential forms will we address differential forms on more general manifolds. You can very generally think of a manifold as a space which is locally Euclidian - that means that if you look closely enough at one small part of a manifold then it basically looks like $\mathbb{R}^n$ for some n.

For the time being we will just work with our familiar old Cartesian coordinate system. We will discuss other coordinate systems later on. We are used to seeing $\mathbb{R}^2$ pictured as a plane with an x and a y axis as in Fig. 2.1. Here we have plotted the points $(2, 1)$, $(-4, 3)$, $(-2, -2)$, and $(1, -4)$ on the xy-plane. Similarly, we are used to seeing $\mathbb{R}^3$ pictured with an x, y, and z axis as show in Fig. 2.2. Here we have plotted the points $(2, 3, 4)$, $(-3, -4, 2)$, and $(4, 1, -3)$. Also, notice that we follow the "right-hand rule" convention in this book when drawing $\mathbb{R}^3$.

Notice the difference in the notations between points in $\mathbb{R}^n$ and vectors in $\mathbb{R}^n$. For example, points in $\mathbb{R}^2$ or $\mathbb{R}^3$ are denoted by $p = (x, y)$ or $p = (x, y, z)$, where $x, y, z \in \mathbb{R}$, whereas vectors in $\mathbb{R}^2$ or $\mathbb{R}^3$ are denoted by

$$v = \begin{bmatrix} x \\ y \end{bmatrix} \text{ or } v = \begin{bmatrix} x \\ y \\ z \end{bmatrix}$$

Fig. 2.3 The manifold $\mathbb{R}^2$ (left) and the vector space $\mathbb{R}^2$ (right)

where $x, y, z \in \mathbb{R}$. Points and vectors in $\mathbb{R}^n$ for arbitrary n are denoted similarly. Here comes a subtle distinction that is almost always glossed over in calculus classes, especially in multivariable or vector calculus, yet it is a distinction that is very important.

- We will call the collection of points $p = (x_1, x_2, \dots, x_n)$, with $x_1, x_2, \dots, x_n \in \mathbb{R}$, the *manifold* $\mathbb{R}^n$.
- We will call the collection of vectors $v = \begin{bmatrix} x_1 \\ x_2 \\ \vdots \\ x_n \end{bmatrix}$, where $x_1, x_2, \dots, x_n \in \mathbb{R}$, the *vector space* $\mathbb{R}^n$.

One of the reasons this distinction is glossed over in calculus classes is that most calculus students have not yet taken a course in linear algebra and do not yet know what a vector space is. Also, it is certainly possible to "do" vector calculus without knowing the technical definition of a vector space by being a little vague and imprecise mathematically speaking. The manifold $\mathbb{R}^2$ and the vector space $\mathbb{R}^2$ look exactly alike yet are totally different spaces. They have been pictured in Fig. 2.3. The manifold $\mathbb{R}^2$ contains points and the vector space $\mathbb{R}^2$ contains vectors. Of course, in the case of $\mathbb{R}^2$, $\mathbb{R}^3$, or $\mathbb{R}^n$ for that matter, these spaces can be naturally identified. That is, they are really the same. So why is making the distinction so important? It is important to make the distinction for a couple of reasons. First, keeping clear track of our spaces will help us understand the theory of differential forms better, and second, when we eventually get to more general manifolds, most manifolds will not have a vector space structure so we do not want to get into the bad habit of thinking of our manifolds as vector spaces too.

Now let us spend a moment reviewing good old-fashioned functions on $\mathbb{R}^2$ and $\mathbb{R}^3$. We will consider real-valued functions, which simply means that the range (or codomain) is the reals $\mathbb{R}$ or some subset of the reals. Real-valued functions from $\mathbb{R}^2$ are the easiest to visualize since they can be graphed in three dimensional space. Consider the real-valued functions $f : \mathbb{R}^2 \to \mathbb{R}$ defined by the following $f(x, y) = x^3 + y^2 - 3xy$. For example, $f(2, 3)$ is given by $(2)^3 + (3)^2 - 3(2)(3) = -1$, $f(5, -2)$ is given by $(5)^3 + (-2)^2 - 3(5)(-2) = 159$ and $f(-3, -1)$ is given by $(-3)^3 + (-1)^2 - 3(-3)(-1) = -35$. A function from $\mathbb{R}^2$ to $\mathbb{R}$ is graphed in $\mathbb{R}^3$ by the set of points $(x, y, f(x, y))$. The function $f(x, y) = x^3 + y^2 - 3xy$ is shown in Fig. 2.4. Sometimes we will write $f(p)$ where $p = (x, y)$. By doing this we are emphasizing that the input (x, y) is a point in the domain.

As a further illustration, the graphs of the functions $f(x, y) = xy$ and $f(x, y) = x^2 + y^2$ are shown in Fig. 2.5. As before, the set of points that are actually graphed are the points $(x, y, f(x, y))$ in $\mathbb{R}^3$, thus we can see that it requires three dimensions to draw the graph of a function $f : \mathbb{R}^2 \to \mathbb{R}$. That means that we can not accurately draw the graph of any function $f : \mathbb{R}^n \to \mathbb{R}$ for $n \geq 3$. However, we often continue to draw inaccurate cartoons similar to Figs. 2.4 and 2.5 when we want to try to visualize or depict functions $f : \mathbb{R}^n \to \mathbb{R}$ where $n \geq 3$.

We will use different name for "functions" on the manifold $\mathbb{R}^n$ and "functions" on the vector space $\mathbb{R}^n$. Functions on the manifold $\mathbb{R}^n$ will simply be called **functions**, or sometimes, if we want to emphasize that range is the set of real numbers, **real-valued functions**. However, our "functions" on the vector space $\mathbb{R}^n$ are called **functionals** when the range is the set of real values and **transformations** when the range is another vector space. We have already spent some time considering a

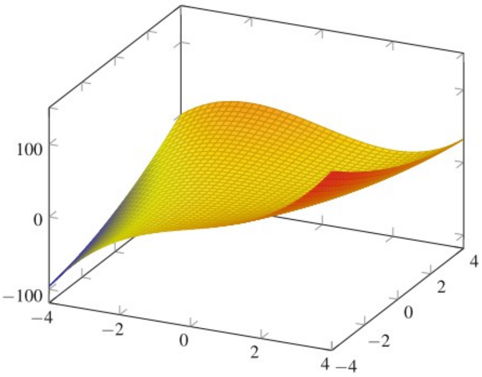

Fig. 2.4 The graph of function $f(x, y) = x^3 + y^2 - 3xy$ is displayed

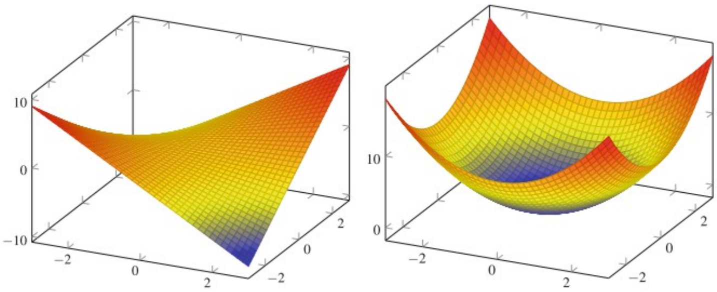

Fig. 2.5 The graphs of the function $f(x, y) = xy$ (left) and $f(x, y) = x^2 + y^2$ (right) as an illustration of the graphs of functions in two variables depicted in $\mathbb{R}^3$

certain class of functionals, the linear functionals that satisfy

$$\begin{aligned} f(v + w) &= f(v) + f(w) \\ f(cv) &= cf(v) \end{aligned}$$

where v and w are vectors and c is a real number. So, the difference between manifolds $\mathbb{R}^n$ and vector spaces $\mathbb{R}^n$ is implicit in our language:

$$\begin{aligned} \text{function } f &: \text{(manifold) } \mathbb{R}^n \longrightarrow \mathbb{R} \\ \text{functional } f &: \text{(vector space) } \mathbb{R}^n \longrightarrow \mathbb{R}. \end{aligned}$$

Now, we will consider a very special function from $\mathbb{R}^n$ to $\mathbb{R}$. We will start by using $\mathbb{R}^2$ as an example. The special functions we want to look at are called the **coordinate functions**. For the moment we will look at the **Cartesian coordinate functions**.

Consider a point p in the manifold $\mathbb{R}^2$ given by the Cartesian coordinates $(3, 5)$. Then the coordinate function

$$\begin{aligned} x : \mathbb{R}^2 &\longrightarrow \mathbb{R} \\ p &\longmapsto x(p) \end{aligned}$$

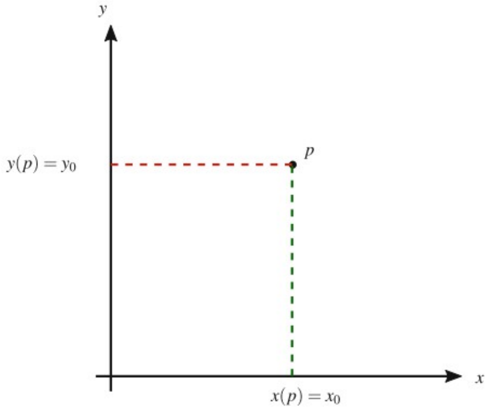

Fig. 2.6 The coordinate functions $x : \mathbb{R}^2 \to \mathbb{R}$ and $y : \mathbb{R}^2 \to \mathbb{R}$ picking off the coordinate values x_0 and y_0, respectively, of the point $p \in \mathbb{R}^2$

picks off the first coordinate, that is, $x(p) = x\big((3, 5)\big) = 3$, and the coordinate function

$$\begin{aligned} y : \mathbb{R}^2 &\longrightarrow \mathbb{R} \\ p &\longmapsto y(p) \end{aligned}$$

picks off the second coordinate, $y(p) = y\big((3, 5)\big) = 5$. This is illustrated in Fig. 2.6.

The fact of the matter is, even though you are used to thinking of (3, 5) as a point, a point is actually more abstract than that. A point exists independent of its coordinates. For example, you will sometimes see something like this,

$$p = \big(x(p), y(p)\big)$$

where, as an example, for the point we were given above we have $x(p) = 3$ and $y(p) = 5$.

There is some ambiguity that we need to get used to here. Often x and y are used to represent the outputs of the coordinate functions x and y. So, we could end up with an ambiguous statement like this

$$\begin{aligned} x(p) &= x \\ y(p) &= y \end{aligned}$$

where the x and the y on the left hand sides of the equations are coordinate functions from $\mathbb{R}^2$ to $\mathbb{R}$, and the x and y on the right hand side are real numbers, that is, elements of $\mathbb{R}$. Learning to recognize when x and y are coordinate functions and when they are real values requires a little practice, you have to look carefully at how they are being used. This distinction may sometimes be pointed out, but it often is glossed over.

Even though points are abstract and independent of coordinates, we can not actually talk about a particular point without giving it an "address." This is actually what coordinate functions do, they are used to give a point an "address."

Coordinate functions on $\mathbb{R}^3$ (and $\mathbb{R}^n$ for that matter) are completely analogous. For example, on $\mathbb{R}^3$ we have the three coordinate functions

$$\begin{aligned} x : \mathbb{R}^3 &\longrightarrow \mathbb{R} \\ p &\longmapsto x(p) \end{aligned} \qquad \begin{aligned} y : \mathbb{R}^3 &\longrightarrow \mathbb{R} \\ p &\longmapsto y(p) \end{aligned} \qquad \begin{aligned} z : \mathbb{R}^3 &\longrightarrow \mathbb{R} \\ p &\longmapsto z(p) \end{aligned}$$

which pick off the x, the y and the z coordinates of the point p as illustrated in Fig. 2.7.

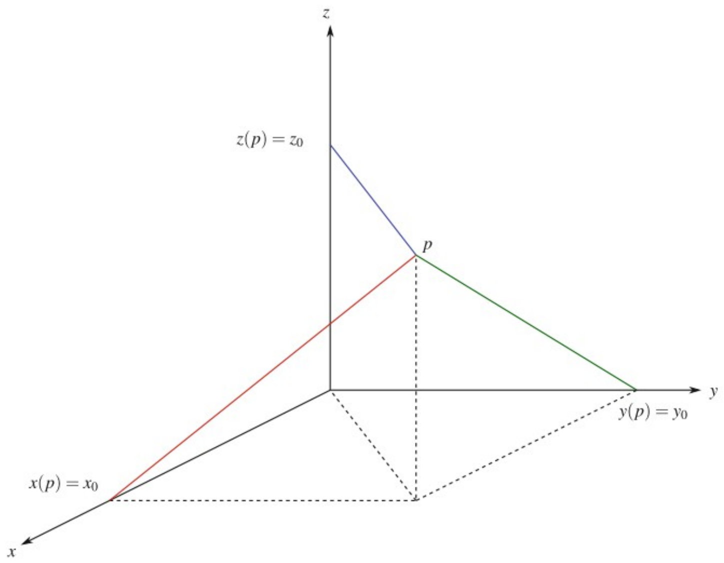

Fig. 2.7 The coordinate functions $x : \mathbb{R}^3 \to \mathbb{R}$, $y : \mathbb{R}^3 \to \mathbb{R}$, and $z : \mathbb{R}^3 \to \mathbb{R}$ picking off the coordinate values x_0, y_0, and z_0 respectively, of the point $p \in \mathbb{R}^3$

Of course Cartesian coordinate functions are not the only coordinate functions there are. Polar coordinate, spherical coordinate, and cylindrical coordinate functions are some other examples you have likely encountered before. We will talk about these coordinate systems in more detail later on but for the moment we consider one example. Consider the point $p = p\big(x(p), y(p)\big) = (3, 5)$. Polar coordinates r and θ are often given by $x = r\cos(\theta)$ and $y = r\sin(\theta)$. Suppose we want to find the "address" of point p in terms of polar coordinates. That is, we want to find $p = \big(r(p), \theta(p)\big)$.

Since we know p in terms of x and y coordinates, we can write $r = \sqrt{x^2 + y^2}$ and $\theta = \arctan\left(\frac{y}{x}\right)$. Then we have

$$\begin{aligned} p = \Big(r(p), \theta(p)\Big) &= \Big(r\Big(x(p), y(p)\Big), \theta\Big(x(p), y(p)\Big)\Big) \\ &= \left(\sqrt{x(p)^2 + y(p)^2}, \arctan\left(\frac{y(p)}{x(p)}\right)\right) \\ &= \left(\sqrt{3^2 + 5^2}, \arctan\left(\frac{5}{3}\right)\right) \\ &= \left(\underbrace{\sqrt{34}}_{r}, \underbrace{\arctan\left(\frac{5}{3}\right)}_{\theta}\right) \\ &\approx \big(5.831, 59.036\big). \end{aligned}$$

Again, the same ambiguity applies, r and θ can either be coordinate functions or the values given by the coordinate functions.

2.2 Tangent Spaces and Vector Fields

Let us recap what we have done so far. We have reviewed vector spaces and talked about $\mathbb{R}^n$ as a vector space, that is, as a collection of vectors of the from

$$v = \begin{bmatrix} x_1 \\ \vdots \\ x_n \end{bmatrix}$$

where $x_1, \ldots, x_n \in \mathbb{R}$. Then we talked about $\mathbb{R}^n$ as a manifold, that is, as a collection of points $(x_1, \ldots, x_n)$ where $x_1, \ldots, x_n \in \mathbb{R}$. We have also reviewed linear functionals on the vector space $\mathbb{R}^n$ and functions on the manifold $\mathbb{R}^n$ and introduced coordinate functions. We will now see how the manifold $\mathbb{R}^n$ is related to vector spaces $\mathbb{R}^n$. Our motivation for this is our desire to do calculus. Well, for the moment to take directional derivatives anyway.

However, to help us picture what is going on a little better we are going to start by considering three manifolds, S^1, S^2, and T. The manifold S^1 is simply a circle, the manifold S^2 is the sphere, and the manifold T is the torus, which looks like a donut. For the moment we are going to be quite imprecise. We want you to walk away with a general feeling for what a manifold is and not overwhelm you with technical details. For the moment we will simply say a **manifold** is a space that is **locally Euclidian**. What we mean by that is if we look at a very small portion of the manifold that portion looks like $\mathbb{R}^n$ for some natural number n.

We will illustrate this idea for the three manifolds we have chosen to look at. The circle S^1 is locally like $\mathbb{R}^1$, which explains the superscript 1 on the S. In Fig. 2.8 we zoom in on a small portion of the one-sphere S^1 a couple of times to see that locally the manifold S^1 looks like $\mathbb{R}^1$. Similarly, in Fig. 2.9 we zoom in on a small portion of the two-sphere S^2 to see that it looks like $\mathbb{R}^2$ locally and in Fig. 2.10 we zoom in on a small portion of the torus T see that it also looks locally like $\mathbb{R}^2$.

The point with these examples is that even though these example manifolds *locally* look like $\mathbb{R}^1$ and $\mathbb{R}^2$, *globally* they do not. That is, their global behavior is more complex; these spaces somehow twist around and reconnect with themselves in a way that Euclidian space does not.

Now we will introduce the idea of a **tangent space**. Again, we want to give you an general feeling for what a tangent space is and not overwhelm you with the technical details, which will be presented in 10.2. From calculus you should recall what the tangent line to a curve at some point of the curve is. Each point of the curve has its own tangent line, as is shown in Fig. 2.11. We can see that the one dimensional curve has tangent spaces that are lines, that is, that are also one dimensional.

Similarly, a two dimensional surface has a tangent plane at each point of the surface, as is pictured in Fig. 2.12. The tangent space to a manifold at the point p is basically the set of all lines that are tangent to smooth curves that go through

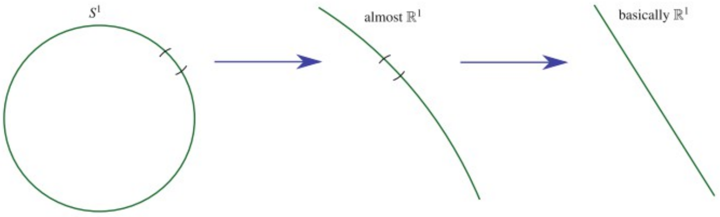

Fig. 2.8 Here a small portion of a one-sphere, or circle, S^1 is zoomed in on to show that locally the manifold S^1 looks like $\mathbb{R}^1$

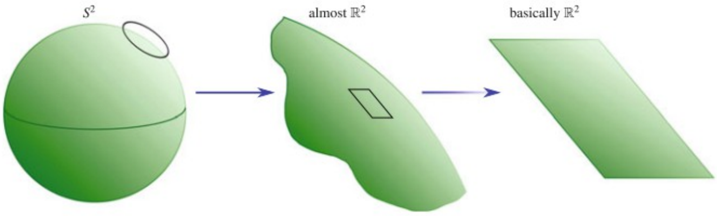

Fig. 2.9 Here a small portion of the two-sphere S^2 is zoomed in on to show that locally the manifold S^2 looks like $\mathbb{R}^2$

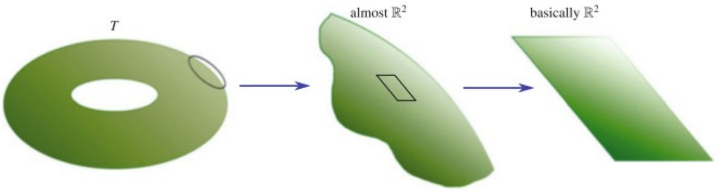

Fig. 2.10 Here a small portion of the torus T is zoomed in on to show that locally the manifold T looks like $\mathbb{R}^2$

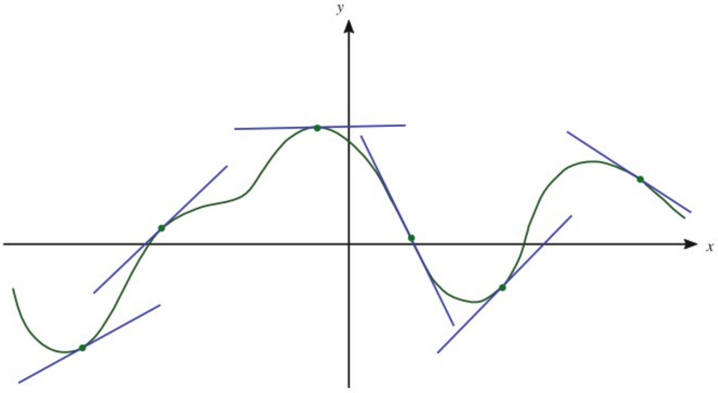

Fig. 2.11 Here a curve is pictured with tangent lines drown at several points

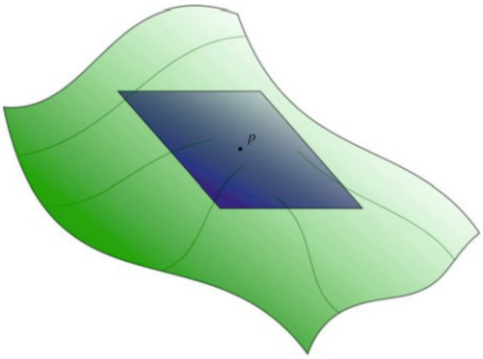

Fig. 2.12 Here a two-dimensional surface is pictured along with a tangent plane drown at one point

the manifold at the point p. This is illustrated in Fig. 2.13 where we have drawn a point p with five smooth curves going through it along with the five tangent lines to the curves at the point p. In both of these pictures the tangent space is a plane.

If you imagine a point in a three dimensional manifold and all the possible curves that can go through that point, and then imagine all the tangent lines to those curves at that point, you will see that the tangent space at that point is three dimensional. It turns out that the tangent space at a "nice" point is the same dimension as the manifold at that point. In this book we will not discuss manifolds with points that are not "nice" in this sense. In fact, the tangent spaces turn out to be nothing more than the vector spaces $\mathbb{R}^n$ for the correct value of n. Because the tangent spaces are vector spaces we think of the tangent space at a point p to be the set of all tangent vectors to the point p. We use special notation for the tangent space. Either T_pM or $T_p(M)$ denotes the tangent space to the manifold M at the point p.

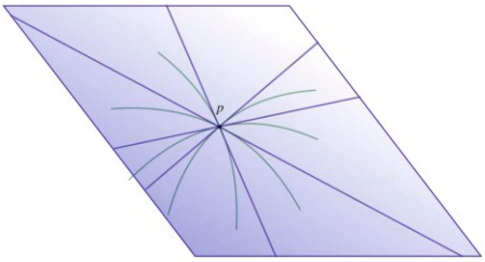

Fig. 2.13 The tangent plane to a two-dimensional surface at the point p is the set of all tangent lines at p to curves in that surface that go through p

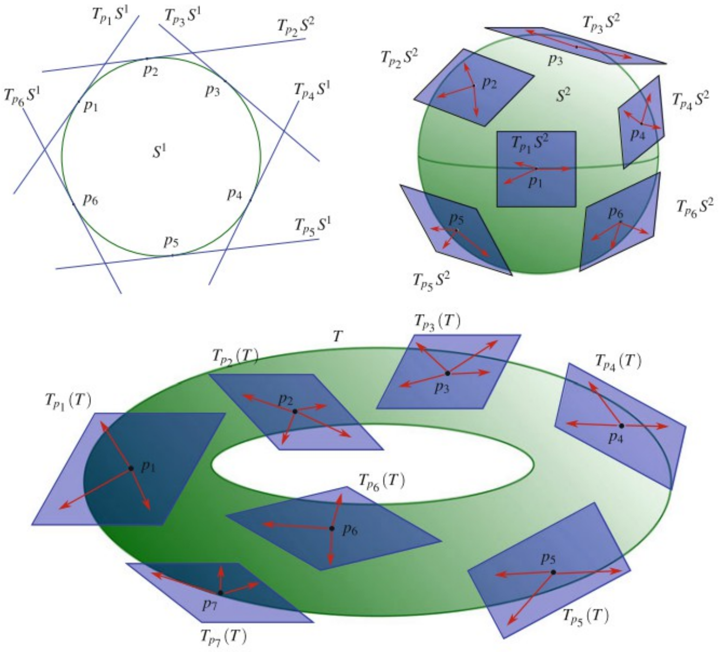

Fig. 2.14 The manifold S^1 along with a number of tangent lines depicted (top left). The manifold S^2 along with a number of tangent planes depicted (top right). The manifold T along with a number of tangent planes depicted (bottom). For both manifolds S^2 and T several vectors in each tangent plane are also depicted

To get a better idea of what the set of tangent spaces to a manifold look like, we have drawn a few tangent spaces to the three simple manifolds we had looked at earlier in Fig. 2.14, the circle S^1, the sphere S^2, and the torus T. For the two dimensional tangent spaces we have also drawn some elements of the tangent spaces, that is, vectors emanating from the point p. The tangent spaces of the circle are denoted by T_pS^1, the tangent spaces of the sphere are denoted by T_pS^2, and the tangent spaces of the torus are denoted by $T_p(T)$. We use the parenthesis here simply because T_pT looks a little odd.

Even though we are quite familiar with the manifolds $\mathbb{R}^2$ and $\mathbb{R}^3$, imagining the tangent spaces to these manifolds is a little strange, though is it something you have been implicitly doing since vector calculus. The tangent space of the manifold $\mathbb{R}^2$ at a point p is the set of all vectors based at the point p. In vector calculus we dealt with vectors with different base points a lot, but we always simply thought of these vectors as being *in* the manifold $\mathbb{R}^2$ or $\mathbb{R}^3$. Now we think of these vectors as belonging to a separate copy of the vector space $\mathbb{R}^2$ or $\mathbb{R}^3$ attached at the point and called the tangent space.

Figure 2.15 tries to help you imagine what is going on. The manifold $\mathbb{R}^2$ is pictured along with the tangent spaces $T_{p_i}\mathbb{R}^2$ at seven different points $p_1, \dots, p_7$. Each of the tangent spaces $T_p\mathbb{R}^2$ is **isomorphic** to ("the same as") $\mathbb{R}^2$. Though we have drawn the tangent spaces at only seven points, there is in fact a separate tangent space $T_p\mathbb{R}^2$ for every single point $p \in \mathbb{R}^2$.

Figure 2.16 tries to help you imagine the tangent spaces to $\mathbb{R}^3$. Again, the manifold $\mathbb{R}^3$ is pictured along with the tangent spaces $T_{p_i}\mathbb{R}^3$ at seven different points $p_1, \dots, p_7$. Each of the tangent spaces $T_p\mathbb{R}^3$ is naturally isomorphic to $\mathbb{R}^3$. Again, though we have drawn the tangent spaces at only seven points, there is in fact a separate tangent space $T_p\mathbb{R}^3$ for every single point $p \in \mathbb{R}^3$.

From now on we will often include the base point of a vector in our notation. For example, the vector v_p means vector v at the base point p of the manifold M. Clearly, the vector v_p belongs to, or is an element of, the tangent space T_pM. So, for example, we have

$$\begin{bmatrix} 1 \\ 1 \end{bmatrix}_{(-2,-3)} \in T_{(-2,-3)}\mathbb{R}^2, \qquad \begin{bmatrix} 1 \\ 1 \end{bmatrix}_{(-1,4)} \in T_{(-1,4)}\mathbb{R}^2, \qquad \begin{bmatrix} 1 \\ 1 \end{bmatrix}_{(2,4)} \in T_{(2,4)}\mathbb{R}^2,$$

and

$$\begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}_{(-2,-3,-5)} \in T_{(-2,-3,-5)}\mathbb{R}^3, \qquad \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}_{(-1,4,3)} \in T_{(-1,4,3)}\mathbb{R}^3, \qquad \begin{bmatrix} 1 \\ 1 \\ 1 \end{bmatrix}_{(2,4,-1)} \in T_{(2,4,-1)}\mathbb{R}^3.$$

The manifold M, along with a copy of the vector space T_pM attached at every point of the manifold is called the **tangent bundle** of the manifold M which is denoted as TM or $T(M)$. Often a cartoon version of the tangent bundle of a manifold M is drawn as in Fig. 2.17 using a one dimensional representation for both the manifold and the tangent spaces.

If M is an n dimensional manifold then TM is $2n$ dimensional. That makes intuitive sense since to specify exactly any element (vector) in TM you need to specify the vector part, which requires n numbers, and the base point, which also requires n numbers. Thus, $T\mathbb{R}^2$ has four dimensions and $T\mathbb{R}^3$ has six dimensions. In fact, the tangent bundle TM of a manifold M is itself also a manifold. Thus, if M is an n dimensional manifold then TM is a $2n$ dimensional manifold.

Now we will very briefly introduce the concept of a **vector field**. Doubtless you have been exposed to the idea of a vector field in vector calculus where it is usually defined on $\mathbb{R}^2$ or $\mathbb{R}^3$ as a vector-valued function that assigns to each point $(x, y) \in \mathbb{R}^2$ or $(x, y, z) \in \mathbb{R}^3$ a vector

$$\begin{bmatrix} v_1 \\ v_2 \end{bmatrix}_{(x,y)} \text{ or } \begin{bmatrix} v_1 \\ v_2 \\ v_3 \end{bmatrix}_{(x,y,z)}.$$

An example of a vector field on $\mathbb{R}^2$ is shown in Fig. 2.18.

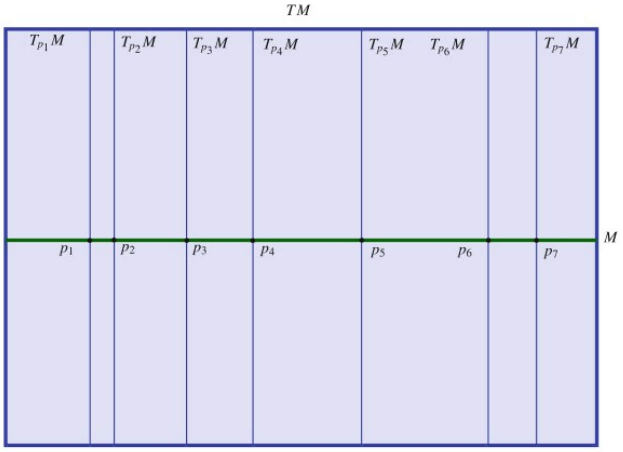

Fig. 2.17 A cartoon of a tangent bundle TM over a manifold M. Seven tangent spaces $T_{p_i}M$ are shown

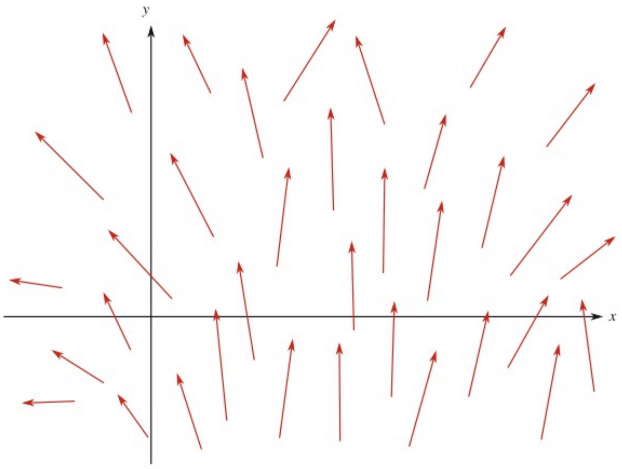

Fig. 2.18 A vector field drawn on the manifold $\mathbb{R}^2$. Recall, each of the vectors show are an element of a tangent space and not actually in the manifold $\mathbb{R}^2$

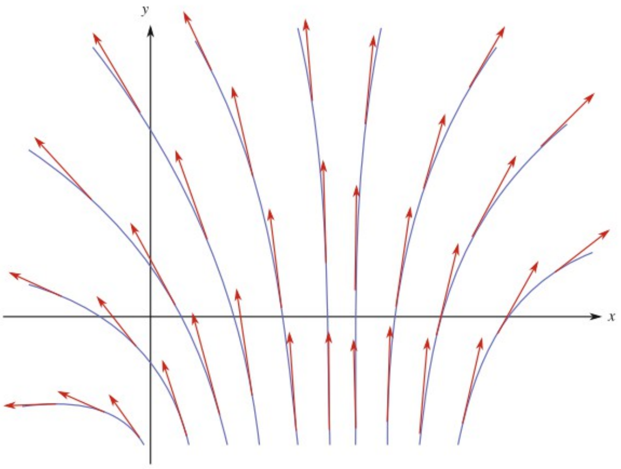

Fig. 2.19 A smooth vector field drawn on the manifold $\mathbb{R}^2$. Again, recall, each of the vectors shown are an element of a tangent space and not actually in the manifold $\mathbb{R}^2$

A vector field is called **smooth** if it is possible to find curves on the manifold such that all the vectors in the vector field are tangent to the curves. These curves are called the **integral curves** of the vector field, and finding them is essentially what differential equations are all about. Figure 2.19 shows several integral curves of a smooth vector field in $\mathbb{R}^3$.

While we certainly are not going to get into differential equations here, what we want to do is introduce a new way of thinking about vector fields. Notice, a vector field on a manifold such as $\mathbb{R}^2$ or $\mathbb{R}^3$ gives us a vector at each point of the manifold. But a vector v_p at a point p of a manifold M is an element of the tangent space at that point, T_pM. So being given a vector field is the same thing as being given an element of each tangent space of M. This is often called a **section** of the tangent bundle TM. Graphically, we often visualize sections of tangent bundles as in Fig. 2.20.

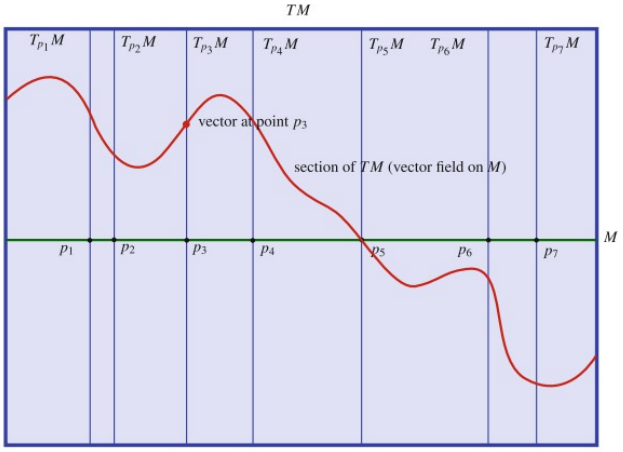

Fig. 2.20 A cartoon of a section of a tangent bundle over the manifold M. The section of TM is simply a vector field on M. The vector in the vector field on M at point p_3 is depicted as the point in $T_{p_3}M$ that is in the section. Notice, in this cartoon representation the vector at the point p_5 would be the zero vector

Question 2.1 Before we get into the next section let's take just a moment to review what derivatives were all about. Consider the function $f : \mathbb{R} \to \mathbb{R}$ given by $f(x) = \frac{x^2}{2} + 2$.

(a) Sketch the graph of the function $f(x) = \frac{x^2}{2} + 2$.
(b) Find the derivative of $f(x)$.
(c) What is $f(2)$? What is $f(3)$? Draw a line between the points $\big(2, f(2)\big)$ and $\big(3, f(3)\big)$.
(d) What is the slope of this secant line?
(e) Write down the limit of the difference quotient definition of derivative.
(f) Use this definition to find the derivative of f at $x = 2$. Does it agree with what you found above?
(g) The derivative of f at $x = 2$ is a number. Explain what this number represents.

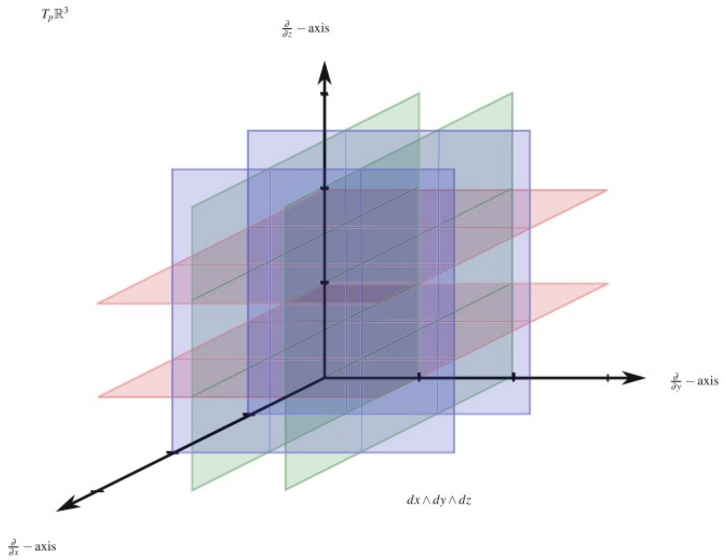
From the above question you should now remember that derivatives are basically slopes of lines tangent to the graph of the function at a certain point.

2.3 Directional Derivatives

Now the time comes to explore why we might actually want to use all of this. Suppose we were given a real-valued function f on the manifold $\mathbb{R}^n$. That is, $f : \mathbb{R}^n \to \mathbb{R}$. How might we use a vector v_p at some given point p on the manifold? One natural thing we could do is take the **directional derivative** of f at the point p in the direction of v_p. Consider Fig. 2.21 where a real-valued function $f : \mathbb{R} \to \mathbb{R}$ is shown. Given a point p in the domain there are two directions that it is possible to move in, left or right. Similarly, if you had a vector based at that point it could either point left, as v_p does, or right, as w_p does. We could ask how the function varies in either of these directions. In Fig. 2.22 a real-valued function $f : \mathbb{R}^2 \to \mathbb{R}$ is depicted. Given a point $p = (x, y)$ in the domain one can go any direction in two dimensions, and a vector based at that point could point in any direction in two dimensions as well. And similarly, we could ask how the function varies in any of these directions. In Fig. 2.23 we choose one of those directions, the direction given by the vector

$$v_p = \begin{bmatrix} a \\ b \end{bmatrix}_{(x,y)}.$$

We are able to use this vector to find the directional derivative of f in the direction v_p at the point p. In other words, we are able to find how f is changing in the direction v_p at the point p.



$T_p\mathbb{R}^3$
$\frac{\partial}{\partial z}$ − axis
$\frac{\partial}{\partial y}$ − axis
$\frac{\partial}{\partial x}$ − axis
$dx \wedge dy \wedge dz$

Fig. 5.30 The three-form $dx \wedge dy \wedge dz$ is made up of "cubes" whose sides are the planes perpendicular to the x-axis, the y-axis, and the z-axis

5.4 Three-Forms in $\mathbb{R}^3$

This is probably the shortest section in the entire book. And for a reason. Drawing three-forms in $T_p\mathbb{R}^3$ is in fact exceedingly simple. The space of three-forms on $\mathbb{R}$, denoted $\bigwedge^3(\mathbb{R})$, is actually of dimension one, which means that every three-form on $\mathbb{R}^3$ is of the form $c dx \wedge dy \wedge dz$ for some $c \in \mathbb{R}$. The one-form dx was given by the planes $x = n$, the one-form dy was given by the planes $y = n$, and the one-form dz was given by the planes $z = n$, where we had $n = 0, \pm 1, \pm 2, \ldots$. The three-form is simply all of these planes being drawn simultaneously, thereby filling space with unit cubes. See Fig. 5.30. For three-forms $a dx \wedge dy \wedge dz$, where $a \in \mathbb{R}$, the usual ambiguity arises.

Question 5.20 Based on Fig. 5.30 sketch three different pictures for the three-form $2dx \wedge dy \wedge dz$.

Question 5.21 Let

$$u = \begin{bmatrix} 1 \\ 0 \\ 0 \end{bmatrix}, v = \begin{bmatrix} 0 \\ 1 \\ 0 \end{bmatrix}, w = \begin{bmatrix} 0 \\ 0 \\ 1 \end{bmatrix}.$$

Evaluate $dx \wedge dy \wedge dz$ on different permutations of u, v, w and use your answers to determine what kind of orientation is $dx \wedge dy \wedge dz$ has. (Note, somehow all three directions have to be taken into account.)

Question 5.22 How might you depict the positive orientation for $dx \wedge dy \wedge dz$ in Fig. 5.30? What about the negative orientation?

5.5 Pictures of Forms on Manifolds

What we have done so far is to attempt to draw graphical representations of one-forms and two-forms in $\mathbb{R}^2$ and one-forms, two-forms, and three-forms in $\mathbb{R}^3$. In each case we looked at some form α_p at the point p and found a representation of α_p in the tangent space at the point p. For a one-form on $\mathbb{R}^2$ our picture was of lines in $T_p\mathbb{R}^2$ (Figs. 5.1–5.7), while for a two-form on $\mathbb{R}^2$ our picture was of boxes in $T_p\mathbb{R}^2$ (Figs. 5.8–5.10). For a one-form in $\mathbb{R}^3$ our picture was of planes in $T_p\mathbb{R}^3$ (Figs. 5.11–5.18), for a two-form in $\mathbb{R}^3$ our picture was of tubes in $T_p\mathbb{R}^3$ (Figs. 5.19–5.29), and for a three-form in $\mathbb{R}^3$ our pictures was of cubes in $T_p\mathbb{R}^3$ (Fig. 5.30).

Sometimes attempts are made to utilize these graphical representations of one-forms and two-forms on $\mathbb{R}^2$ and one-forms, two-forms, and three-forms on $\mathbb{R}^3$ to "draw" forms on the whole manifold, at least for manifolds that are two or three dimensional. There are two ways that this is generally done. The first method at least makes sense mathematically, though it can still end up being incomplete in some sense and can potentially misrepresent the differential form. The second method, unfortunately, has some serious mathematical shortcomings, in addition to potentially misrepresenting the differential form. But when these methods do work they can be an extremely helpful and illuminating way to think about differential forms on two and three dimensional manifolds. It is best to keep in the back of your mind that the pictures these methods give are merely cartoons at best.

First, we will present the first method of visualizing forms on manifolds. Essentially what is done here is that a lattice of points $p_{ij} = (x_i, y_j)$ on the manifold is chosen and the line-stacks that represent the one-form in $T_{p_{ij}}M$ are drawn on the manifold at each of these lattice points. Figure 5.31 shows how this is done for a series of simple one-forms on $\mathbb{R}^2$. The arrow points indicate positive orientation. Of course, we can choose lattices of points on the manifold with differing densities. Figure 5.32 shows the same one-form $xdx + ydy$ on $\mathbb{R}^2$ using two different lattices of points. A two-form would be similar, only with a small grid of boxes drawn at each point. The drawback of this method is the spacing of the lattice of points; it is entirely possible that important details of the differential form can be missed if one chooses an inappropriate lattice. Be that as it may, one generally still obtains a reasonable cartoon that can at least help one imagine the differential form.

For three dimensional manifolds the pictures are analogous. First a three-dimensional lattice of points $p_{ijk} = (x_i, y_j, z_k)$ is chosen on the manifold. A one-form would then be represented as small stacks of sheets at each point p_{ijk}, a two-form would be represented with small bundles of tubes at each point p_{ijk}, and a three-form would be represented with small sets of cubes at each point p_{ijk}.

The second method does something similar, but tries to take it one step further. Consider Fig. 5.32 again. In the second image the lattice of points was chosen close enough so that, particularly in the middle, they start to merge into each other and form concentric circles. In the second method the little pictures at the lattice points are connected up to each other to provide one continuous image on the manifold. When this is actually possible the images are very appealing and simple to think about. First we will look at how method two works when it is appropriate and then we will briefly discuss how method two fails in general.

As an example, a generic one-form α on $\mathbb{R}^3$ is shown in Fig. 5.33. Here the line-stacks at the lattice points (not shown) are connected, as well as is possible, to generate curves that cover the manifold. The value $\alpha(v)$ is (approximately) given by the number of curves the vector v pierces. The case of two-forms on the manifold $\mathbb{R}^2$ is handled identically, only instead of small stacks of lines at each lattice point one would have small patches of boxes. Again, it may be possible to connect up the boxes to give a rough image of the two-form on the manifold. Consider Fig. 5.34. Here a two-form on manifold $\mathbb{R}^2$ is depicted on the manifold $\mathbb{R}^2$. In order to find the value of the two-form α at any given point p two vectors at that point need to be given, v_1 and v_2. The value $\alpha_p(v_1, v_2)$ is then given by the number of boxes that are inside the parallelepiped spanned by v_1 and v_2.

Attempts to picture one-forms, two-forms, and three-forms on the manifold $\mathbb{R}^3$ are very similar. Again, a lattice of points $p_{ijk} = (x_i, y_j, z_k)$ is chosen and at each of these points the picture of the form in $T_{p_{ijk}}\mathbb{R}^3$ is found. For a one-form α at each point p_{ijk} one would have a stack of two-dimensional sheets, similar to Fig. 5.17. Small copies of each of these pictures would then be superimposed on the manifold $\mathbb{R}^3$ at each lattice point. One would then try to connect up these sheets, as best as one could, to arrive at a picture similar to that of Fig. 5.35. How closely the sheets are packed (in other words, how far apart the sheets are from each other) is determined by the particular one-form. To find the (approximate) value of $\alpha(v)$ one would then count the number of sheets the vector v pierces. So, the sheets of the one-form 10α are ten times as close to each other as the sheets of the one-form α.

For a two-form α at each point p_{ijk} one would have a bundle of "tubes" similar to Fig. 5.23. At each lattice point the bundle of tubes would have varying densities and be in different directions. One would then try to connect up these sheets, as best as one could, to arrive at a picture similar to that of Fig. 5.36, where tubes of varying sizes twist through $\mathbb{R}^3$. The density at which the tubes are packed depends on the exact nature of the two-form α. In order to (approximately) find $\alpha(v_p, w_p)$ one finds the parallelepiped spanned by v_p and w_p and counts the number of tubes that go through this parallelepiped.

For a three-form α at each point p_{ijk} one would have a little set of cubes, similar to Fig. 5.30. One could imagine Rubik's cubes of varying sizes and orientations at each lattice point. Then these cubes are all connected up as well as possible to fill $\mathbb{R}^3$ with little cubes. We will not attempted to show that here. Finding the (approximate) value of $\alpha(u_p, v_p, w_p)$ amounts to counting the number of cubes that are inside the parallelepiped spanned by u_p, v_p, w_p.

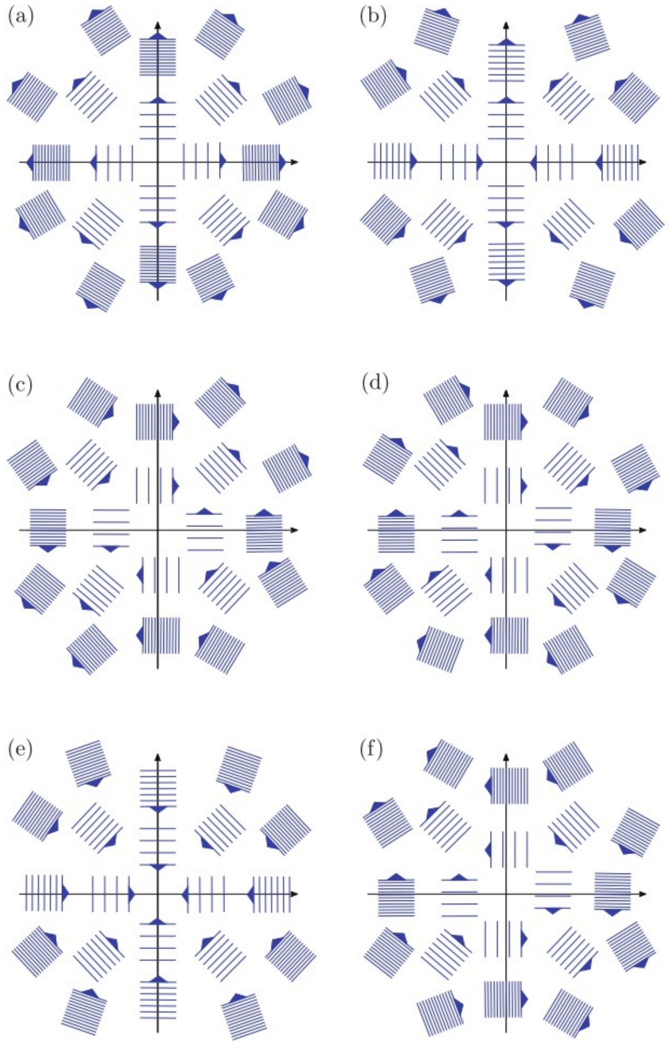


Fig. 5.31 One-forms on the manifold $\mathbb{R}^2$ represented as a grid of line-stacks on the manifold $\mathbb{R}^2$. The arrow points indicate positive direction (Images generated with Vector Field Analyzer II, Version 2, Kawski, 2001) . (**a**) $xdx + ydy$. (**b**) $-xdx + ydy$. (**c**) $ydx + xdy$. (**d**) $ydx - xdy$. (**e**) $-xdx - ydy$. (**f**) $-ydx - xdy$

There is something very appealing about this way of looking at differential forms, and in certain instances it helps provide an additional way of thinking about differential forms on two-dimensional and three-dimensional manifolds. Unfortunately, in general method two fails. In fact, one does not have to look very far to find examples of forms where it is actually impossible to visualize them using method two. One of the real issues is the "connecting" bit. Mathematically this is a complete slight-of-hand with no reasonable justification. In fact, each of the line-stacks for a one-form are in a different tangent space so "connecting" the line-stacks simply doesn't make sense. And even when we draw the pictures on the manifold as we have done, there is no reason to suppose that the line-stacks at points close to each other would be oriented in a way that would allow them to be connected, as was the case in Fig. 5.32. For a general one-form they need not be. And of course this applies to the plane-stacks and tube-bundles for three-dimensional manifolds as well.

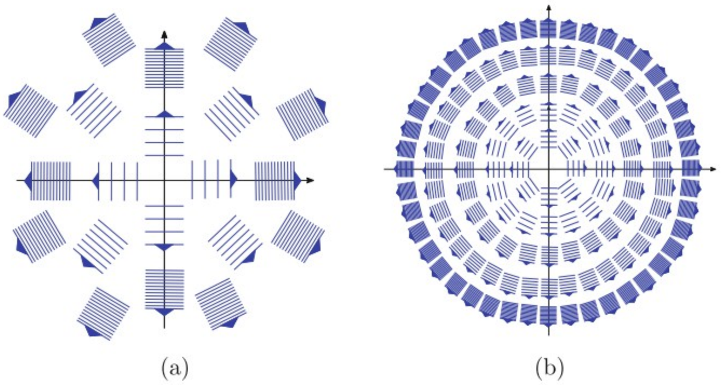

Fig. 5.32 The one-form $xdx + ydy$ on the manifold $\mathbb{R}^2$ represented as a grid of line-stacks using two different arrays of points. The arrow points indicate positive direction. Notice how in the image on the right the line-stacks in the middle start to look like they are merging into concentric circles (Images generated with Vector Field Analyzer II, Version 2, Kawski, 2001)

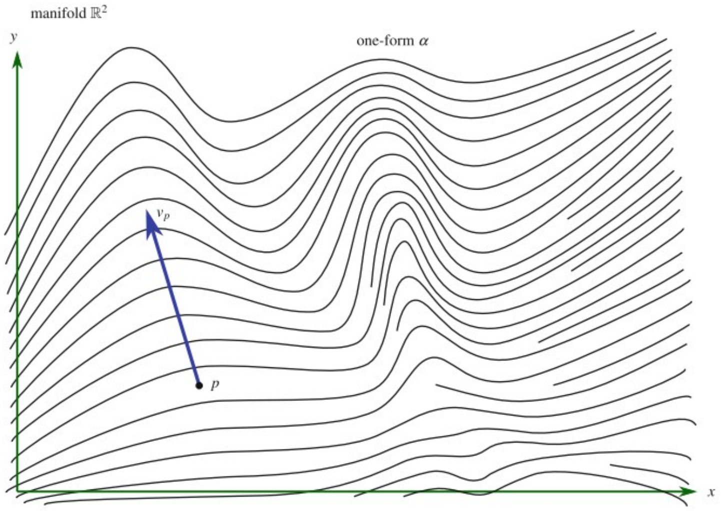

Fig. 5.33 A one-form α is shown on the manifold $\mathbb{R}^2$ with all the "line stacks" connected up smoothly as curves. The one-form applied to a vector is (approximately) equal to the number of curves "pierced" by the vector. Here, $\alpha(v_p) \approx 6$

A necessary, but not sufficient, requirement is that the distribution given by the kernel of the differential form be integrable. This would give what is called a foliation of the manifold which would allow the line-stacks, plane-stacks, or tube-bundles to line up. Exploring and explaining this is beyond the scope of this book. It is simply sufficient to realize that even a one-form on $\mathbb{R}^3$ as simple as $xdy + dz$ can not be visualized using method two.

However, this way of visualizing differential forms does appear in physics sometimes. Physicists are not so concerned about a completely general way of visualizing forms, they are interested in a way of visualizing forms that works for the physical problems and situations they are dealing with. Thus this method does have some utility in certain situations. When it is appropriate it does in fact provides a very nice way of thinking about forms. In fact, it gives a nice picture to go along with Stokes' theorem that is very appealing and will be presented in Sect. 11.6.

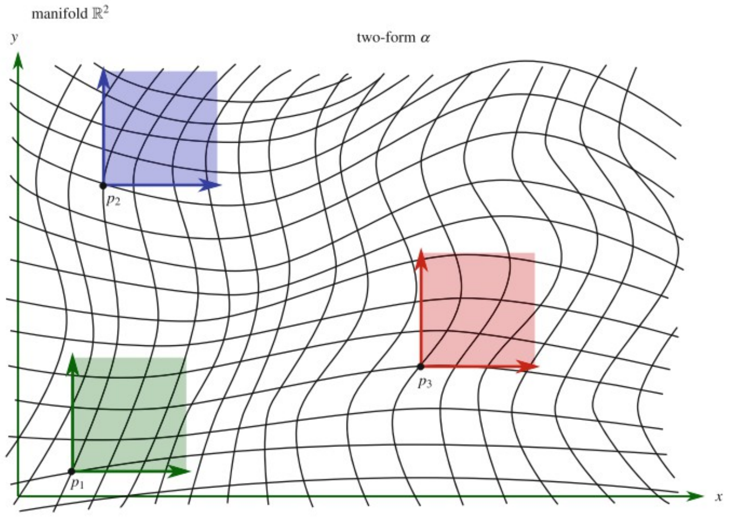

Fig. 5.34 A two-form α is shown on the manifold $\mathbb{R}^2$ with all boxes connected up smoothly. The unit vectors e_1 and e_2 are depicted at points p_1 (green), p_2 (blue), and p_3 (red). One (approximately) finds $\alpha_{p_i}(e_1, e_2)$ by counting the number of boxes that fall within the parallelepiped spanned by e_1 and e_2 at each of these points. Thus $\alpha_{p_1}(e_1, e_2) \approx 12$, $\alpha_{p_2}(e_1, e_2) \approx 16$, and $\alpha_{p_3}(e_1, e_2) \approx 9$. It is clear that while this is a nice picture the answers it gives are only very approximate

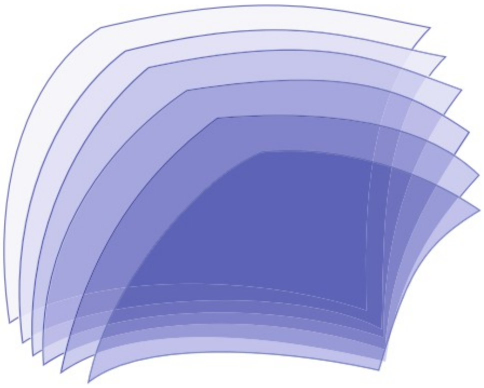

Fig. 5.35 A generic one-form in $\mathbb{R}^3$ is comprised of sheets filling $\mathbb{R}^3$

5.6 A Visual Introduction to the Hodge Star Operator

Introducing the Hodge star operator in a mathematically rigorous way at this point is a little tricky since much of the necessary mathematics has not yet been introduced, yet the geometric pictures of the Hodge star operator that go along with this chapter are really quite nice and easy to understand, so now is a natural time to do it. Thus we will try to strike a balance, providing some of the mathematics behind the pictures but not enough to overwhelm you with theoretical details. For the moment we will stick to the three dimensional case and give plausibility arguments instead of rigorous proofs.

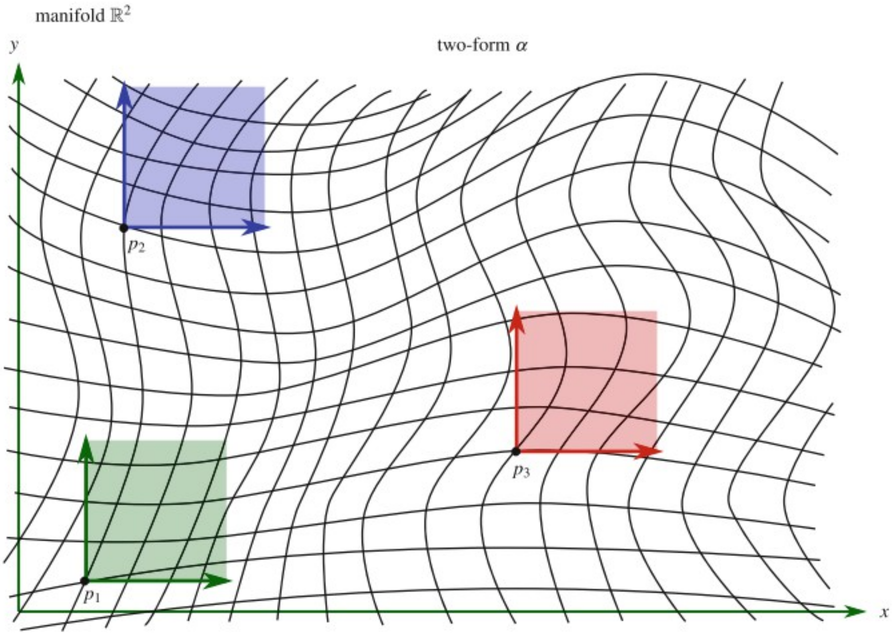

Fig. 5.34 A two-form α is shown on the manifold $\mathbb{R}^2$ with all boxes connected up smoothly. The unit vectors e_1 and e_2 are depicted at points p_1 (green), p_2 (blue), and p_3 (red). One (approximately) finds $\alpha_{p_i}(e_1, e_2)$ by counting the number of boxes that fall within the parallelepiped spanned by e_1 and e_2 at each of these points. Thus $\alpha_{p_1}(e_1, e_2) \approx 12$, $\alpha_{p_2}(e_1, e_2) \approx 16$, and $\alpha_{p_3}(e_1, e_2) \approx 9$. It is clear that while this is a nice picture the answers it gives are only very approximate

Length and Time Are Relative Quantities

> [In order to measure the Lorentz] contraction we should have to operate with two perpendicular rods, and with two mutually interfering pencils of light, allowing the one to travel to and fro along the first rod, and the other along the second rod. But in this way we should come back once more to the Michelson experiment . . .
>
> *H. A. Lorentz (1895)*

> The special relativity theory resulted in appreciable advances [among them was that] it enforced the need for clarification of the fundamental concepts in epistemological terms.
>
> *A. Einstein (1923)*

A noncircular and unambiguous method for measuring length using light rays depended on Einstein's extending to every inertial reference system the axiom concerning the propagation of light relative to ether-fixed reference systems. The relativity of time and simultaneity was a startling consequence of Einstein's having combined axiomatics with an epistemological analysis of the measurement of time and length. Consequently, Einstein may well have believed it necessary to prepare the reader of 1905 for the consequences of an axiomatic approach to electrodynamics via kinematics, by presenting in §2 an illustrative example of how an observer in one inertial reference system notes how observers in another inertial system check the synchronization of their clocks.

Einstein began §2 by restating the two postulates that he had proposed in the introductory section [§2, 1–12]:

> §2. *On the Relativity of Lengths and Times*

> The following considerations are based on the principle of relativity and on the principle of the constancy of the velocity of light. We define these two principles thus—
>
> 1. The laws by which the states of physical systems undergo changes are independent of whether these changes of state are referred to one or the other of two coordinate systems moving relatively to each other in uniform translational motion.
>
> 2. Any ray of light moves in the "resting" coordinate system with the definite velocity c, which is independent of whether the ray was emitted by a resting or by a moving body. Consequently,
>
> $$\text{velocity} = \frac{\text{light path}}{\text{time interval}}$$
>
> where time interval is to be understood in the sense of the definition in §1.
>
> [In 1905 Einstein used the terms postulate and principle interchangeably.]

Having in §1 broken the vicious circle in clock synchronization, Einstein could define the velocity of light as:

$$\text{“velocity} = \frac{\text{light path}}{\text{time interval}}\text{”} \tag{5.1}$$

where the light path need not be closed.

In fact, Einstein (1907e) rewrote Equation (5.1) as

$$c = r/(t_B - t_A) \tag{5.2}$$

where r is the distance between A and B and he prefaced Eq. (5.2) with the statement that c was a "universal constant." Einstein continued in (1907e): "It is by no means natural to expect that the hypothesis stated above, which we call the principle of the constancy of the velocity of light, should be actually satisfied in nature, yet—at least for a coordinate system of a certain state of motion—it is made likely by the confirmations which Lorentz's theory, that is based on the assumption of an absolutely resting ether, have obtained by experiment." Einstein's two footnotes to this passage stated that by "Lorentz's theory" he meant the one in the (1895), and in the second footnote he wrote: "In particular the fact that this theory [Lorentz's (1895)] of the dragging coefficient (Fizeau's experiment) is in agreement with the available data." Therefore, for Einstein, Lorentz's (1895) explanation of Fizeau's 1851 experiment furnished sufficient support for the "principle of the constancy of the velocity of light."

The universality of the second principle is perhaps clouded by Einstein's use in 1905 of the term "resting system": yet any inertial system can be the "resting system." Throughout the 1905 paper, Einstein referred to a particular inertial reference system K as the resting system in order to emphasize how, in a certain sense, the relativity theory was a generalization of Lorentz's electromagnetic theory in which K was the ether-fixed reference system. As Einstein (1907e) wrote, the special relativity theory "originally arose from the coalescence of H. A. Lorentz's theory and the principle of relativity [from mechanics]."

Einstein continued in the relativity paper [§2, 13–58] with an epistemological analysis, based upon in principle operational definitions, of the concepts of simultaneity and length as these quantities referred to observers in different inertial reference systems.

Using Einstein's notation from his §3, consider two inertial reference systems k and K, equipped with measuring rods and clocks that are synchronized according to the procedure in §1. Suppose that initially k and K are relatively at rest and are superposed, i.e., their x-, y-, and z-axes are aligned. Observers in k and K measure the length of a rod lying along their common x-axes by comparing it with identical measuring rods at relative rest, i.e., by a congruence measurement. Let this length be l. Then k is accelerated to a velocity v relative to K, and Einstein assumes that the rod's characteristics are unaffected by the sudden acceleration.

Einstein next presented two in-principle operational procedures, or *Gedanken* experiments, in which we could "imagine [the moving rod's] length to be determined." (1) When an observer resting in *k* determined the rod's length by a congruence measurement, "according to the principle of relativity," the result had to be l. The magnitude of any discrepancy would be a measure of violation of this principle. Einstein defined the length l as "the length of the rod in the moving system."[1] (2) An observer at rest in K also measured the rod's length. "At a definite time," i.e., instantaneously, the observer in K marked off on K's x-axis the positions of the moving rod's end points A and B. Einstein referred to this length as r_{AB}—"the length of the (moving) rod in the resting system." According to the "two principles" of Einstein's theory the lengths l and r_{AB} differ, although, as Einstein emphasized, "current kinematics tacitly assumes [them to be] precisely equal." The crux of the matter was that the high velocity of light led scientists to assume the equivalence of "these two operations" and so the moving rod in "geometrical respects could be perfectly represented by *the same* body *at rest* in a definite position." Here Einstein carefully, albeit implicity, differentiated between two different notions of a body's shape—the geometrical and what he referred to (1907e) as the "kinematical." The observer in k measures the geometrical shape, and the K-observer the kinematical shape; "current kinematics tacitly" assumed their equality.

"We imagine further," wrote Einstein in the relativity paper, that the clocks at A and B in k are always synchronized with those in K. Einstein then offered the following *Gedanken* experiment. "Imagine" that two observers in k at A and B check their clocks' synchronization, using the two-way, two-clock procedure from §1, and assume also that an observer in K monitors this operation with clocks that are synchronized with those at A and B in k. In consequence, the observer in K notes three events E_1, E_2 and E_3 on K's clocks: E_1—a ray of light leaves A when A coincides with the position of a clock in K at time t_A; E_2—after traveling the distance r_{AB} (relative to K) the ray is received at B when B coincides with a clock in K at time t_B; E_3—the ray returns to A after traveling the distance r_{AB} when A

coincides with the clock in K at time t'_A. (Einstein's footnote emphasized that the times discussed were always those in K.) Einstein's mathematical analysis relates E_1 with E_2, and E_3 with E_4 as follows:

$$c(t_B - t_A) = r_{AB} + v(t_B - t_A), \tag{5.3}$$

$$c(t'_A - t_B) = r_{AB} - v(t'_A - t_B), \tag{5.4}$$

and he used the second postulate for calculating the left-hand sides of Eqs. (5.3) and (5.4). From Eqs. (5.3) and (5.4) follow Einstein's results:

$$t_B - t_A = r_{AB}/(c - v), \tag{5.5}$$

$$t'_A - t_B = r_{AB}/(c + v). \tag{5.6}$$

Thus, if the clocks at A and B on the moving rod remain in synchrony with those in K, they are not synchronous to observers in k. Consequently, wrote Einstein, "we can attribute no ***absolute*** meaning to the concept of simultaneity"—simultaneity is a relative concept. Einstein continued by emphasizing a consequence of the relativity of simultaneity: two spatially separated events that are simultaneous in K are not simultaneous in k, which "is in motion relatively to" K.

If, for the purpose of defining time, terms of order v/c are neglected, i.e., c is considered to be much larger than every other velocity as the ether theorists assumed, then Eqs. (5.5) and (5.6) become equal and the clocks at A and B remain in synchrony.

As far as I know Einstein's demonstration in §2 of the relativity of simultaneity is rarely analyzed. Most likely the reason is that the relativistic transformation equations for the space and time coordinates provide the quickest means for deducing the properties of time and simultaneity in moving reference systems. But Einstein's purpose in §2 was essentially epistemological and he did not require excess mathematical baggage to make his point—that is, by referring all measured quantities to the "resting system" K, whose analogue in the ether-based theories satisfied a principle of relativity and a light axiom, Einstein analyzed the meaning of the time of two moving clocks A and B by exploring how observers in another inertial reference system measure the time for a to-and-fro light exchange between A and B.

But what about the relativity of lengths which Einstein signaled in the title to this §2? Perhaps Einstein wished the reader to deduce a rough version of this result, thereby also allowing the reader to be convinced that it followed from the relativity of simultaneity. For example, at this point in the relativity paper, the reader could have deduced the relativity of length as follows. The observer in k at A registers the time interval for light to traverse to-and-fro the rod of length l in k, $\Delta t' = t'_A - t_A$ as

$$\Delta t' = 2l/c. \tag{5.7}$$

From Eqs. (5.5) and (5.6) the observer in K registers the time interval as

$$\Delta t = 2r_{AB}/c(1 - v^2/c^2). \tag{5.8}$$

Comparing these two time intervals yields

$$\frac{\Delta t'}{\Delta t} = \frac{l(1 - v^2/c^2)}{r_{AB}}. \tag{5.9}$$

We cannot progress any further toward an exact result, however, without knowing how r_{AB} and l are related—that is, we need the transformation equations relating the space and time coordinates in k and K. Perhaps Einstein wanted the reader to realize from Eq. (5.9) that in a geometry where lengths were measured using light rays and where clocks were synchronized by exchanging light signals—and thus simultaneity was a relative notion (i.e., $\Delta t' \neq \Delta t$)—then r_{AB} could not equal l. Or perhaps Einstein was inviting the reader to substitute into Eq. (5.9) a mathematically equivalent result from Lorentz's electrodynamics—that is, $r_{AB} = l\sqrt{1 - v^2/c^2}$, the Lorentz contraction, thereby obtaining the result from Einstein's §4 for the relativity of time.

The notion of measuring lengths using light rays had been proposed before Einstein by A. A. Michelson (1881) and (1887), Lorentz [(1892b), (1895)] and Poincaré [(1905a), (1906)]. Lorentz and Poincaré had proposed, and then rejected, two methods for measuring the Lorentz contraction: (1) a congruence measurement, but the measuring rod would likewise undergo a contraction; (2) a light geometry using two transverse rods of equal length, but this was just another Michelson-Morley experiment. Einstein realized that unambiguous length measurement of moving objects using light rays had to be taken in combination with properly synchronized clocks. To this we add Einstein's insistence that the problem of determining changes of length should for the present be treated as a kinematical problem.

In summary, the far-reaching results of §2 were that there were no such notions as the true time or the true length of an object; rather these were relative concepts: for example, the length of the rod was either l or r_{AB}, depending upon the rod's motion relative to an inertial observer.

Footnote

1. Einstein (1921b) elaborated on the relativistic notion of congruence as follows: We make two "tracts," i.e., marks, on a practically rigid body. If the tracts on B were congruent with those on another practically rigid body A, when A and B were at relative rest, they would be congruent whenever A and B were brought together.

7

The Relativity of Length and Time

> *A priori* it is quite clear that we must learn something about the physical behaviour of measuring-rods and clocks from the equations of transformation, for the magnitudes x, y, z, t are nothing more nor less than the results of measurements obtainable by means of measuring-rods and clocks. If we had based our considerations on the Galilei transformation we should not have obtained a contraction of the rod as a consequence of its motion.
>
> *A. Einstein (1917a)*

Straightaway [§4, 1–2] Einstein emphasized the "physical meaning" of the results to follow: "Physical Meaning of the Equations Obtained Concerning Moving Rigid Bodies and Moving Clocks."

7.1 Moving Bodies: Einstein's Length Contraction

> [If] one should define as 'time' what Lorentz introduced as an auxiliary quantity, and called the local time [then] the hypothesis of H. A. Lorentz and Fitzgerald appears as a secondary consequence of the theory.
>
> *A. Einstein (1907e)*

Einstein quickly demonstrated that a body having a spherical shape relative to an observer in its rest system k, Eq. [§4.1], appeared to be an ellipsoid of revolution to an observer in K, Eq. [§4.2] [§4, 3–13]. Although the sphere's dimensions normal to its direction of motion remain unchanged, its dimension along the common direction of the x-axes of k and K "appears shortened in the ratio 1: $\sqrt{1 - v^2/c^2}$,

i.e., the greater the value of v, the greater the shortening"; consequently, length is a relative quantity.[1] The terseness of Einstein's derivation of the contraction of moving bodies was perhaps meant to demonstrate not only the power of his axiomatic method vis-à-vis Lorentz's in 1895 which required interlocking hypotheses and fictitious reference systems, but also to emphasize that the Lorentz contraction is a "secondary consequence of the theory." In addition, Einstein's derivation set the stage for §8 where he discusses the transformation properties of the energy of a light pulse.

As v approaches c the contraction in the direction of motion becomes more pronounced (from Eq. [§4.3] the semi-minor axis is $R\sqrt{1 - v^2/c^2}$). The ellipsoid gets flatter until when $v = c$ it appears to an observer in K as a plane perpendicular to the ξ-axis; nevertheless, to an observer in k the object remains a sphere as required by the principle of relativity. For $v > c$ the ellipsoid's semi-minor axis becomes imaginary, and so, as Einstein wrote, "our deliberations become meaningless."[2] (This was also Wien's (1904b) reason for c being the ultimate velocity, and from his readings in the *Annalen* Einstein could have been aware of speculations on hyperlight velocities, particularly the controversy between Abraham (1904b) and Wien (1904b).) Perhaps Einstein did not mention here that unphysical results ensue also for $v = c$ because this was obvious from the relativistic transformations of §3. This result may have provided further evidence for the impossibility of catching up with a point on a light wave, thereby viewing it as a standing wave. In (1917a) Einstein again demonstrated from the length contraction that the velocity of light in vacuum is the ultimate velocity, and he added (1917a)—

> Of course this feature of the velocity c as a limiting velocity also follows clearly from the equations of the Lorentz transformation, for these become meaningless if we choose values of v greater than c.

Einstein's statement supports my assertion above that certain results concerning $v \geq c$ were contained already in §3 of the 1905 relativity paper.[3] Einstein concluded his analysis of the shape of a moving body by asserting the reciprocity of length contraction.

Einstein's footnote to the passage under discussion ("That is, a body possessing spherical form when examined at rest.") refers to what in (1907e) he defined as the "geometrical shape"; he went on to define the shape measured by the observer in K as the "kinematical shape." Einstein's definitions served to emphasize that his length contraction differed fundamentally from Lorentz's which asserted that something happened to the rod in S_r, but compensating effects prevented the inertial observer from ascertaining changes in shape. Einstein's (1907e) derivation of the relativistic contraction exposed more clearly than the one in 1905, the relation between the relativities of length and time: In k there is a rod of length $\xi_2 - \xi_1 = l_0$. Two observers in K simultaneously, i.e., $t_1 = t_2$, mark on K's axis the rod's length as $x_2 - x_1 = l$. From Eq. (6.53) Einstein obtained $l = l_0\sqrt{1 - v^2/c^2}$.[4]

7.2 Moving Clocks: The Relativity of Time

Consider [§4, 20–48] that K's x-axis is lined with synchronized clocks, and at k's origin there is one clock. If the origins of k and K coincided at $t = \tau = 0$, then at a later time t the origin of k has moved a distance $x = vt$ relative to K's origin, and [see Eq. (6.52)] the clock at k's origin registers a time observed from K of

$$\tau = t\sqrt{1 - v^2/c^2} \tag{7.1}$$

where the quantity τ is the elapsed time on the clock at k's origin, and t is the time on a clock located at $x = vt$ on K's x-axis; consequently, the slowing down of a moving clock, i.e., time dilation, is measured by comparing one clock with at least two others. In order to emphasize the physical content of time dilation, Einstein rewrote the result as

$$\tau = t - (1 - \sqrt{1 - v^2/c^2})t, \tag{7.2}$$

so the time interval in k is thus slower than the one in K by an amount

$$(1 - \sqrt{1 - v^2/c^2}). \tag{7.3}$$

Expanding the square root in Eq. (7.3), and retaining terms up to second order in v/c, gives $\frac{1}{2}(v^2/c^2)t$. Thus, like length time too was a relative quantity which depended on only the magnitude of the relative velocity between two inertial reference systems. The relativity of time was a new result of Einstein's theory, and Einstein proceeded to investigate it further.

Suppose that separated clocks at A and B on K's x-axis are properly synchronized. Let the clock at A be instantaneously accelerated to the velocity v and transported over to B where it is instantaneously decelerated to rest.[5] A "peculiar consequence" of the prediction of the relativity of time is that the clocked moved from A to B is not synchronous with the one that remained at rest at position B: it is slower than the one at B by an amount of time $(1 - \sqrt{1 - v^2/c^2})$. This difference disposed of Poincaré's 1898 suggestion for synchronizing distant clocks by transporting a clock synchronous with a master clock. Einstein then took this "peculiar consequence" one step further by investigating the case in which the points A and B coincided, and their synchronized clocks C_1 and C_2 were side by side in K. Clock C_1 remains at rest but C_2 undergoes a round trip journey along the sides of a polygon. We may assume that C_2 moves in a succession of inertial reference systems $\mathrm{k}_1, \ldots, \mathrm{k}_n$, and may thus neglect the abrupt accelerations at each corner of the polygonal path when C_2 is transferred from one inertial system to another. Since each inertial system moves with velocity v relative to K, then Einstein claimed that when C_2 returned to K it lagged behind C_1 by the amount $(1 - \sqrt{1 - v^2/c^2})$, and he assumed the validity of this result when the polygon was replaced by a continuous curve. As an example, Einstein predicted that a clock placed at the equator ran slower than a clock placed at one of the poles. His extension to the case where C_2's trajectory was a continuous curve was unwarranted in 1905, but perhaps he considered that this case could always be treated as the limiting case of a many-sided polygon.[6] (Sommerfeld's footnote to this passage asserts that a pendulum-clock had to be excluded from the considerations of §4 because its oscillations are determined by gravity and hence cannot be discussed kinematically. See Appendix.)

Einstein's (1907e) discussion of time dilation did not contain any "peculiar consequences" because he proposed a real experiment, and not a *Gedanken* experiment, to verify the time dilation phenomenon. In 1907 Einstein went far beyond his intent in 1905 of basing relativity theory upon clocks and measuring rods taken as irreducible structures; now he defined a clock as any periodic process—for example, an atomic oscillator emitting a frequency ν_0 as measured in k. From Eq. (7.1) an observer in K measures the frequency

$$\nu = \nu_0\sqrt{1 - v^2/c^2}, \tag{7.4}$$

and Einstein wrote that "the equation [7.4] admits of a very interesting application" since Stark (1906) had observed a Doppler shift in the radiation emitted by canal rays. The "interesting application" of Eq. (7.4) was that it predicted a Doppler effect when the observer's line of sight was normal to the emitter's direction of motion, i.e., a transverse Doppler effect.[7] Einstein asserted that observation of this effect vindicated also time dilation because "we can consider the ion to be a clock." Lorentz's theory did not predict a transverse Doppler effect, although Einstein made no mention of this point (see Chapter 10).

Einstein's prediction was tested successfully in 1937 by two American physicists H. E. Ives and G. R. Stilwell, although Ives maintained that their research verified the "Larmor-Lorentz" theory (1938).[8]

7.3 On the Reciprocity of Relativistic Phenomena

> The behaviour of measuring rods and clocks in translational motion, when viewed superficially, gives rise to a *remarkable paradox* which on closer examination, however, vanishes (italics in original).
>
> *H. A. Lorentz (1910–1912)*

In his lectures at Leiden University (1910–1912) Lorentz analyzed two paradoxes rooted in inferring that the reciprocity of the relativistic contraction and time dilation were achieved merely by interchanging Greek and Roman letters, and replacing v with $-v$. After all, according to the relativity theory all effects were relative. Lorentz first discussed the length contraction.

Consider that the reference systems K and k are equipped with identical meter sticks of length l and are positioned on the systems' x-axes; Lorentz referred to these rods in k and K as 1 and 2, respectively. Rod 1, wrote Lorentz, "appears" to the K-observer to be smaller than the rod 2; rod 2 appears to the k-observer as smaller than rod 1. "But how," continued Lorentz, "can the rod 1 be shorter than and, at the same time, longer than rod 2?" There is no paradox here, rather, Lorentz

Accordingly, we wish to determine the relativistically invariant mass m_0 of the system S, and the velocity $\mathbf{v}_0$ relative to $\Sigma_{\mathbf{0}}$ of a fictitious inertial frame, called the center of momentum frame, relative to which the three-momentum of S vanishes.

Assuming that the four-momentum is additive, the sum of the four-momenta of the N particles of the system S gives the four-momentum $(m_0\gamma_{\mathbf{v}_0}, m_0\gamma_{\mathbf{v}_0}\mathbf{v}_0)^t$ of S. Accordingly,

$$\sum_{k=1}^{N} m_k \begin{pmatrix} \gamma_{\mathbf{v}_k} \\ \gamma_{\mathbf{v}_k}\mathbf{v}_k \end{pmatrix} = m_0 \begin{pmatrix} \gamma_{\mathbf{v}_0} \\ \gamma_{\mathbf{v}_0}\mathbf{v}_0 \end{pmatrix}, \tag{3.14}$$

where

(i) The invariant masses $m_k > 0$ and the velocities $\mathbf{v}_k \in \mathbb{R}_c^n$, $k = 1, \ldots, N$, relative to $\Sigma_{\mathbf{0}}$ of the constituent particles of S are given, while

(ii) The invariant mass m_0 of S and the velocity $\mathbf{v}_0$ of the center of momentum frame of S relative to $\Sigma_{\mathbf{0}}$ are to be determined uniquely by the *Resultant Relativistically Invariant Mass Theorem*, which is Theorem 3.2 in Sect. 3.4

If $m_0 > 0$ and $\mathbf{v}_0 \in \mathbb{R}_c^n$ that satisfy (3.14) exist then, as anticipated, the three-momentum of the system S relative to its center of momentum frame vanishes since, by (3.8) and (3.14), the four-momentum of S relative to its center of momentum frame is given by

$$\begin{aligned} L(\ominus\mathbf{v}_0)\sum_{k=1}^{N} m_k \begin{pmatrix} \gamma_{\mathbf{v}_k} \\ \gamma_{\mathbf{v}_k}\mathbf{v}_k \end{pmatrix} &= L(\ominus\mathbf{v}_0) m_0 \begin{pmatrix} \gamma_{\mathbf{v}_0} \\ \gamma_{\mathbf{v}_0}\mathbf{v}_0 \end{pmatrix} \\ &= m_0 \begin{pmatrix} \gamma_{\ominus\mathbf{v}_0\oplus\mathbf{v}_0} \\ \gamma_{\ominus\mathbf{v}_0\oplus\mathbf{v}_0}(\ominus\mathbf{v}_0\oplus\mathbf{v}_0) \end{pmatrix} = m_0 \begin{pmatrix} 1 \\ \mathbf{0} \end{pmatrix}, \end{aligned} \tag{3.15}$$

noting that $\gamma_{\ominus\mathbf{v}_0\oplus\mathbf{v}_0} = \gamma_{\mathbf{0}} = 1$.

3.4 The Resultant Relativistically Invariant Mass Theorem

Lemma 3.1 below presents an identity that we need for the proof of the *Resultant Relativistically Invariant Mass Theorem* 3.2.

Lemma 3.1 *Let N be any positive integer, and let $m_k \in \mathbb{R}$ and $\mathbf{v}_k \in \mathbb{R}_c^n$, $k = 1, \ldots, N$, be N real numbers and N points of an Einstein gyrogroup $\mathbb{R}_c^n = (\mathbb{R}_c^n, \oplus)$. Then*

$$\left(\sum_{k=1}^{N} m_k\gamma_{\mathbf{v}_k}\frac{\mathbf{v}_k}{c}\right)^2 = \left(\sum_{k=1}^{N} m_k\gamma_{\mathbf{v}_k}\right)^2 - \left\{\left(\sum_{k=1}^{N} m_k\right)^2 + 2\sum_{\substack{j,k=1\\ j<k}}^{h} m_j m_k(\gamma_{\ominus\mathbf{v}_j\oplus\mathbf{v}_k} - 1)\right\}. \tag{3.16}$$

Proof The proof is given by the following chain of equations, which are numbered for subsequent explanation:

$$
\begin{aligned}
&\left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \frac{\mathbf{v}_k}{c}\right)^2 \\
&\overbrace{=\!=}^{(1)} \sum_{k=1}^{N} m_k^2 \gamma_{\mathbf{v}_k}^2 \frac{\mathbf{v}_k^2}{c^2} + 2 \sum_{\substack{j,k=1\\ j<k}}^{h} m_j m_k \gamma_{\mathbf{v}_j} \gamma_{\mathbf{v}_k} \frac{\mathbf{v}_j \cdot \mathbf{v}_k}{c^2} \\

&\overbrace{=\!=}^{(5)} \left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\right)^2 - \left\{\left(\sum_{k=1}^{N} m_k\right)^2 + 2 \sum_{\substack{j,k=1\\ j<k}}^{h} m_j m_k (\gamma_{\ominus \mathbf{v}_j \oplus \mathbf{v}_k} - 1)\right\}. \qquad (3.17)
\end{aligned}
$$

The assumption $\mathbf{v}_k \in \mathbb{R}_c^n$ implies, by (1.3), p. 4, that all gamma factors in (3.16)–(3.17) are real and greater than 1. Derivation of the numbered equalities in (3.17) follows:

1. This equation is obtained by an expansion of the square of a sum of vectors in $\mathbb{R}^n$.
2. Follows from Item 1 by (1.9)–(1.10), p. 5.
3. Follows from Item 2 by an obvious expansion.
4. Follows from Item 3 by an expansion of the square of a sum of real numbers.
5. Follows from Item 4 by an expansion of another square of a sum of real numbers. □

Einstein velocity addition law (1.2), p. 4, admits the following theorem:

Theorem 3.2 (Resultant Relativistically Invariant Mass Theorem) *Let* $(\mathbb{R}_c^n, \oplus)$ *be an Einstein gyrogroup, and let* $m_k \in \mathbb{R}$ *and* $\mathbf{v}_k \in \mathbb{R}_c^n$, $k = 1, 2, \ldots, N$, *be* N *real* *numbers and N elements of* $\mathbb{R}_c^n$ *satisfying*

$$\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \neq 0. \tag{3.18}$$

Furthermore, let

$$\sum_{k=1}^{N} m_k \begin{pmatrix} \gamma_{\mathbf{v}_k} \\ \gamma_{\mathbf{v}_k} \mathbf{v}_k \end{pmatrix} = m_0 \begin{pmatrix} \gamma_{\mathbf{v}_0} \\ \gamma_{\mathbf{v}_0} \mathbf{v}_0 \end{pmatrix} \tag{3.19}$$

be an $(n+1)$*-vector equation for the two unknowns* $m_0 \in \mathbb{R}$ *and* $\mathbf{v}_0 \in \mathbb{R}^n$.

Then (3.19) *possesses a unique solution* $(m_0, \mathbf{v}_0)$, $m_0 \neq 0$, $\mathbf{v}_0 \in \mathbb{R}_c^n$, *satisfying the following three identities for all* $\mathbf{w} \in \mathbb{R}_c^n$ *(including, in particular, the interesting special case of* $\mathbf{w} = \mathbf{0}$*):*

$$\mathbf{w} \oplus \mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{w} \oplus \mathbf{v}_k} (\mathbf{w} \oplus \mathbf{v}_k)}{\sum_{k=1}^{N} m_k \gamma_{\mathbf{w} \oplus \mathbf{v}_k}}, \tag{3.20}$$

$$\gamma_{\mathbf{w} \oplus \mathbf{v}_0} = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{w} \oplus \mathbf{v}_k}}{m_0}, \tag{3.21}$$

$$\gamma_{\mathbf{w} \oplus \mathbf{v}_0} (\mathbf{w} \oplus \mathbf{v}_0) = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{w} \oplus \mathbf{v}_k} (\mathbf{w} \oplus \mathbf{v}_0)}{m_0}, \tag{3.22}$$

where

$$m_0 \ = \ \sqrt{\left(\sum_{k=1}^{N} m_k \right)^2 + 2 \sum_{\substack{j,k=1 \\ j<k}}^{N} m_j m_k (\gamma_{\ominus(\mathbf{w} \oplus \mathbf{v}_j) \oplus (\mathbf{w} \oplus \mathbf{v}_k)} - 1)}. \tag{3.23}$$

Proof Following (3.18), we assume, without loss of generality, that

$$\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} > 0 \tag{3.24}$$

(otherwise, we replace each m_k by $-m_k$, resulting in the replacement of m_0 by $-m_0$). Let us consider the following four equations, (3.25)–(3.28), which are specialized from (3.20)–(3.23) by taking $\mathbf{w} = \mathbf{0}$:

$$\mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \mathbf{v}_k}{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}}, \tag{3.25}$$

$$\gamma_{\mathbf{v}_0} = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}}{m_0}, \tag{3.26}$$

$$\gamma_{\mathbf{v}_0}\mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\mathbf{v}_0}{m_0}, \tag{3.27}$$

where

$$m_0 \;=\; \sqrt{\left(\sum_{k=1}^{N} m_k\right)^2 + 2\sum_{\substack{j,k=1\\ j<k}}^{N} m_j m_k (\gamma_{\ominus\mathbf{v}_j\oplus\mathbf{v}_k} - 1)}. \tag{3.28}$$

The proof of this theorem consists of two parts. In the first part of the proof, we show that if (3.19) for the unknowns $\mathbf{v}_0 \in \mathbb{R}^n$ and $m_0 \in \mathbb{R}$ possesses a solution, then the solution must be given uniquely by $\mathbf{v}_0$ of (3.25) and m_0 of (3.28), with $\mathbf{v}_0 \in \mathbb{R}^n_c$ and $m_0 > 0$, satisfying (3.26)–(3.27).

In the second part of the proof, we show that $\mathbf{v}_0$ of (3.25) and m_0 of (3.28), indeed, form a solution of (3.19) for the unknowns $\mathbf{v}_0 \in \mathbb{R}^n_c$ and $m_0 > 0$, and that the solution satisfies (3.20)–(3.23).

Part I In this part of the proof, we assume that there exist $m_0 \in \mathbb{R}$ and $\mathbf{v}_0 \in \mathbb{R}^n$ that satisfy (3.19). Then, the norms of the two sides of (3.19) are equal while, by (3.11), the norm of the right-hand side of (3.19) is m_0. Hence, the norm of the left-hand side of (3.19) equals m_0 as well, obtaining the following chain of equations, which are numbered for subsequent explanation:

$$\begin{aligned}
m_0^2 &\overbrace{=\!=}^{(1)} \left\| \sum_{k=1}^{N} m_k \begin{pmatrix} \gamma_{\mathbf{v}_k} \\ \gamma_{\mathbf{v}_k}\mathbf{v}_k \end{pmatrix} \right\|^2 \\
&\overbrace{=\!=}^{(2)} \left\| \begin{pmatrix} \sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \\ \sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\mathbf{v}_k \end{pmatrix} \right\|^2 \\
&\overbrace{=\!=}^{(3)} \left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\right)^2 - \left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\frac{\mathbf{v}_k}{c}\right)^2 \\
&\overbrace{=\!=}^{(4)} \left(\sum_{k=1}^{N} m_k\right)^2 + 2\sum_{\substack{j,k=1\\ j<k}}^{h} m_j m_k \gamma_{\ominus\mathbf{v}_j\oplus\mathbf{v}_k} - 1.
\end{aligned} \tag{3.29}$$

Derivation of the numbered equalities in (3.29) follows:

1. This equation follows from the result that the norm of the left-hand side of (3.19) equals the norm of the right-hand side of (3.19), the latter being m_0 by (3.11).
2. Follows from Item 1 by the common "four-vector" addition of $(n+1)$-vectors (where $n = 3$ in physical applications).
3. Follows from Item 2 by (3.10).
4. Follows from Item 3 by Identity (3.16) of Lemma 3.1.

It follows from the upper entry of (3.19), along with Assumption (3.24) that

$$m_0 > 0. \tag{3.30}$$

We thus obtained in (3.29) the desired equation, (3.28), for m_0.

Hence, if $m_0 \in \mathbb{R}$ and $\mathbf{v}_0 \in \mathbb{R}^n$ that satisfy (3.19) exist, m_0 is positive and must be given by (3.28). Clearly, $\mathbf{v}_0 \in \mathbb{R}_c^n$ since $\gamma_{\mathbf{v}_0}$ is real, as we see from (3.19).

By assumption, $\mathbf{v}_0$ satisfies (3.19). Equation (3.19) is equivalent to two equations, formed by the upper entry and by the lower entry of (3.19). Dividing the lower entry of (3.19) by its upper entry, noting that $m_0 \neq 0$ by (3.30), we obtain (3.25).

Similarly, dividing the upper entry of (3.19) by $m_0 > 0$ we obtain (3.26), and dividing the lower entry of (3.19) by $m_0 > 0$ we obtain (3.27).

Hence, if $m_0 \in \mathbb{R}$ and $\mathbf{v}_0 \in \mathbb{R}^n$ that satisfy (3.19) exist, then $m_0 > 0$, $\mathbf{v}_0 \in \mathbb{R}_c^n$, and they must be given by (3.28) and (3.25), and satisfy (3.26)–(3.27).

Part II In Part I, we have shown that if (3.19) possesses a solution for the unknowns $\mathbf{v}_0 \in \mathbb{R}^n$ and $m_0 \in \mathbb{R}$, then $\mathbf{v}_0 \in \mathbb{R}_c^n$ is given uniquely by (3.25) and $m_0 > 0$ is given uniquely by (3.28), satisfying (3.26)–(3.27). We will now show that, indeed, $\mathbf{v}_0 \in \mathbb{R}_c^n$, given by (3.25), and $m_0 > 0$, given by (3.28), form a solution of (3.19), and that the solution satisfies (3.20)–(3.23). Accordingly, in this second part of the proof we assume that $\mathbf{v}_0 \in \mathbb{R}_c^n$ and $m_0 > 0$ are given by (3.25) and (3.28), and we will prove that the pair $(m_0, \mathbf{v}_0)$ forms a solution of (3.19).

It follows from Identity (3.16) of Lemma 3.1, along with m_0 of (3.28) that

$$\left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \frac{\mathbf{v}_k}{c}\right)^2 = \left(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}\right)^2 - m_0^2. \tag{3.31}$$

Hence, by (3.25) and (3.31), we have the following chain of equations, which are numbered for subsequent explanation:

$$\begin{aligned}\frac{\mathbf{v}_0^2}{c^2} &\overbrace{=\!=}^{(1)} \frac{(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \frac{\mathbf{v}_k}{c})^2}{(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k})^2} \\ &\overbrace{=\!=}^{(2)} \frac{(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k})^2 - m_0^2}{(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k})^2} \\ &=\!= 1 - \frac{m_0^2}{(\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k})^2}.\end{aligned} \tag{3.32}$$

Derivation of the numbered equalities in (3.32) follows:

1. This equation is given by Assumption (3.25).
2. Follows from Item 1 by (3.31).

It follows from (3.32) that

$$\gamma_{\mathbf{v}_0} = \frac{1}{\sqrt{1-\frac{\mathbf{v}_0^2}{c^2}}} = \frac{\sum_{k=1}^N m_k \gamma_{\mathbf{v}_k}}{m_0}, \tag{3.33}$$

thus verifying (3.26).

Following (3.26) and (3.25), we have

$$\gamma_{\mathbf{v}_0}\mathbf{v}_0 = \frac{\sum_{k=1}^N m_k \gamma_{\mathbf{v}_k}\mathbf{v}_k}{m_0}, \tag{3.34}$$

thus verifying (3.27).

Finally, (3.33) implies that m_0 and $\mathbf{v}_0$ satisfy the upper entry of (3.19) and, similarly, (3.34) implies that m_0 and $\mathbf{v}_0$ satisfy the lower entry of (3.19). Hence, the pair consisting of m_0 and $\mathbf{v}_0$ forms a solution of (3.19). We have thus shown that $\mathbf{v}_0 \in \mathbb{R}_c^n$ and $m_0 > 0$ given by (3.25) and (3.28) form a solution of (3.19), and that this solution satisfies (3.26)–(3.28).

To complete the proof it remains to show that the pair $(m_0, \mathbf{v}_0)$ satisfies (3.20)–(3.23) as well.

Let us first show that m_0 given by (3.28) is given by (3.23) as well. Indeed, following (1.3), p. 4, (1.33), p. 10, and (1.65), p. 18, we have

$$\gamma_{\ominus(\mathbf{w}\oplus\mathbf{v}_j)\oplus(\mathbf{w}\oplus\mathbf{v}_k)} = \gamma_{\ominus\mathbf{v}_j\oplus\mathbf{v}_k}, \tag{3.35}$$

implying that the right-hand sides of (3.23) and (3.28) are equal, so that m_0 is independent of $\mathbf{w} \in \mathbb{R}_c^n$, as desired. As such, m_0 is given by each of (3.23) and (3.28).

We have thus shown that the unique solution of (3.19) is formed by $\mathbf{v}_0 \in \mathbb{R}_c^n$ and $m_0 > 0$ that are given by (3.25) and (3.28), and that the solution satisfies (3.26)–(3.27). It, therefore, remains to show that the solution satisfies (3.20)–(3.22) as well.

Applying the Lorentz boost $L(\mathbf{w})$, $\mathbf{w} \in \mathbb{R}_c^n$, to each side of (3.19), we have

$$L(\mathbf{w})\sum_{k=1}^N m_k \begin{pmatrix} \gamma_{\mathbf{v}_k} \\ \gamma_{\mathbf{v}_k}\mathbf{v}_k \end{pmatrix} = L(\mathbf{w}) m_0 \begin{pmatrix} \gamma_{\mathbf{v}_0} \\ \gamma_{\mathbf{v}_0}\mathbf{v}_0 \end{pmatrix}. \tag{3.36}$$

Following the linearity of the Lorentz boost, illustrated in (3.8) and (3.9), (3.36) can be written as

$$\sum_{k=1}^N m_k \begin{pmatrix} \gamma_{\mathbf{w}\oplus\mathbf{v}_k} \\ \gamma_{\mathbf{w}\oplus\mathbf{v}_k}(\mathbf{w}\oplus\mathbf{v}_k) \end{pmatrix} = m_0 \begin{pmatrix} \gamma_{\mathbf{w}\oplus\mathbf{v}_0} \\ \gamma_{\mathbf{w}\oplus\mathbf{v}_0}(\mathbf{w}\oplus\mathbf{v}_0\ ) \end{pmatrix}. \tag{3.37}$$

Equation (3.37) is identical with (3.19) in which $\mathbf{v}_k \in \mathbb{R}_c^n$ is replaced by $\mathbf{w}\oplus\mathbf{v}_k \in \mathbb{R}_c^n$, $k = 0, 1, \ldots, N$.

But, the unique solution of (3.19) is the pair $(m_0 > 0, \mathbf{v}_0 \in \mathbb{R}_c^n)$ that satisfies (3.25)–(3.28). Hence, the unique solution of (3.37) is the pair $(m_0 > 0, \mathbf{w}\oplus\mathbf{v}_0 \in \mathbb{R}_c^n)$

that satisfies (3.20)–(3.23). Hence, the unique solution ($m_0 > 0$, $\mathbf{v}_0 \in \mathbb{R}^n_c$) of (3.19) satisfies not only (3.25)–(3.28) but, more generally, (3.20)–(3.23), and the proof is complete. □

In physical applications to particle systems, the real numbers m_k in Theorem 3.2 represent particle masses. As such, they are positive so that Assumption (3.24) is satisfied. However, anticipating applications of Theorem 3.2 to barycentric coordinates in hyperbolic geometry, in Chap. 4, we need the validity of Theorem 3.2 for real numbers m_k that need not be positive as well.

We have thus established in Theorem 3.2 the following four results concerning an isolated system S, (3.12),

$$S = S(m_k, \mathbf{v}_k, \Sigma_{\mathbf{0}}, k = 1, \ldots, N) \tag{3.38}$$

of N noninteracting material particles the kth particle of which has invariant mass $m_k > 0$ and velocity $\mathbf{v}_k \in \mathbb{R}^n_c$ relative to an inertial frame $\Sigma_{\mathbf{0}}$, $k = 1, \ldots, N$:

1. The relativistically invariant (or, rest) mass m_0 of the system S is given by

$$m_0 = \sqrt{\left(\sum_{k=1}^{N} m_k\right)^2 + 2\sum_{\substack{j,k=1\\ j<k}}^{N} m_j m_k (\gamma_{\ominus\mathbf{v}_j \oplus \mathbf{v}_k} - 1)} \tag{3.39}$$

   according to (3.23) with $\mathbf{w} = \mathbf{0}$.
2. The relativistic mass of the system S is

$$m_0 \gamma_{\mathbf{v}_0} \tag{3.40}$$

   relative to the rest frame $\Sigma_{\mathbf{0}}$, where $\mathbf{v}_0$ is the velocity of the center of momentum frame of S relative to $\Sigma_{\mathbf{0}}$, given by

$$\mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} \mathbf{v}_k}{\sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k}} \tag{3.41}$$

   according to (3.20) with $\mathbf{w} = \mathbf{0}$.
3. Like energy and momentum, the relativistic mass is additive, that is, in particular for the system S relative to the rest frame $\Sigma_{\mathbf{0}}$, by (3.21) with $\mathbf{w} = \mathbf{0}$,

$$m_0 \gamma_{\mathbf{v}_0} = \sum_{k=1}^{N} m_k \gamma_{\mathbf{v}_k} . \tag{3.42}$$

4. The relativistic mass $m_0 \gamma_{\mathbf{v}_0}$ of a system meshes extraordinarily well with the Minkowskian four-vector formalism of special relativity. In particular, for the system S relative to the rest frame $\Sigma_{\mathbf{0}}$, we have, by (3.19),

$$\sum_{k=1}^{N} \begin{pmatrix} m_k \gamma_{\mathbf{v}_k} \\ m_k \gamma_{\mathbf{v}_k} \mathbf{v}_k \end{pmatrix} = \begin{pmatrix} m_0 \gamma_{\mathbf{v}_0} \\ m_0 \gamma_{\mathbf{v}_0} \mathbf{v}_0 \end{pmatrix}, \tag{3.43}$$

where m_0 and $\mathbf{v}_0$ are given uniquely by (3.39) and (3.41).

Thus, the relativistically invariant mass m_0 of a particle system S in (3.39) gives rise to its associated relativistic mass $m_0\gamma_{\mathbf{v}_0}$ relative to the rest frame $\Sigma_\mathbf{0}$. The latter, in turn, brings in (3.43) the concept of the relativistic mass into conformity with the Minkowskian four-vector formalism of special relativity. Moreover, we will see in Sects. 3.7 and 3.8 that the relativistically invariant mass m_0 of a particle system S provides a natural interpretation of observations in astrophysics and in particle physics.

To appreciate the power and elegance of Theorem 3.2 in relativistic mechanics in terms of novel analogies that it shares with familiar results in classical mechanics, we present below the classical counterpart, Theorem 3.3, of Theorem 3.2. The latter is obtained from the former by approaching the Newtonian limit when c tends to infinity. The resulting Theorem 3.3 is immediate, and its importance in classical mechanics is well-known.

Theorem 3.3 (Resultant Newtonian Invariant Mass Theorem) *Let* $(\mathbb{R}^n,+)$ *be a Euclidean* n*-space, and let* $m_k \in \mathbb{R}$ *and* $\mathbf{v}_k \in \mathbb{R}^n$, $k=1,2,\ldots,N$, *be* N *real numbers and* N *elements of* $\mathbb{R}^n$ *satisfying*

$$\sum_{k=1}^{N} m_k \neq 0. \tag{3.44}$$

Furthermore, let

$$\sum_{k=1}^{N} m_k \begin{pmatrix} 1 \\ \mathbf{v}_k \end{pmatrix} = m_0 \begin{pmatrix} 1 \\ \mathbf{v}_0 \end{pmatrix} \tag{3.45}$$

be an $(n+1)$*-vector equation for the two unknowns* $m_0 \in \mathbb{R}$ *and* $\mathbf{v}_0 \in \mathbb{R}^n$.

Then (3.45) *possesses a unique solution* $(m_0, \mathbf{v}_0)$, $m_0 \neq 0$, *satisfying the following equations for all* $\mathbf{w} \in \mathbb{R}^n$ *(including, in particular, the interesting special case of* $\mathbf{w}=\mathbf{0}$*):*

$$\mathbf{w}+\mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k(\mathbf{w}+\mathbf{v}_k)}{\sum_{k=1}^{N} m_k} \tag{3.46}$$

and

$$m_0 = \sum_{k=1}^{N} m_k. \tag{3.47}$$

Proof While the proof of Theorem 3.3 is trivial, our point is to present a proof that emphasizes how Theorem 3.3 is derived from Theorem 3.2. Indeed, in the limit as $c \to \infty$, the results of Theorem 3.2 tend to corresponding results of Theorem 3.3, noting that in this limit gamma factors tend to 1. Accordingly, Theorem 3.3 is a special case of Theorem 3.2 corresponding to $c=\infty$. □

In physical applications to particle systems, the real numbers m_k in Theorem 3.3 represent particle masses and, hence, they are positive. However, anticipating applications of Theorem 3.3 to barycentric coordinates in Euclidean geometry, in Chap. 4, we need the validity of Theorem 3.3 for real numbers m_k that need not be positive as well.

Identity (3.46) of Theorem 3.3 is immediate. Yet, it is geometrically important. The geometric importance of the validity of (3.46) for all $\mathbf{w} \in \mathbb{R}^n$ lies on its implication that the velocity $\mathbf{v}_0$ of the center of momentum frame of a particle system relative to a given inertial rest frame in classical mechanics is independent of the choice of the origin of the classical velocity space $\mathbb{R}^n$ with its underlying standard model of Euclidean geometry.

Unlike Identity (3.46) of Theorem 3.3, which is immediate, its counterpart in Theorem 3.2, Identity (3.20), is not immediate. Yet, in full analogy with Theorem 3.3, the validity of Identity (3.20) in Theorem 3.2 for all $\mathbf{w} \in \mathbb{R}_c^n$ is geometrically important. This geometric importance of Identity (3.20) lies on its implication that the velocity $\mathbf{v}_0$ of the center of momentum frame of a particle system relative to a given inertial rest frame in relativistic mechanics is independent of the choice of the origin of the relativistic velocity space $\mathbb{R}_c^n$ with its underlying Cartesian–Beltrami–Klein ball model of hyperbolic geometry.

3.5 Mass and Velocity of Particle Systems

In this section, we emphasize the analogies that the classical mass and velocity of a particle system share with their relativistic counterparts. Let

$$\begin{aligned} S_{newton} &= S_{newton}\big(m_k, \mathbf{v}_k \in \mathbb{R}^n, \Sigma_{\mathbf{0}}, k = 1, \ldots, N\big), \\ S_{einstein} &= S_{einstein}\big(m_k, \mathbf{v}_k \in \mathbb{R}_c^n, \Sigma_{\mathbf{0}}, k = 1, \ldots, N\big) \end{aligned} \tag{3.48}$$

be a Newtonian particle system and its corresponding Einsteinian particle system. Each of these is an isolated system of N noninteracting material particles the kth particle of which has invariant mass $m_k > 0$ and velocity $\mathbf{v}_k$ relative to a rest frame $\Sigma_{\mathbf{0}}$. These velocities are Newtonian, $\mathbf{v}_k \in \mathbb{R}^n$, for the Newtonian system S_{newton} and Einsteinian, $\mathbf{v}_k \in \mathbb{R}_c^n$, for the Einsteinian system $S_{einstein}$.

The mass m_0 in Identity (3.45) of Theorem 3.3 is the Newtonian mass of the Newtonian particle system S_{newton}. It is given by, (3.47),

$$m_0 = \sum_{k=1}^{N} m_k. \tag{3.49}$$

The velocity $\mathbf{v}_0 \in \mathbb{R}^n$ in Identity (3.45) is the Newtonian velocity of the center of momentum frame of the system S_{newton} relative to $\Sigma_{\mathbf{0}}$. It is given by (3.46) with $\mathbf{w} = \mathbf{0}$,

$$\mathbf{v}_0 = \frac{\sum_{k=1}^{N} m_k \mathbf{v}_k}{\sum_{k=1}^{N} m_k} \tag{3.50}$$

253. TEOREMA 67. "El perímetro de un polígono regular circunscrito de 2 n lados, es menor que el perímetro del polígono regular de n lados, circunscrito a la misma circunferencia.

HIPÓTESIS: $ABCD \cdots$ (Fig. 216) es un polígono regular de n lados circunscrito a la circunferencia O.

TESIS: $\overline{MN} + \overline{NO} + \overline{OP} + \overline{PQ} + \cdots \overline{AB} + \overline{BC} + \overline{CD} + \cdots.$

NOTA. **Las demostraciones de los teoremas 66 y 67, las dejamos al alumno. Recuerde que: "La menor distancia entre dos puntos, es el segmento que los une".**

254. LONGITUD DE LA CIRCUNFERENCIA.

Observemos que al duplicar el número de lados, el perímetro de un polígono regular inscrito en una circunferencia aumenta y el perímetro disminuye cuando el polígono es circunscrito.

Ejemplo. Sea el triángulo inscrito $\triangle ABC$ (Fig. 217) y el circunscrito $\triangle A'B'C'$ a la misma circunferencia.

El perímetro del triángulo inscrito P_3 es menor que el perímetro del triángulo circunscrito P'_3, es decir: $P_3 < P'_3$.
Si duplicamos el número de lados de ambos polígonos tendremos un hexágono inscrito y otro circunscrito y en ellos resultará:

$$P_6 < P'_6.$$

Nótese que P ha aumentado $(P_6 > P_3)$ y que P' ha disminuído $(P'_6 < P'_3)$. Esto, expresado matemáticamente y restando ordenadamente, sería:

$$\begin{array}{l} P'_3 > P'_6 \\ \underline{P_3 < P_6} \\ \therefore\ P'_3 = P_3 > P'_6 - P_6 \end{array}$$

Análogamente resultaría:

$$P'_6 - P_6 > P'_{12} - P_{12}$$
$$P'_{12} - P_{12} > P'_{24} - P_{24}$$
$$P'_{24} - P_{24} > P'_{48} - P_{48}, \text{ etc.}$$

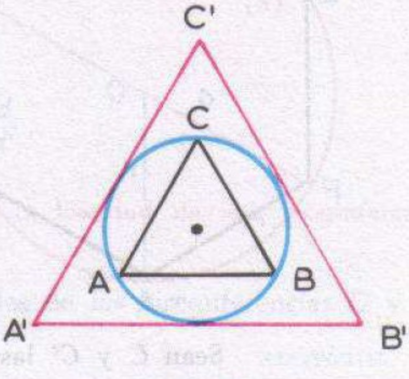

Fig 217

Es decir, a medida que se va duplicando el número de lados de los polígonos inscritos y circunscritos, la diferencia entre sus perímetros se va haciendo cada vez más pequeña, llegando a ser tan pequeña como se quiera.

Si el número de lados de estos polígonos continúa duplicándose indefinidamente, la diferencia entre ambos perímetros tiende a cero. En matemáticas se dice que ambas sucesiones P_3, P_6, P_{12} $\cdots$ y P'_3, P'_6, P'_{12} $\cdots$ de perímetros tienen un límite común el cual se llama *longitud de la circunferencia*.

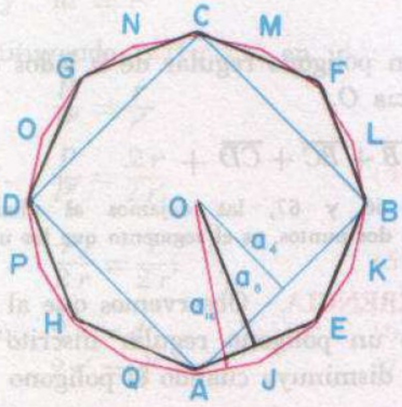

Fig. 218

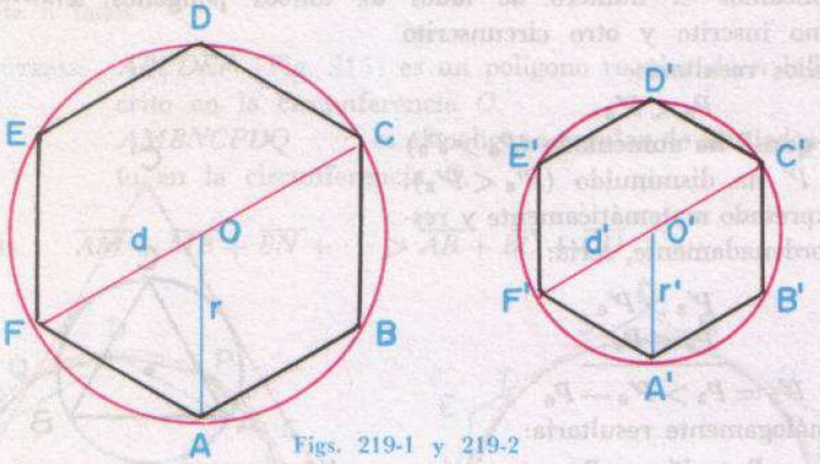
255. RELACION ENTRE LA APOTEMA Y EL RADIO Observemos (Fig. 218) que a medida que se duplica el número de lados de un polígono inscrito, la apotema se va haciendo cada vez mayor y acercándose indefinidamente al valor del radio. El radio del polígono no varía y siempre es igual al radio de la circunferencia circunscrita.

256. TEOREMA 68. PROPORCIONALIDAD ENTRE LAS LONGITUDES DE CIRCUNFERENCIAS Y SUS RADIOS O DIÁMETROS. **"La razón de las longitudes de dos circunferencias cualesquiera es igual a la razón de sus radios y de sus diámetros"**



Figs. 219-1 y 219-2

HIPÓTESIS: Sean C y C' las longitudes de las circunferencias O y O' (Fig. 219) de radios r y r' y diámetros d y d'.

TESIS: $\dfrac{C}{C'} = \dfrac{r}{r'} = \dfrac{d}{d'}$.

Construcción auxiliar. Inscribamos en cada una de esas dos circunferencias un polígono regular, ambos del mismo número de lados. Sean $ABCDEF$ y $A'B'C'D'E'F'$ esos polígonos y sean P y P' sus perímetros.

DEMOSTRACIÓN:

$\frac{P}{P'} = \frac{r}{r'}$ Porque la razón de los perímetros de dos polígonos regulares del mismo número de lados es igual a la razón de sus radios (por ser los polígonos semejantes).

$\frac{\text{lím } P}{\text{lím } P'} = \frac{r}{r'}$ (1) Porque la proporcionalidad anterior se cumple cualquiera que sea el número de lados del polígono.

Pero: $\text{lím } P = C$ (2)
y $\text{lím } P' = C'$ (3) Por definición de longitud de circunferencia.

Sustituyendo (2) y (3), en (1), tenemos:

$$\frac{C}{C'} = \frac{r}{r'} \qquad (4)$$

Multiplicando por 2, los dos términos de la 2ª razón:

$$\frac{C}{C'} = \frac{2r}{2r'} \qquad (5)$$

Pero: $2r = d$ (6)
y $2r' = d'$ (7)

Sustituyendo (6) y (7) en (5), tenemos:

$$\frac{C}{C'} = \frac{d}{d'} \qquad (8)$$

Comparando (4) y (8), tenemos:

$$\frac{C}{C'} = \frac{r}{r'} = \frac{d}{d'}.$$

257. COROLARIO. "La razón entre la longitud de una circunferencia y su diámetro, es una cantidad constante"

HIPÓTESIS: Sean C y C' las longitudes de las circunferencias O y O' de diámetros d y d'.

TESIS: $\frac{C}{d} = \frac{C'}{d'}$.

DEMOSTRACIÓN:

$\frac{C}{C'} = \frac{d}{d'}$ Teorema anterior;

$\therefore \frac{C}{d} = \frac{C'}{d'}$ Intercambiando los medios

258. EL NUMERO π. El valor constante de la razón de la longitud de una circunferencia a su diámetro, se representa por la letra griega π (pí). Es decir:

$$\frac{C}{d} = \pi.$$

Este número π, es un número irracional, es decir, no se puede expresar por ningún número entero o fraccionario. Se ha calculado con muchas cifras decimales y unos cuantos valores aproximados son los siguientes:

$$\pi = \frac{22}{7}$$
$$\pi = 3.14$$
$$\pi = 3.1416$$
$$\pi = \frac{355}{113}$$
$$\pi = 3{,}1415926535 \cdots$$

Generalmente se usa el valor 3.14 o 3.1416.

259. COROLARIO. "La longitud de una circunferencia es igual al duplo de π, multiplicado por el radio".

DEMOSTRACIÓN:

$\frac{C}{d} = \pi$ Por definición;

$\therefore \quad C = \pi d \qquad (1)$ Despejando C;

y como: $d = 2r \qquad (2)$ Definición;

sustituyendo (2) en (1), tenemos:

$$C = \pi(2r) \quad \therefore \quad C = 2\pi r.$$

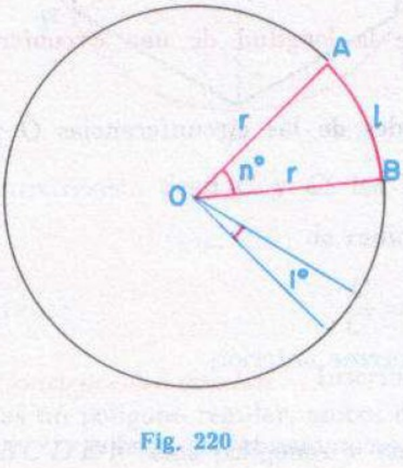


Fig. 220

260. CALCULO DE LA LONGITUD DE UNA CIRCUNFERENCIA.

Hallar la longitud de la circunferencia cuyo radio vale 6 cm.

Fórmula: $C = 2\pi r$

$$C = 2 \times 3.14 \times 6$$
$$C = 12 \times 3.14$$
$$C = 37.68 \text{ cm.}$$

261. LONGITUD DE UN ARCO DE CIRCUNFERENCIA DE $n°$. Si $C = 2\pi r$ es la longitud de la circunferencia (360°) la longitud del arco de 1° será $\frac{2\pi r}{360}$ porque 1° es $\frac{1}{360}$ de una circunferencia. (Fig. 220)

Y la longitud, l, de un arco de $n°$ será:

$$l = \frac{2\pi r n°}{360°}$$

$$\therefore \quad l = \frac{\pi r n°}{180°} \qquad \text{Simplificando.}$$

262. CALCULO DE VALORES APROXIMADOS DE π. Tomando $r = 1$, calculemos los perímetros de los hexágonos regulares inscrito y circunscrito.

INSCRITO. $r = 1,\ l_6 = r$ $\quad P_6 = 6\, l_6,$

$l_6 = 1 \quad \therefore\ P_6 = 6 \times 1 = 6.$

CIRCUNSCRITOS. $L_n = \frac{2\, r\, l_n}{\sqrt{4\, r^2 - l_n^2}}$

$$\therefore \quad L_6 = \frac{2 \times 1 \times 1}{\sqrt{4 \times 1^2 - 1^2}} = \frac{2}{\sqrt{3}} = \frac{2\sqrt{3}}{3} = 1.1547$$

$$\therefore \quad P' = 6\, L_6 = 6 \times 1.1547 = 6.9282$$

Valores aproximados de π:

$$\frac{P}{d} = \frac{6}{2} = 3 \quad \text{y} \quad \frac{P'}{d} = \frac{6.9282}{2} = 3.4641$$

Duplicando el número de lados de dichos polígonos, obtendríamos para el dodecágono:

Fórmula: $l_{2n} = \sqrt{2\, r^2 - r\sqrt{4\, r^2 - l_n^2}}$

$$l_{12} = \sqrt{2 \times 1^2 - 1\sqrt{4 \times 1^2 - 1^2}} = \sqrt{2 - \sqrt{4 - 1}}$$

$$= \sqrt{2 - \sqrt{3}} = \sqrt{2 - 1.7321} = \sqrt{0.2679}$$

$$= 0.5176.$$

$$\therefore \quad P_{12} = 12 \times 0.5176 = 6.2116.$$

Análogamente para el circunscrito, tendríamos:

$$P'_{12} = 12 \times L_{12} = 12 \times 0.5358 = 6.4307.$$

Valores aproximados de π:

$$\frac{P}{d} = \frac{6.2116}{2} = 3.1058 \quad \text{y} \quad \frac{P'}{d} = \frac{6.4307}{2} = 3.2153.$$

Continuando este proceso podríamos formar el siguiente cuadro:

Número de lados	POLIGONO INSCRITO			POLIGONO CIRCUNSCRITO		
	l_n	P	$\frac{P}{d}$	L_n	P'	$\frac{P'}{d}$
6	1	6	3	1.1547	6.9282	3.464
12	0.5176	6.2116	3.1058	0.5358	6.4307	3.2153
24	0.2610	6.2652	3.1326	0.2633	6.3193	3.1596
48	0.1308	6.2787	3.1393	0.1310	6.2921	3.1460
96	0.0654	6.2820	3.1410	0.0654	6.2854	3.1427
192	0.0327	6.2829	3.1414	0.0327	6.2837	3.1418
384	0.0163	6.2831	3.1415	0.0163	6.2833	3.1416
768	0.0081	6.2831	3.1415	0.0081	6.2832	3.1416

Las razones $\frac{P}{d}$ y $\frac{P'}{d}$ tienden al valor de π.

Comparando las tres primeras y tomando las cifras comunes, tenemos el valor $\pi = 3$.

Comparando las tres siguientes tenemos $\pi = 3.1$.

Comparando las razones correspondientes a los polígonos de 96 lados, obtenemos $\pi = 3.14$.

Continuando este proceso, podemos obtener el valor de π con la aproximación que se desee. Este método se conoce con el nombre de "*método de los perímetros*".

Como puede observarse, el método es muy laborioso.

263. METODO GRAFICO PARA RECTIFICAR APROXIMADAMENTE UNA CIRCUNFERENCIA. Rectificar una circunferencia es obtener un segmento rectilíneo cuya longitud sea igual a la de la curva.

1) Tracemos un diámetro $\overline{AB}$ (Fig. 221).

2) Por A, tracemos la tangente.

3) Sobre dicha tangente y a partir de A tomemos tres diámetros. Se obtiene el punto E.

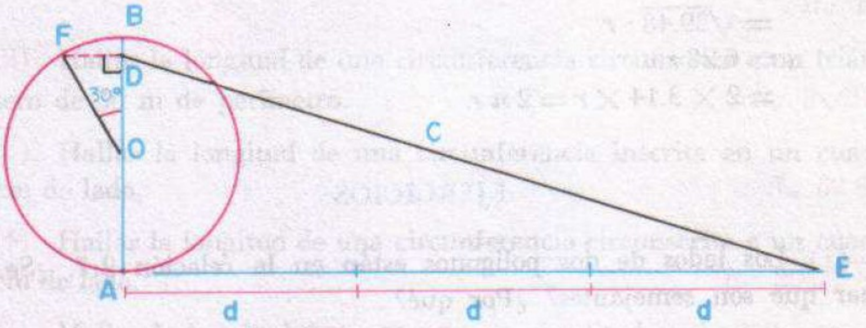

Fig 221

4) Tracemos $\angle BOF = 30°$.

5) Bajemos $\overline{FD} \perp \overline{OB}$.

6) Unamos D con E. $\overline{DE}$ es la solución del problema.

264 JUSTIFICACION DE LA CONSTRUCCION ANTERIOR.

En el $\triangle AED$:

$$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AD})^2 \qquad (1) \quad \text{Teorema de Pitágoras.}$$

Pero: $\overline{AD} = \overline{AO} + \overline{OD}$ (2) Suma de segmentos.

Sustituyendo (2) en (1), tenemos:

$$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AO} + \overline{OD})^2 \qquad (3)$$

Pero: $\overline{EA} = 3\,d = 6\,r$ (4) Construcción;

$\overline{AO} = r$ (5) Construcción.

$\overline{OD} = a_6 = \dfrac{r\sqrt{3}}{2}$ (6) Apotema de un hexágono inscrito; $\angle DOF = 30°$.

Sustituyendo (4), (5) y (6), en (3), tenemos:

$$\begin{aligned}(\overline{DE})^2 &= (6\,r)^2 + \left[r + \frac{r\sqrt{3}}{2}\right]^2 \\ &= 36\,r^2 + r^2 + r^2\sqrt{3} + \frac{3\,r^2}{4} \\ &= r^2\,(36 + 1)\,\sqrt{3} + \frac{3}{4} \qquad \text{Sacando } r^2 \text{ en factor común;} \\ &= r^2\,(36 + 1 + 1.73 + 0.75) \\ &= r^2\,(39.48) \\ &= 39.48\,r^2\end{aligned}$$

$$\begin{aligned}\therefore\quad \overline{DE}^2 &= \sqrt{39.48\,r^2}\\ &= \sqrt{39.48}\cdot r\\ &= 6.28\,r\\ &= 2\times 3.14\times r = 2\pi r.\end{aligned}$$

EJERCICIOS

(1) Los lados de dos polígonos están en la relación 2:7. ¿Se puede afirmar que son semejantes? ¿Por qué?

R.: No. Falta la igualdad de los ángulos.

(2) Dos eptágonos son equiángulos. ¿Se puede afirmar que son semejantes? ¿Por qué? *R.:* No. Falta la proporcionalidad de los lados.

(3) Dos rectángulos son semejantes. Los anchos respectivos son 16 y 24 metros y el primero tiene 30 m de largo. ¿Cuál es el largo del segundo?

R.: 45 m.

(4) Los lados de dos decágonos regulares miden 3 y 5 m. Hallar las razones de: *a*) sus lados; *b*) sus perímetros; *c*) sus radios; *d*) sus diámetros; *e*) sus apotemas. *R.:* $\frac{l}{l'}=\frac{P}{P'}=\frac{r}{r'}=\frac{d}{d'}=\frac{a}{a'}=\frac{3}{5}$.

(5) En una circunferencia de 10 m de diámetro, el lado del polígono regular de 48 lados, inscrito en la misma, mide 1.3 m. Calcular el lado de otro polígono regular del mismo número de lados, inscrito en una circunferencia de 12.5 m de radio. *R.:* 3.25 m.

(6) El perímetro de un polígono regular de 96 lados mide 31.2 m y su radio 10 m. Calcular el radio de otro polígono regular del mismo número de lados, si uno de estos lados mide 4.5 m. *R.:* 138.2 m.

(7) Hallar la longitud de una circunferencia cuyo radio mide 9 cm.

R.: 56.54 cm.

(8) Hallar la longitud de una circunferencia cuyo diámetro mide 15 cm.

R.: 47.12 cm.

(9) Hallar el radio de una circunferencia cuya longitud es 628 cm.

R.: 1 m.

(10) Hallar el diámetro de una circunferencia cuya longitud es 424 m.

R.: 134.96 m.

(11) Hallar el radio de una circunferencia cuya longitud es igual a la

264 JUSTIFICACION DE LA CONSTRUCCION ANTERIOR.

En el $\triangle AED$:

$$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AD})^2 \qquad (1) \quad \text{Teorema de Pitágoras.}$$

Pero: $\overline{AD} = \overline{AO} + \overline{OD}$ (2) Suma de segmentos.

Sustituyendo (2) en (1), tenemos:

$$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AO} + \overline{OD})^2 \qquad (3)$$

Pero: $\overline{EA} = 3\,d = 6\,r$ (4) Construcción;

$\overline{AO} = r$ (5) Construcción.

$\overline{OD} = a_6 = \dfrac{r\sqrt{3}}{2}$ (6) Apotema de un hexágono inscrito; $\angle DOF = 30°$.

Sustituyendo (4), (5) y (6), en (3), tenemos:

$$\begin{aligned}
(\overline{DE})^2 &= (6\,r)^2 + \left[r + \frac{r\sqrt{3}}{2}\right]^2 \\
&= 36\,r^2 + r^2 + r^2\sqrt{3} + \frac{3\,r^2}{4} \\
&= r^2\,(36+1)\sqrt{3} + \frac{3}{4} && \text{Sacando } r^2 \text{ en factor común;} \\
&= r^2\,(36 + 1 + 1.73 + 0.75) \\
&= r^2\,(39.48) \\
&= 39.48\,r^2
\end{aligned}$$

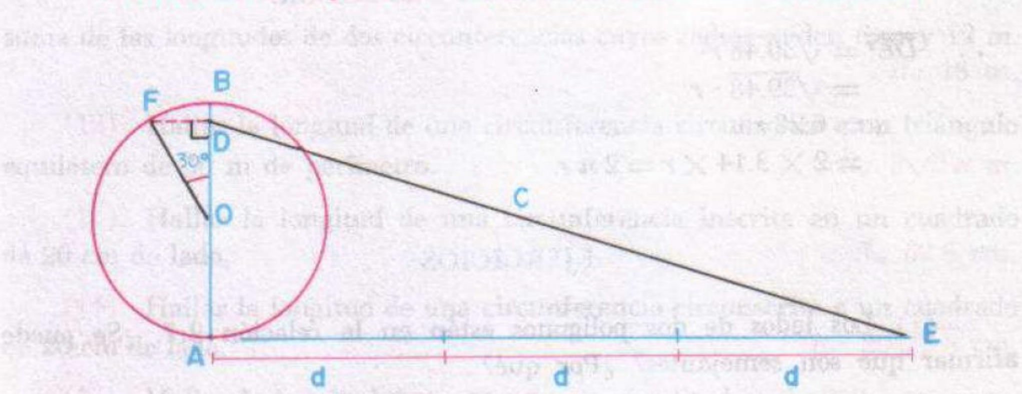

Fig. 221

4) Tracemos $\angle BOF = 30°$.

5) Bajemos $\overline{FD} \perp \overline{OB}$.

6) Unamos D con E. $\overline{DE}$ es la solución del problema.

264 JUSTIFICACION DE LA CONSTRUCCION ANTERIOR.

En el $\triangle AED$:

$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AD})^2$ (1) Teorema de Pitágoras.

Pero: $\overline{AD} = \overline{AO} + \overline{OD}$ (2) Suma de segmentos.

Sustituyendo (2) en (1), tenemos:

$(\overline{DE})^2 = (\overline{EA})^2 + (\overline{AO} + \overline{OD})^2$ (3)

Pero: $\overline{EA} = 3d = 6r$ (4) Construcción;

$\overline{AO} = r$ (5) Construcción.

$\overline{OD} = a_6 = \frac{r\sqrt{3}}{2}$ (6) Apotema de un hexágono inscrito; $\angle DOF = 30°$.

Sustituyendo (4), (5) y (6), en (3), tenemos:

$$
\begin{aligned}
(\overline{DE})^2 &= (6r)^2 + \left[r + \frac{r\sqrt{3}}{2} \right]^2 \\
&= 36r^2 + r^2 + r^2\sqrt{3} + \frac{3r^2}{4} \\
&= r^2 (36 + 1)\sqrt{3} + \frac{3}{4} \\
&= r^2 (36 + 1 + 1.73 + 0.75) \\
&= r^2 (39.48) \\
&= 39.48\, r^2
\end{aligned}
$$

Sacando r^2 en factor común;

$$\therefore \quad \overline{DE^2} = \sqrt{39.48\,r^2}$$
$$= \sqrt{39.48} \cdot r$$
$$= 6.28\,r$$
$$= 2 \times 3.14 \times r = 2\pi r.$$

PAPIRO DE RHIND. Centuria (18-16 a. d. C.) El documento egipcio más importante que se conoce es el Papiro de Rhind, atribuido a Ahmes, quien dejó sentado que el área del círculo (B) era casi 3 1/7 veces el área del cuadrado (A) que se trazara con su radio. Al llevar a la realidad las magistrales obras de las pirámides, es evidente que conocían los egipcios cómo trazar una perpendicular a una línea. Asimismo sabían hallar el área del cuadrado y el triángulo y el uso de la plomada.

1

Generalidades

1. EL METODO DEDUCTIVO. Es el usado en la ciencia y, principalmente, en la Geometría. Este método consiste en encadenar conocimientos que se suponen verdaderos de manera tal, que se obtienen nuevos conocimientos. Es decir, obtener nuevas proposiciones como consecuencia lógica de otras anteriores.

No todas las propiedades son consecuencia de otras. Hay algunas que se aceptan como ciertas por sí mismas: son los *axiomas y postulados*.

Hay además las definiciones que son proposiciones que exponen con claridad y precisión los caracteres de una cosa. Una característica de la Geometría moderna consiste en evitar la definición de conceptos primarios que tenían poco o ningún sentido. Así, por ejemplo, las definiciones tan conocidas de

Euclides: "Punto es lo que no tiene partes" "Línea es una longitud sin anchura", etc., se basan en conceptos (partes, anchura) cuya definición es más compleja que lo que se trata de definir.

2. AXIOMA. Es una proposición tan sencilla y evidente que se admite sin demostración.

Ejemplo. El todo es mayor que cualquiera de sus partes.

3. POSTULADO. Es una proposición no tan evidente como un axioma pero que también se admite sin demostración.

Ejemplo. Hay infinitos puntos.

4. TEOREMA. Es una proposición que puede ser demostrada. La demostración consta de un conjunto de razonamientos que conducen a la evidencia de la verdad de la proposición.

En el enunciado de todo teorema se distinguen dos partes: la hipótesis, que es lo que se supone, y la tesis que es lo que se quiere demostrar.

Ejemplo. La suma de los ángulos interiores de un triángulo vale dos rectos.

HIPÓTESIS. A, B y C son los ángulos interiores de un triángulo.

TESIS. La suma de los ángulos A, B y C vale dos rectos.

En la demostración se utilizan los conocimientos adquiridos hasta aquel momento, enlazados de una manera lógica.

5. COROLARIO. Es una proposición que se deduce de un teorema como consecuencia del mismo.

Ejemplo. Del teorema: La suma de los ángulos interiores de un triángulo es igual a dos rectos, se deduce el siguiente corolario: La suma de los ángulos agudos de un triángulo rectángulo vale un recto.

6. TEOREMA RECIPROCO. Todo teorema tiene su recíproco. La hipótesis y la tesis del recíproco son, respectivamente, la tesis y la hipótesis del otro teorema que, en este caso, se llama teorema directo.

Ejemplo. El recíproco del teorema: La suma de los ángulos interiores de un triángulo vale dos rectos dice: Si la suma de los ángulos interiores de un polígono vale dos rectos el polígono es un triángulo.

La hipótesis y la tesis del recíproco son:

HIPÓTESIS. Tenemos un polígono cuyos ángulos interiores suman dos rectos.

TESIS. El polígono es un triángulo.

No siempre los teoremas recíprocos son verdaderos. Así, por ejemplo, hay un teorema que dice: "Las diagonales de un cuadrado son iguales" y su recíproco dice: "Si las diagonales de un paralelogramo son iguales la figura es un cuadrado". Este recíproco es falso porque la figura puede ser un rectángulo que también tiene sus diagonales iguales.

7. LEMA. Es una proposición que sirve de base a la demostración de un teorema. Es como un "teorema preliminar" a otro que se considera más importante.

Ejemplo. Para demostrar el volumen de una pirámide se tiene que demostrar antes el lema que dice: "Un prisma triangular se puede descomponer en tres tetraedros equivalentes".

Actualmente se ha prescindido bastante del uso de la palabra lema y se le suele llamar teorema o bien teorema preliminar.

8. ESCOLIO. Es una observación que se hace sobre un teorema previamente demostrado.

Ejemplo. Después de demostrar el teorema que dice: **En una misma circunferencia o en circunferencias iguales a mayor arco corresponde mayor cuerda** (considerando arcos menores que una semicircunferencia), se podría añadir, como escolio: "**Si no se consideran arcos menores que una semicircunferencia, a mayor arco corresponde menor cuerda**".

Actualmente apenas se usa la palabra escolio para sustituto de observación.

9. PROBLEMA. Es una proposición en la que se pide construir una figura que reuna ciertas condiciones (los problemas gráficos) o bien calcular el valor de alguna magnitud geométrica (los problemas numéricos).

Ejemplo de problema gráfico. Construir la circunferencia que pasa por tres puntos dados.

Ejemplo de problema numérico. Calcular la altura de un triángulo equilátero cuyo lado mide 6 cm.

10. EL PUNTO. Ya hemos dicho que el punto no se define. La idea de punto está sugerida por la huella que deja en el papel un lápiz bien afilado.

Un punto geométrico es imaginado tan pequeño que carece de dimensión

Admitimos el siguiente postulado:

Hay infinitos puntos

Notación: Los puntos se suelen designar por letras mayúsculas y representar por un trazo, un circulito o una cruz. Así decimos el punto A; el punto B; etc. (Fig. 1).

Fig. 1

11. LA LINEA. Son tipos especiales de conjuntos de puntos. Entre los más notables están:

La *línea recta*. **Una imagen de este conjunto de puntos es un rayo luminoso, el borde de una regla, etc.**

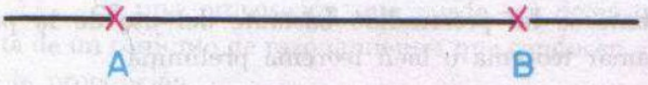

Fig. 2

Una recta geométrica se extiende sin límite en dos sentidos. No comienza ni termina. Admitimos los siguientes postulados:

Por dos puntos pasa una recta y solamente una.

Dos rectas no pueden tener más que un solo punto común.

La recta se suele designar por dos de sus puntos con el símbolo $\leftrightarrow$ encima. Así, la recta AB (Fig. 2) se representa $\overleftrightarrow{AB}$.

La línea curva. **Una imagen de línea curva es la circunferencia. Actualmente se considera que las líneas curvas pueden tener trazos rectos o no tenerlos (Fig 3).**

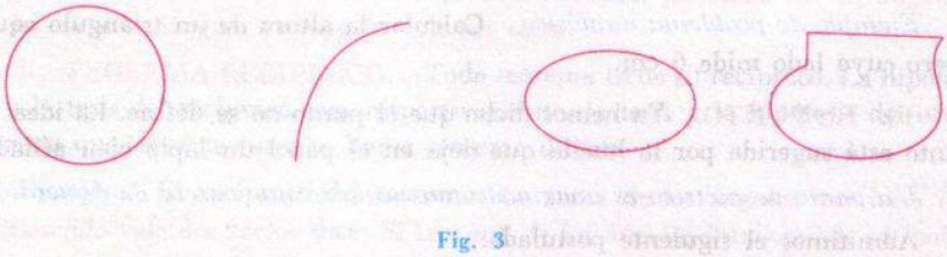

Fig. 3

Un tipo especial de curva es la línea quebrada, formada por trazos rectos. Al principio extraña llamar curva a una línea formada por trazos rectos, pero conviene acostumbrarse a esta nueva nomenclatura por la utilidad que tiene en estudios más avanzados.

Otro tipo especial de curva es la curva simple cerrada. Es la que se puede trazar de tal manera que empieza y termina en el mismo punto y éste es el único que se toca dos veces. Este tipo de curva tiene un interior y un exterior y admitimos el siguiente postulado:

Al unir un punto interior A con uno exterior B **(Fig. 4)** *de una curva simple cerrada se corta dicha curva.*

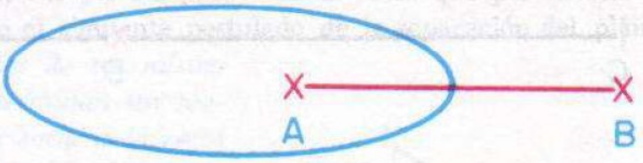

Fig. 4

Una línea tiene una sola dimensión: longitud.

12. CUERPOS FISICOS Y CUERPOS GEOMETRICOS. Son cuerpos físicos todas las cosas que nos rodean: libros, lápices, mesas, etc. Tienen forma, color, están hechos de una sustancia determinada y ocupan un lugar en el espacio.

Hay esquemas ideales de ciertos cuerpos físicos de los cuales la Geometría considera solamente su forma y su tamaño. Son los cuerpos geométricos o sólidos (Fig. 5)**. Son los prismas, conos, esferas, etc.**

Los sólidos tienen tres dimensiones: largo, ancho y alto.

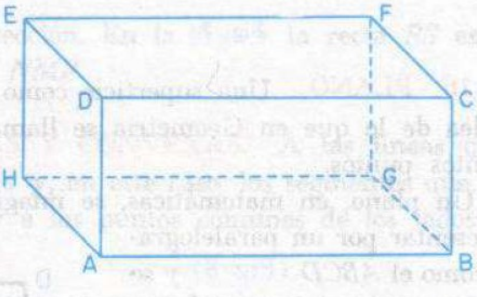

Fig. 5

13. SUPERFICIES. Son los límites que separan a los cuerpos del espacio que los rodea.

Las superficies tienen dos dimensiones: largo y ancho.

Ejemplo. ***ABCD* es una parte, llamada cara, de la superficie de la figura 5.**

14. SEMIRRECTA. Si sobre una recta señalamos un punto *A*, se llama semirrecta al conjunto de puntos formado por el *A* y todos los que le siguen

o todos los que le preceden. El punto A es el origen de la semirrecta.

Una semirrecta se suele representar por el origen y otro punto de ella, con el símbolo — encima.

Así, la semirrecta de origen C y otro punto D (Fig. 6) se representa por $\overrightarrow{CD}$.

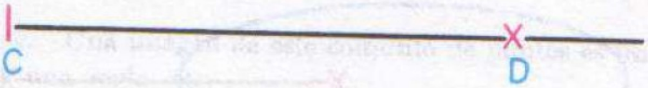

Fig. 6

15. SEGMENTO. Si sobre una recta señalamos dos puntos A y B, se llama segmento al conjunto de puntos comprendidos entre A y B más estos dos puntos que se llaman extremos del segmento. Generalmente al que se nombre en primer lugar se le llama origen y al otro, extremo.

Se admite el siguiente postulado:

La distancia más corta entre dos puntos es el segmento que los une.

Un segmento se designa por las letras de sus extremos y con un trazo encima.

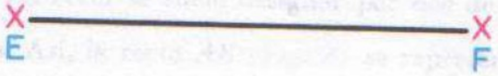

Fig. 7

Ejemplo. El segmento EF (Fig. 7) se representa así: $\overline{EF}$.

16. PLANO. Una superficie como una pared, el piso, etc., nos sugiere la idea de lo que en Geometría se llama plano. Son conjuntos parciales de infinitos puntos.

Un plano, en matemáticas, se imagina de extensión ilimitada. Se suele representar por un paralelogramo como el $ABCD$ (Fig 8) y se nombra por tres de sus puntos no alineados o por una letra griega. Así el plano de la Fig. 8 se nombra: plano ABC o bien plano α.

Dos propiedades características de los planos son las dadas por los siguientes postulados:

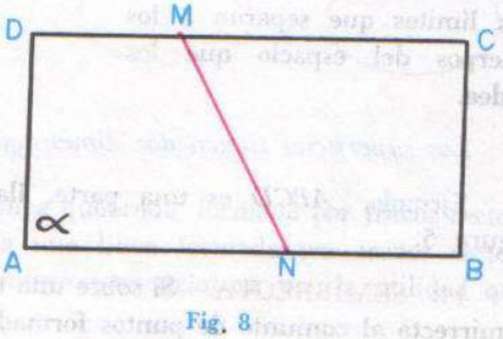

Fig. 8

Por tres puntos no alineados pasa un plano y solamente uno.

Si una recta tiene dos puntos comunes con un plano, toda la recta está contenida en el plano.

17. SEMIPLANO. Toda recta $\overleftrightarrow{MN}$ (Fig. 8) de un plano lo divide en dos regiones llamada semiplanos. Cada punto del plano pertenece a uno de los semiplanos, excepto los puntos de la recta que pertenecen a los dos.

Se admite el siguiente postulado de la separación del plano:

Dos puntos de un mismo semiplano determinan un segmento que no corta a la recta que da origen a los dos semiplanos; y dos puntos de distinto semiplano determinan un segmento que corta a la recta.

18. INTERSECCION DE PLANOS. Se admite el siguiente postulado:

Si dos planos tienen un punto común tienen una recta común.

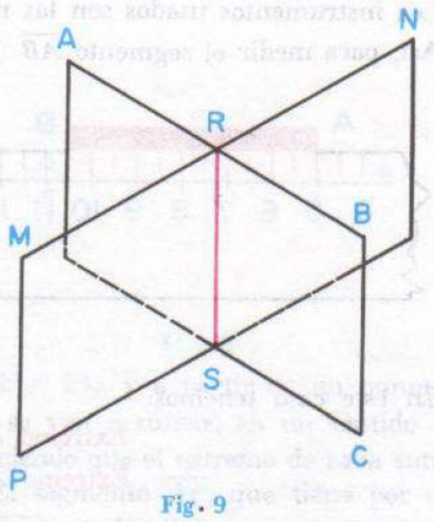

Fig. 9

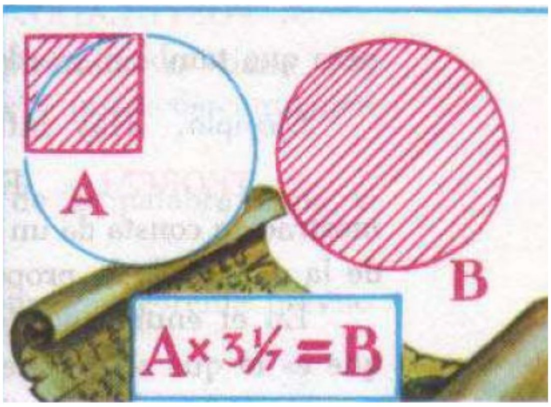
En este caso se dice que los dos planos se cortan y a la recta común se le llama recta de intersección. En la Fig. 9 la recta *RS* es la intersección de los dos planos *ABC* y *NMP*.

19. POLIGONALES CONCAVAS Y CONVEXAS. A las líneas quebradas se les llama también *poligonales* y, en este caso, los segmentos que las forman reciben el nombre de *lados* y a los puntos comunes de los lados se les llama *vértices*.

Una poligonal es convexa(Fig. 10-A) si al prolongar en los dos sentidos uno cualquiera de sus lados, toda la poligonal queda en un mismo semiplano.

Se llama poligonal cóncava(Fig. 10-B) si al prolongar en los dos sentidos alguno de sus lados, parte de la poligonal queda en un semiplano y parte en el otro.

20. MEDIDA DE SEGMENTOS. Medir un segmento es compararlo con otro elegido como unidad. Para este fin se usan las unidades de longitud del sistema métrico decimal, del sistema inglés o de cualquier otro sistema.



% / B

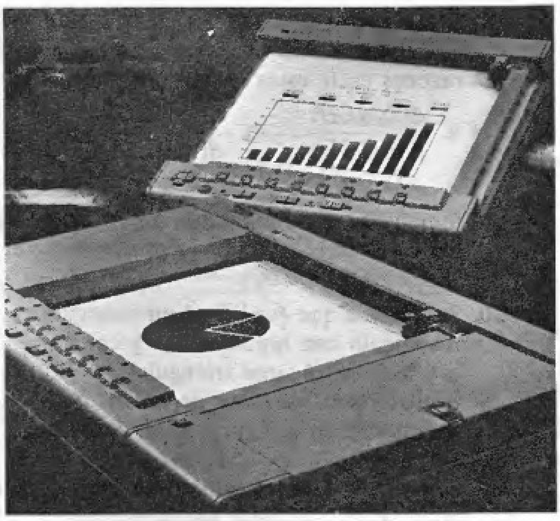
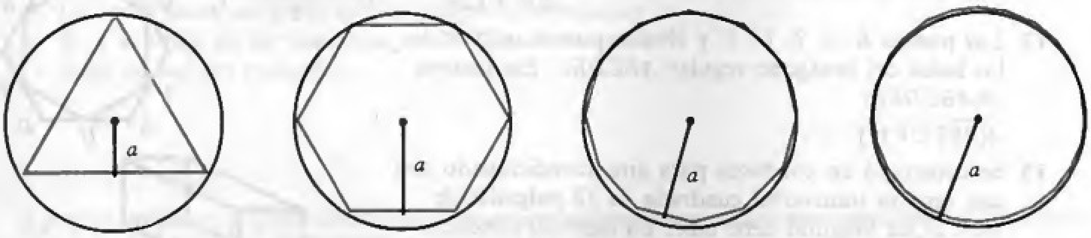
11.6 La razón entre la circunferencia y el diámetro de un círculo



En las gráficas por computador, la impresora dibuja algo que parecen ser líneas curvas. En realidad, la pluma del graficador dibuja segmentos sucesivos de recta tan cortos que el efecto final es una línea curva. Este mismo concepto se emplea para encontrar la circunferencia de un círculo.

Estas figuras muestran una secuencia de polígonos regulares que poco a poco se aproximan a un círculo.



Al incrementarse el número de lados de un polígono regular, poco a poco su forma se aproxima a la de un círculo circunscrito. Además, su perímetro se aproxima a un número fijo que recibe el nombre de *circunferencia* del círculo, y la apotema se acerca al radio del círculo circunscrito.

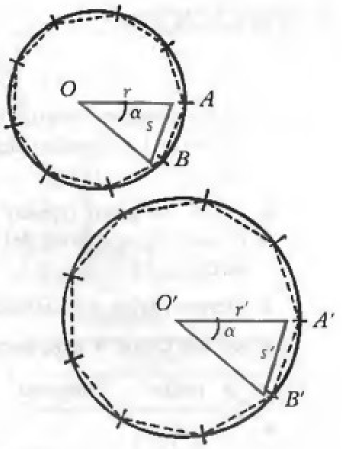
El siguiente teorema es básico para la teoría de los círculos.

Definición 11.6

La **circunferencia de un círculo** es el número al que se aproximan los perímetros de los polígonos regulares inscritos conforme se incrementa el número de lados de los polígonos regulares.

Teorema 11.8 La razón entre la circunferencia y el diámetro es la misma para todos los círculos.

EXPLICACION DE LA PRUEBA



1. Selecciónense dos círculos cualesquiera e inscríbase en ellos un polígono regular de n lados.
2. Un par de triángulos isósceles semejantes $\triangle AOB$ y $\triangle A'O'B'$ están determinados por un lado de cada polígono.
3. Por tanto, las razones $\frac{s}{r}$ y $\frac{s'}{r'}$ son iguales y $\frac{ns}{r} = \frac{n's'}{r'}$.
4. Los números ns y $n's'$ igualan los perímetros p y p' de los dos polígonos regulares. Por tanto,
$$\frac{p}{r} = \frac{p'}{r'}.$$
5. Al incrementarse el número de lados n, los perímetros p y p' se aproximan a las circunferencias C y C'. Por tanto,
$$\frac{C}{r} = \frac{C'}{r'} \text{ y } \frac{C}{2r} = \frac{C'}{2r'}.$$

La razón $\frac{C}{d}$ es un número irracional, lo que significa que no puede escribirse exactamente como un decimal. Algunas aproximaciones de este número son 3.14, $3\frac{1}{7}$ y 3.14159.

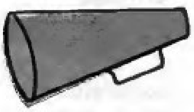
Definición 11.7

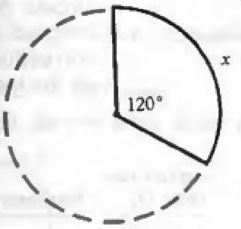
La **razón** $\frac{C}{d}$, que es el mismo número real para cualquier círculo, se representa por π (la letra griega pi).

Teorema 11.9 Dado un círculo de radio r y diámetro d, la circunferencia C está dada por la fórmula $C = \pi d = 2\pi r$.

APLICACION

El animador de un espectáculo quiere diseñar un modelo para un megáfono. Este diseño es una porción de un círculo limitado por un ángulo central y su arco interceptado. Si los lados del modelo tienen 15 pulgadas y el ángulo central mide 120°, encuéntrese la longitud del arco interceptado.





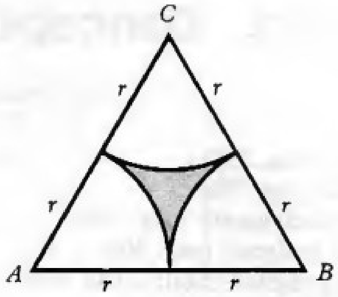
Solución. Puede establecerse una proporción entre la longitud del arco, la circunferencia del círculo, la medida del ángulo central y la medida en grados del círculo.

$$\frac{120}{360} = \frac{x}{\text{circunferencia}} = \frac{x}{2\pi 15}$$

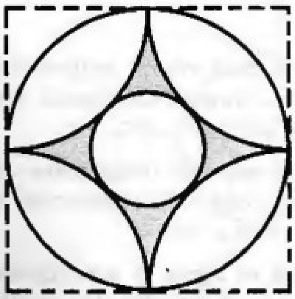
$$\frac{1}{3} = \frac{x}{30\pi \text{ pulgadas}} \quad \text{o} \quad x = 10\pi \doteq 31.4 \text{ pulgadas}$$

($ $!

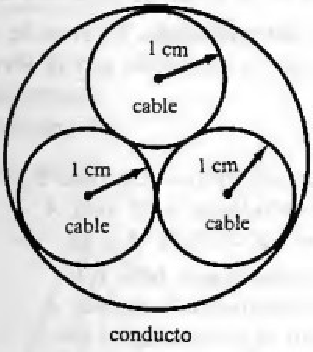
28. Si $\triangle ABC$ es un triángulo equilátero, ¿qué fracción del triángulo está sombreada?



29. En la figura siguiente, el círculo pequeño es tangente a cuatro arcos circulares. ¿Qué fracción del círculo grande está sombreada?



30. Los conductos de cables telefónicos están construidos para contener tres cables (todos circulares y tangentes al conducto y entre sí) de 1 cm de radio. ¿Qué fracción del conducto está ocupada por los cables?



SOLUCION DE PROBLEMAS

Los puntos A', B' y C' son puntos de trisección de los lados de $\triangle ABC$. El área de la región triangular sombreada es $\underline{?}$ del área de $\triangle ABC$.
Empléese una cuadrícula pequeña o alguna técnica de medición para determinar si la región blanca debe llenarse con la fracción $\frac{1}{5}$, $\frac{1}{6}$, $\frac{1}{7}$ ó $\frac{1}{8}$.

CHAPTER 17

3-D GEOMETRY

In This Chapter

- Overview
- 3-D Vectors
- Rendering
- Casting a Ray

Overview

Thus far, most of the discussion in this book has involved 2-D problems. While adding a third dimension is mostly just a matter of adding another number, doing so has many implications. For one thing, since your computer screen has two dimensions, not three, when you enter the third dimension, you must find some way to flatten the extra dimension back to a 2-D image. Further, objects in 3-D have sides that are visible and that occlude other sides. To understand how to work with such problems, in this chapter you'll start by looking at how 3-D space can be represented.

3-D Vectors

By now you are used to representing a point in 2-D space in terms of a pair of Cartesian coordinates measured along two dimensions (*x* and *y*) from a fixed origin. Adding the third dimension (*z*, for example) involves little more than adding a third number to a list.

Adding the Third Dimension

As with 2-D geometry, with 3-D geometry you start by creating a space. Creating a 3-D space involves defining three orthogonal (mutually perpendicular) axes and an origin. How you orient the axes is arbitrary. You can point your axes in any direction you like. It is conventional, however, to consider the x-axis as "left to right," the y-axis as "down to up" and the z-axis as "front to back." If you move down two units, right one unit and forward three units, your actions correspond to the vector $(1 - 23)^T$.

Note

One of the most common orientations of a 3-D space involves a *left-hand axis*. With the left-handed axes, imagine grasping the *z*-axis with your left hand, with the thumb pointing in the positive *z* direction. Your fingers curl around from the positive *x* to the positive *y* direction.

The three-dimensional vector is represented in the same way as the two-dimensional vector. You just add one more component. Most other aspects of vector geometry stay the same. In fact, there is only one addition, which will be discussed shortly. As an example of how 3-D vectors work, consider applying the Pythagorean Theorem. You represent the magnitude of a 3-D vector $(x \quad y \quad z)^T$ as $\sqrt{x^2 + y^2 + z^2}$. The dot product is given by multiplying three instead of two components pairwise:

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} \cdot \begin{pmatrix} d \\ e \\ f \end{pmatrix} = ad + be + cf$$

Just as in 2-D space, in 3-D space you can define a *line* by using a point with position vector **p** and a direction vector **v** so that every point on the line has position **p** + t**v** for some t. You can also define a *plane* in 3-D space in much the same way. As shown in figure 17.1, you might employ a point **p** and two non-collinear vectors **v** and **w**, so that each point on the plane is **p** + t**v** + s**w** for some s and t. Another approach is to choose a point **p** and a normal vector **n**. The vector **n** is perpendicular to all the vectors in the plane. While this second method is more efficient, it is less convenient for some calculations. For this reason, in some contexts in this and subsequent chapters, the first approach will be used.

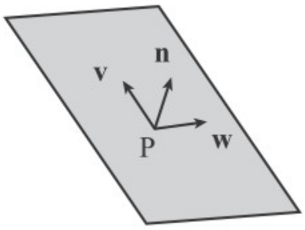

Figure 17.1
Defining a plane.

It's worth noting that the normal gives you a useful equation relating points on a plane. If the normal is $(a \quad b \quad c)^T$, then the points on the plane all conform to the equation $ax + by + cz = d$, where d is the perpendicular distance of the plane from the origin. This is the 3-D equivalent to the line equation $ay + bx = c$. In addition, note that if **n** is a unit vector and **p** is on the plane, then $d = \mathbf{p} \cdot \mathbf{n}$.

The Vector (Cross) Product

Dot products involving 3-D values work much the same way as 2-D dot products. However, when working in three dimensions, you have a new way to combine two vectors. This is known as the *vector product*, or more commonly the *cross product*. The vector or cross product is usually designated with a multiplication sign. For example, you represent the vector or cross product of the vectors **x** and **w** as $\mathbf{x} \times \mathbf{w}$. Unlike the dot product, which returns a scalar value, the cross product returns a vector. In other words given two vectors, the vector product returns a third vector that is perpendicular to the two vectors you have used in the product. The result is essentially the three-dimensional equivalent to the `normalVector()` function introduced in Chapter 5.

Calculating the vector product is a little more awkward than calculating the dot product. The formula for accomplishing this is as follows:

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} \times \begin{pmatrix} d \\ e \\ f \end{pmatrix} = \begin{pmatrix} bf - cd \\ cd - fa \\ ae - bd \end{pmatrix}$$

To remember the equation, one approach is to think of it as a determinant represented by a 3 × 3 matrix:

$$\begin{pmatrix} \mathbf{i} & \mathbf{j} & \mathbf{k} \\ a & b & c \\ d & e & f \end{pmatrix}$$

In this matrix, since **i**, **j**, **k** are the basis vectors $(1 \quad 0 \quad 0)^T$, $(0 \quad 1 \quad 0)^T$, and $(0 \quad 0 \quad 1)^T$, each element of the determinant corresponds to one component of the cross product vector. Given this understanding, you can then develop the `crossProduct()` function fairly readily:

```
function crossProduct(v1, v2)
   set x to v1[2]*v2[3]-v2[2]*v1[3]
   set y to v1[3]*v2[1]-v1[1]*v2[3]
   set z to v1[1]*v2[2]-v1[2]*v2[1]
   return vector(x,y,z)
end function
```

Here is a list of some of the most prominent features or properties of the cross product:

- The cross product is not commutative. In fact, $\mathbf{v} \times \mathbf{w} = -\mathbf{w} \times \mathbf{v}$. Nor is it associative. In general, $\mathbf{u} \times (\mathbf{v} \times \mathbf{w}) \neq (\mathbf{v} \times \mathbf{w}) \times \mathbf{w}$.
- The cross product is distributive over addition: $\mathbf{u} \times (\mathbf{v} + \mathbf{w}) = \mathbf{u} \times \mathbf{v} + \mathbf{u} \times \mathbf{w}$.
- The cross product of a vector with itself is the zero vector.
- If you take the scalar product with either of the two original vectors, if the two vectors are perpendicular, you get zero.
- If **v** and **w** are orthogonal unit vectors, the cross product is also a unit vector.
- Generally, if the angle between **v** and **w** is θ, then $|\mathbf{v} \times \mathbf{w}| = |\mathbf{v}|\,|\mathbf{w}| \sin \theta$.
- The magnitude of the cross product of two vectors is the area of the parallelogram whose sides are defined by the vectors. In other words, the area of the shape ABCD, where $\overrightarrow{AB} = \overrightarrow{DC} = \mathbf{v}$ and $\overrightarrow{BC} = \overrightarrow{AD} = \mathbf{w}$, equals $|\mathbf{v} \times \mathbf{w}|$.
- The direction of the cross product always follows the same handedness as the axes. Stated differently, if you rotate the space so that the input vectors are aligned as closely as possible to the *x*- and *y*-axes, the output vector is aligned in the positive *z*-direction. As long as your basis maintains the same handedness, the cross-product is independent of the basis.

Using the Cross Product

The cross product, like the dot product, is a useful way to *regularize* a situation. Regularization involves removing unnecessary elements. For example, suppose you have a plane for which you know the normal **n** but want to describe it instead by using two vectors on the plane. You can employ the cross product to do this. First, choose an arbitrary vector **w** that is not collinear with **n**. Next, take the cross product **w** × **n**. This gives a new vector **v** that is perpendicular to **n** (and also to **w**) and that therefore lies in the plane you are interested in. Finally, take the cross product again to get **u** = **v** × **n**. Taking the cross product gives a second vector perpendicular to **n**, which is also perpendicular to **v**.

Note

> When you work with 3-D calculations, it becomes difficult to remember the distinction between *position* and *direction* vectors. A position vector goes from the origin to a given point. Generally, a direction vector goes from a point established by a position vector to another point established by a position vector.

Another common use for the cross product is to find an *axis of rotation*. You'll look at this further later, but for now consider Figure 17.2. An arrow at **p** is pointing along the vector **v**, and you want it instead to point along the vector **w**. By finding the cross product **v** × **w**, you have a vector perpendicular to both. This serves as an axis of rotation. You can rotate the arrow around this vector to turn it in the right direction. What's more, by finding the dot product **v** × **w**, you can also calculate the angle of rotation.

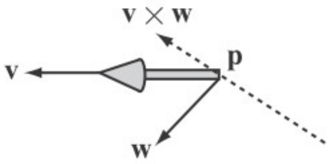

Figure 17.2

Using the vector and scalar products to calculate a rotation.

As a further exploration of the dot products, it's worth noting one more important calculation. This calculation involves the point of intersection of a line and a plane. Suppose you have a line defined by the point P and a vector **u**, and a plane defined by a point Q and a normal **n**. As illustrated by Figure 17.3, your objective is to know a value *t*, such that **p** + *t***u** lies on the plane.

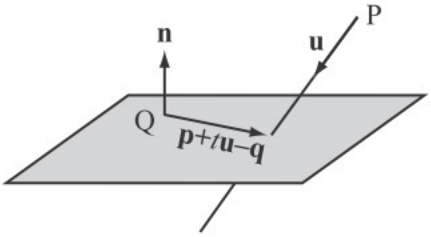

Figure 17.3

Finding the point of intersection of a line and a plane.

There are several ways to discover the value of t. One in particular keeps things simple. Notice that for any point **a** on the plane, **a** – **q** is perpendicular to **n**. In particular,

$$(\mathbf{p} + t\mathbf{u} - \mathbf{q}) \cdot \mathbf{n} = 0$$

Because the scalar product is associative, you can reason that $(\mathbf{p} - \mathbf{q}) \cdot \mathbf{n} = t\mathbf{u} \cdot \mathbf{n}$. As a result, can also reason that

$$t = \frac{(\mathbf{p} - \mathbf{q}) \cdot \mathbf{n}}{\mathbf{u} \cdot \mathbf{n}}$$

As you might expect, however, since there is no intersection between the line and plane, this approach fails when **u** and **n** are perpendicular. Otherwise, it is quick and reliable.

You can use a similar technique to find the line of intersection of two planes. Accordingly, if two planes are represented by the points **p** and **q** and the normals **n** and **m**, respectively, then as shown in Figure 17.4, your objective is to find the line that lies on both planes.

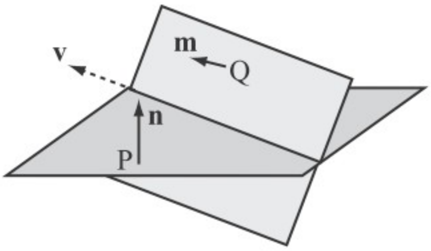

Figure 17.4

The line of intersection of two planes.

To find the line, first notice that since this line lies on both planes, it must be perpendicular to both **n** and **m**. Given that it is perpendicular, you can find its direction vector **v** as **n** × **m**. Having gone this far, you now need only to find a single point on the line. To find this point, you apply the previous result. You choose an arbitrary vector in the first plane (a good choice is **n** × **v**) and see where the line through **p** along this vector intersects the second plane. The `linePlaneIntersection()` and `planePlaneIntersection()` functions encapsulate these activities. Interactions of lines and planes are attended to by the first function:

```
function linePlaneIntersection(linePt, lineVect, planePt, planeNormal)
   set d to dotProduct(lineVect,planeNormal)
   if d=0 then return "no intersection"
   set v to linePt-planePt
   return dotProduct(v,planeNormal)/d
end function
```

The second function attends to intersections of planes:

```
function planePlaneIntersection (pt1, normal1, pt2, normal2)
   set v to crossProduct(normal1,normal2)
   set u to crossProduct(normal1, v)
   set p to linePlaneIntersection(pt1, u, pt2, normal2)
   if p="no intersection" then return p
   return array(p,v)
end function
```

Homogeneous Coordinates

Although you need only three coordinates to represent 3-D space, in practice you often use four. There are a number of reasons for this, and discussion of these reasons will be presented in Chapter 18. However, for now, consider that in addition to the *x*, *y*, and *z* coordinates, you add one more, usually designated as *w*. The result is a four-dimensional vector. This vector follows the rules that have been reviewed for two- and three-dimensional vectors.

While adding a fourth coordinate value might seem arbitrary and confusing, the w-coordinate comes in very handy in a number of instances. The w-coordinate is referred to as a *homogeneous coordinate*. The term *homogeneous* means something like "having a similar dimension." For a position vector, w is set to 1. For a direction vector, w it is 0. To see how this works out, consider the following equation:

$$\begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} - \begin{pmatrix} a \\ b \\ c \\ 1 \end{pmatrix} = \begin{pmatrix} x-a \\ y-b \\ z-c \\ 0 \end{pmatrix}$$

The vector from one position vector to another should have a zero w-component. However, at this point, it is not important to emphasize this point too strongly. As becomes clear upon further study, vector addition with homogeneous coordinates is not quite the same as vector addition using only normal coordinates.

Still, to understand the purpose of homogeneous coordinates in 3-D calculations, it's helpful to briefly draw from a discussion of two-dimensional activities. As shown by Figure 17.5, a two-dimensional plane is defined using axes x' and y'. The plane is placed in a three-dimensional space with axes x, y, and w, and it coincides with the $w = 1$ plane. As a result, any point (x', y') in the plane coincides with a point $(x, y, 1)$ in the 3-D space.

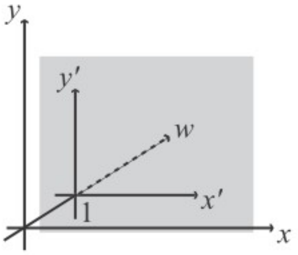

Figure 17.5

Homogeneous coordinates in 2-D.

However, it's not just points on the plane that you can map to the 2-D space. You can also compress the whole of the 3-D space onto the plane by a process of projection. As shown by Figure 17.6, for any point P, you draw a line from the 3-D origin through P and find its point of intersection with the plane.

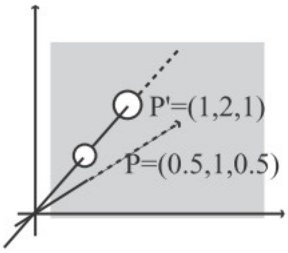

Figure 17.6

Projecting 3-D homogeneous space to the plane.

You can even do this with homogeneous points that have $w = 0$. Although the line OP is parallel to the plane, you still say that it intersects the plane "at infinity." In other words, it intersects the plane infinitely far along the line on the plane parallel to OP. In all other cases, the point on the plane that corresponds to (x, y, w) is $\left(\frac{x}{w}, \frac{y}{w}\right)$. In the strictest sense, in fact, there is no difference between the homogeneous points (x, y, w) and $\left(\frac{x}{w}, \frac{y}{w}, 1\right)$. Mathematically, they are considered to be equal. The outcome is that homogeneous coordinates are scale-invariant. If you multiply them by a constant factor, they remain the same.

As an introduction to using homogeneous coordinates, look again at the problem of finding the point of intersection of two lines in 2-D. The line through (a, b) with a vector $\begin{pmatrix} p \\ q \end{pmatrix}$ can be represented by the equations

$$a + tp = x$$

$$b + tq = y$$

which give

$$\frac{x-a}{p} = \frac{y-b}{q}$$

$$qx - py - aq + bp = 0$$

In general, a line in 2-D can be represented as $ax + by + c = 0$. Using homogeneous coordinates, this is expressed as $ax + by + cw = 0$. Comparing these two forms of expression, you can see that a line in 2-D corresponds to a plane in homogeneous coordinate space. If you represent two lines in this way, you can find their point of intersection using this approach:

$$ax + by + cw = 0$$

$$px + qy + rw = 0$$

$$\frac{x}{w} = \frac{br - cq}{aq - bp}$$

$$\frac{y}{w} = \frac{cp - ar}{aq - bp}$$

From these operations, you end up with the homogeneous coordinates ($br - cq$, $cp - ar$, $aq - bp$). Notice that if $aq - bp = 0$, then the two lines are parallel. One resulting observation is that while in standard coordinates there is no solution to the equation, in homogeneous coordinates the two lines meet at a point at infinity with $w = 0$. Further, the position vector of this point is given by the cross product

$$\begin{pmatrix} a \\ b \\ c \end{pmatrix} \times \begin{pmatrix} p \\ q \\ r \end{pmatrix}$$

The cross product makes sense when you consider that since the two vectors give the normals of the planes in 3-D space, their cross product gives the intersection of the planes. The intersection of the planes corresponds to the intersection of the 2-D lines.

Homogeneous coordinates will be addressed again in the next chapter, where attention is given to how they can be applied in 3-D. Still, it is beneficial to keep them in mind as you read the next section, where I'll discuss the projection plane for 3-D rendering. The two are closely related.

Rendering

The process of translating a 3-D scene into a 2-D picture is called *rendering*. While this is a complex process that you'll return to at a later stage, at this point, it is worthwhile to consider a few preliminaries, some of which involve the physical media through which rendering is accomplished.

The Projection Plane

With respect to projection planes, it is helpful first to consider how your eyes receive light reflected from the objects around them. Since light rays travel in a straight line, if you draw a line from your eye out into the world, what you see is the first thing in line with your eye, and your field of vision encompasses anything taken in by the lines coming from you within a particular angle from your eye.

To consider this in light of what happens in the construction of a 3-D world, imagine an observer standing still and looking straight ahead. The world visible to the observer, from the area straight ahead to the peripheral regions on the sides and top and bottom, constitutes the view *frustum*, as shown in Figure 17.7. The frustum is cut or intersected by different *viewing* or *projection planes*. Figure 17.7 shows two planes, the near plane and the far plane.

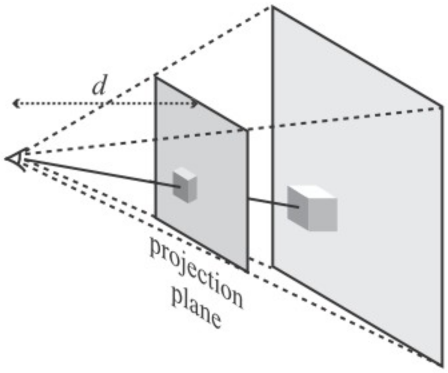

Figure 17.7
The field of view and the view frustum.

Note

> One of the difficulties in describing 3-D geometry is drawing clear diagrams on a 2-D page. Figure 17.7 shows a 3-D cube transformed into a 2-D picture on the projection plane.

The planes in the frustum are the primary devices used to translate a 3-D into a 2-D image. Referring to Figure 17.7, imagine that an observer is viewing the 3-D world as shown by the projection plane at some distance *d*. To work out what is to be found at each point of the plane, you can draw a line from the observer and see what it hits. This is called *raytracing*. For real-time animation, you can calculate where in the space each object is, draw a line to the observer, and see where this line intersects the plane. The precise situation is complicated by lights and texturing, but this is the essential principle.

As illustrated by Figure 17.8, to find the point on the projection plane that corresponds to a particular point in space, assume that the observer is facing in the direction **n**. The point you are interested in is at point **p**. Likewise, assume that the projection plane is at a perpendicular distance *d* from the observer, who is at the point **o**.

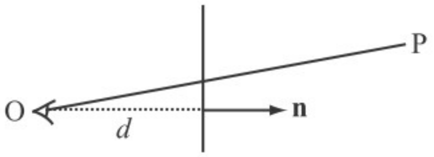

Figure 17.8

Projecting a point to the projection plane.

Figure 17.8 represents a cross-section, and in it a line is drawn from the point at P to the observer. This line passes through the projection plane at some unknown point. The situation depicted, then, is nearly the same as what is represented by Figure 17.7.

In mathematical terms, the plane normal of Figure 17.8 is the same as the direction the observer is facing. You can find a reference point on the plane drawn at the center of the screen as $\mathbf{o} + d\mathbf{n}$, assuming $\mathbf{n}$ is normalized. So the point on the projection plane corresponding to P is given by the intersection of the line starting at P in the direction $\mathbf{o} - \mathbf{p}$ with this plane, which is the point $\mathbf{p} + t(\mathbf{o} - \mathbf{p})$, where

$$t = \frac{(\mathbf{p} - (\mathbf{o} + d\mathbf{n})) \cdot \mathbf{n}}{(\mathbf{o} - \mathbf{p}) \cdot \mathbf{n}} = -d\frac{\mathbf{n} \cdot \mathbf{n}}{(\mathbf{o} - \mathbf{p}) \cdot \mathbf{n}} - 1 = \frac{d}{(\mathbf{p} - \mathbf{o}) \cdot \mathbf{n}} - 1$$

Note that since $\mathbf{n}$ is normalized, $\mathbf{n} \cdot \mathbf{n} = 1$.

Having calculated what the projection plane looks like, you can now draw its contents at the correct size on the computer screen, called a *viewport*. There are a number of different ways you can do this. One way involves specifying the scale. For example, you might determine that one unit of the projection plane corresponds to one pixel on the screen. As shown in Figure 17.9, more commonly you specify the viewport by giving one of the maximum angles in the field of view of the observer, such as the angle θ. In some instances, the whole field of view angle, given by 2θ, is specified.

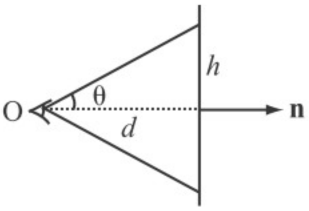

Figure 17.9

Specifying the field of view.

Since you know that $\tan\theta = \frac{h}{d}$, you also know the height of the topmost point on the projection plane. This then becomes a scale for drawing to the screen.

This approach to calculation, however, can become highly overcomplicated, since you don't need the value of d. All you actually need to know is the size of the picture on the screen and the angle of the field of view. To make the figures come out correctly, you can then set your projection screen at the appropriate place. Then you simply need to use similar triangles.

You can calculate the distance of the point from the observer along the camera vector to be $(\mathbf{p} - \mathbf{o}) \cdot \mathbf{n}$ and its vertical displacement as $(\mathbf{p} - \mathbf{o}) \cdot \mathbf{u}$, where $\mathbf{u}$ is the "up" vector of the camera. If the projection plane is to have a height of h, then you must also have that $d = \frac{h}{\tan\theta}$, so the height of the point as projected onto the screen is given by $\frac{h_{\max} \cdot (\mathbf{p} - \mathbf{o}) \cdot \mathbf{u}}{\tan\theta (\mathbf{p} - \mathbf{o}) \cdot \mathbf{n}}$. Here's a function that draws together some of the previous observations, translating a point in space to a point on the screen. As arguments, the `pos3DToScreenPos()` function takes the observer position and normal, the vertical field of view angle, the height of the screen, and the up-vector of the observer.

```
function pos3DToScreenPos(pt, observerPos, observerVect,
                          observerUp, fov, h)
   set observerRight to crossProduct(observerUp, observerVect)
   set v to pt-observerPos
   set z to dotProduct(v,observerVect)
   set d to h * tan(fov)
   set x to d*dotProduct(v,observerRight)/z
   set y to d*dotProduct(v,observerUp)/z
   return vector(x,-y)
end function
```

The `pos3DToScreenPos()` function returns the point's position on the screen relative to the center of the 3-D viewport. The position of y is measured downward. Since in practice you precalculate many such values, the function could be made more efficient. In addition, there are also some complications about points behind the observer. On the other hand, in practice you can let your 3-D card handle this part, as will become apparent momentarily.

To explore further how an image is displayed, as mentioned previously, the set of points that is visible to a particular observer is called the view frustum. As illustrated by Figure 17.7 (shown previously), the view frustum is defined in part by the base of a truncated pyramid. A pyramid is a six-sided shape. Its sides are at an angle determined by the field of view. Its front and back faces are determined arbitrarily and are sometimes referred to as the *hither* and *yon* of the camera. While you can theoretically see infinitely far and infinitely near, when rendering it is convenient to *clip* the scene at a certain distance, often using fogging to obscure the distant objects before they disappear from view.

In the equation for screen projection, notice that although changing $\mathbf{o}$ and θ both affect the image on screen, they do so in different ways. Moving the observer while leaving θ constant moves the view frustum. It changes the scale of the image linearly. By changing the field of view, however, the shape of the view frustum can be changed. This is like altering the angle of a camera lens. Choosing the correct field of view for your scene can take a little fiddling with the parameters to make something that looks right, just as a director or cinematographer may spend a long time choosing the right lens. None is more correct, but they have different visual effects. The most natural-feeling will be a viewing angle that is the same as the angle the computer user has to the computer screen—but this depends on how near they are to the screen and the resolution they are using.

Perspective

Perspective is a technique for representing objects on a flat surface. The technique in art of using perspective was mathematically defined during the Renaissance, but the basic principles of perspective had been used prior to that. As defined mathematically, perspective is the approach used to render a 3-D scene on paper. While useful for drawing, however, it must be technically translated if it is to be an effective approach to rendering images on a monitor.

To draw a scene in perspective, you start by creating a horizon. The horizon is supposed to be drawn at the height of the observer's eyes. Each point on the horizon is a vanishing point. The vanishing point represents an object infinitely far away along a line drawn from the observer's vertical axis. As shown in Figure 17.10, the classic example of this is a road stretching into the distance.

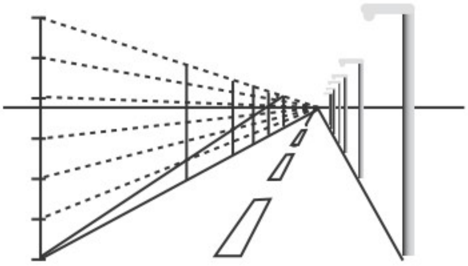

Figure 17.10

A perspective drawing.

In Figure 17.10, in addition to the road, a number of lampposts are drawn. If you were to travel along the road, the lampposts would be spaced along the road, as would be the lines on the road. The dotted lines on the left of the figure illustrate the basic technique. Two types of lines are used. Those that begin with the first post and converge at a point in the horizon are called orthogonal lines. Those that represent the lampposts or are transverse lines.

To develop the perspective, you divide the transverse line of the front post into several equal parts, joining each one to the vanishing point using an orthogonal line. You then draw in a line from the bottom of the first post to the top of the post that represents the visible background. Your remaining lampposts are placed so that they coincide with the points where the this line meets the orthogonal lines.

Mathematically, you can calculate that the image size of an object decays exponentially with distance:

$$\text{Height in image} = \text{height} \times e^{-k(d - d_0)}$$

where k is some constant and d_0 is the distance of an object whose height in the image is equal to its height in reality. There's nothing special about using e in the equation. Any base will do if you scale k accordingly.

The reason that perspective is not particularly useful in computer 3-D engines is that it requires many recalculations if your observer moves. However, if you're working with simple scenes and a fixed observer, it can be an easy way to create a quick 3-D effect. Exploring the difference between drawing and rendering involves seeing how the values k and d_0 in perspective drawing relate to d and θ in standard 3-D rendering.

Orthographic Projections

Although the standard perspective projection method described in the previous section is the most common way to draw a 3-D scene, other methods prove more useful in some circumstances, particularly in architectural and technical drawings.

Standard perspective projection is sometimes called *central projection*. With central projection, something distinctive occurs as you move farther away from the projection plane. As shown in Figure 17.11, as d increases and θ decreases, the objects on the screen always appear the same size, and the view frustum becomes a simple box.

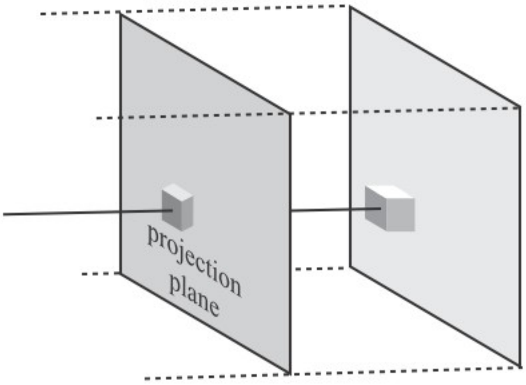

Figure 17.11

Orthographic projection.

The image shown in Figure 17.11 is called *orthographic*. When the object you are looking at is at a different angle, it can also be called *oblique*, *axonometric*, or *isometric*, but all these are equivalent to the orthographic view. Only the orientation of the object has changed. In an orthographic view, the distance of an object from the viewer or any other object has no effect on its size. It does, however, affect the position of the object on the screen and the drawing order. Otherwise, all you need to know is the size of the viewport.

In gaming, the most common of these orthographic views is the *isometric* view. This is where you look down on an object in an orthographic projection at such an angle that each side of the object is at the same angle to the projection plane, so they are all viewed as the same length. (You'll look at isometric games briefly in Part V.)

One more projection technique is worth noting. Instead of a projection plane, you use a *projection sphere* or *cylinder* around the observer. In some ways, you might imagine this to be more realistic. After all, you aren't actually looking at the world through a window but through two movable eyes. However, using a projection sphere creates some rather strange effects. One example is the Mercator projection of the earth, which is the most commonly seen map of the planet. In a Mercator projection, you imagine placing the earth inside a cylinder of paper and shining a light from the center. The shadow cast on the cylinder forms a map, which you can then unroll.

This is a good way to deal with the problem of mapping a spherical object like the earth onto a planar map, but it has some problems. Among other things, measuring distance is extremely difficult. The farther away you move from the equator, the more spread out the map is, until the North Pole is actually infinitely spread out, and infinitely high up the cylinder. On a map, this is why Greenland is so enormously out of proportion to its actual size. Navigating through a world using this kind of projection would be very weird and confusing.

Casting a Ray

As became evident in the discussion of 2-D images, it can often be useful to get a list of all objects along a *ray*. A ray is a line with one point of termination that extends infinitely. Chapter 10 discussed how to calculate the intersection of a ray with a plane. In the next couple of chapters, you'll calculate ray collisions for both simple shapes and polygonal meshes. In the current passage, it is worthwhile to look at a few applications of this method, assuming that you can employ a 3-D engine to calculate the ray for you.

As anticipated by the discussion in Chapter 10, *raycasting* is useful in many circumstances, but two are the most common. The first is in user interaction. For example, consider a situation that arises when someone clicks on the 3-D scene and must calculate what object is underneath it. The second is in collision detection. Consider a situation in which one or more rays cast in front of a shape can be used like the beam of a headlamp to determine whether there are any obstacles ahead.

Using a 3-D Engine to Find Objects Along a Path

The basic principle of raycasting is that you send a query to your real-time engine, passing it a starting point and a direction vector. The query then returns a list of models with which the ray intersects. Depending on your particular 3-D engine, the query might contain some optimization methods. In some cases, for example, you can specify a maximum number of models to return, a list of models to check against, and a maximum length for the ray. More detailed results might involve collision points and collision normals or the texture coordinates clicked on.

A good example of how this can be useful is in *terrain following*. Terrain following involves an object that is moving along a ground of varying height. Suppose your ground is a continuous triangular mesh, and you are creating a 4 × 4 vehicle that is driving along the terrain. How can you make the vehicle move realistically across the various bumps? To do so, you must know how high each wheel needs to be, orienting the vehicle accordingly.

One way to assess the heights of bumps is to store the information about the ground as a 2-D height map. This approach provides rapid information, but at the same time, it also requires high amounts of storage space. Another method—which might be quicker, depending on the speed of your 3-D engine and card and the complexity of the geometry of the terrain—is to cast a ray downward from each wheel and orient according to the collision points. This approach has the additional advantage of working equally well with a terrain that is changing over time, such as water waves.

A similar simple example is gunfire. In a first-person shooter (FPS), each player or enemy has a weapon that generally fires in a straight line. At the moment the gun is fired, a quick raycasting collision check determines where it will hit.

The technique is less useful when dealing with objects three or four times bigger than the mesh against which they are colliding. It is also not very useful with objects that are colliding with other objects that may be smaller. In such cases, you must use a large number of rays to determine whether the path is definitely clear. Certain workarounds are available, however. For example, if the objects are significantly different in size, it becomes possible to approximate the collision by using a proxy shape, such as a sphere or bounding box.

Picking, Dragging, and Dropping

Using interaction requires raycasting. The simplest example is when the player of your game clicks on the screen to select an object in 3-D space. How do you determine which object they have clicked on?

By choosing a point on the screen, your user has actually selected an angle for a ray. In fact, you're running the process of drawing a 3-D point to the screen in reverse. The simplest way to determine this point is to use the projection screen method to find a particular 3-D point under the mouse position. You then use this point to create your direction vector. To do this, as shown in previous calculations in this chapter, you need the field of view angle θ and the height h of the viewport. Then the distance to the projection plane can be found as $d = \frac{h}{\tan\theta}$.

Having found this distance, and knowing the camera's forward and up-vectors, you can quickly calculate the point under the mouse. The `screenPosTo3DPos()` function performs this calculation:

```
function screenPosTo3DPos(viewportPos, observerPos,
                          observerVect, observerUp, fov, h)
   set observerRight to crossProduct(observerUp, observerVect)
   set d to h / tan(fov)
   return observerVect*d - observerUp*viewportPos[2] +
                           observerRight*viewportPos[1]
end function
```

You now have all you need to cast a ray. The start point is the camera position, and the direction is the vector to the point you found. This tells you the model clicked on.

Suppose you need to drag the model to a new position. This question gives you a technical problem. While there are three dimensions to move it in, there are only two dimensions for the mouse. Somehow, the user's movements need to be translated into 3-D space.

How the movements are translated depends on the particular circumstances. Consider what happens if the model is part of a plane. It might be an object on the ground, a sliding tile, or a picture on the wall. If this is the case, then your two directions of motion are sufficient. You need only to find a way to constrain the motion in the particular direction.

If the model is free to move in space but not rotate, then the best solution is likely to combine the mouse movement with a key. You might program your game so that the user presses the Shift key while moving the mouse. This might cause the object to move in the camera's *xz*-plane rather than the *xy*-plane. Alternatively, while making the drag occur only in the current *xy*-plane, you can allow the user to move freely around the object, changing the plane of view or providing multiple views of the same object. Finally, if the model is supposed to be rotating in place, then mouse movements can correspond to rotations in the direction of two axes.

To accomplish such tasks, you can start with constraining to the plane. This is an extension of what you've already seen. As the mouse moves, you cast a ray from its current position to the plane you're interested in. You can use this as the new position for the dragged object, offsetting it by its height or radius as appropriate. As a note, the position does not have to be a on a plane. It can be rough terrain or even other models. Think about the pool game example, which involved a "ghost" ball demonstrating where a collision would occur.

For a more sophisticated variant, you can "fake" the ray position so that the users feel they're dragging the middle of the object instead of its base. Figure 17.12 illustrates how this might work. First, you calculate the current offset of the base of the object from its midpoint as they appear on the screen coordinates. After that, you apply this offset to the current mouse position to get the ground position you're interested in. Now you drag the object to sit correctly at that position. The user isn't precisely dragging the midpoint of the object, but it feels that way.

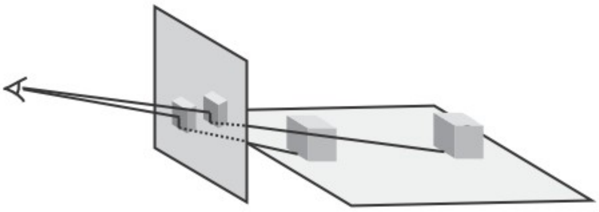

Figure 17.12
Dragging an object along the plane.

Dragging the object freely in space is an extension of this. You'll always have to constrain to a plane. However, you can give a freer choice as to what plane that is. Generally, while the most natural approach involves using a plane normal to the camera, you can also use one normal to the up-vector, or any other vector that seems convenient.

A much more difficult problem comes when you want to allow the user to rotate objects with the mouse. You can start with the simplest of these situations, which is when you want players to be able to rotate themselves, as in a mouse-driven FPS. In that case, a mouse movement corresponds to a camera rotation.

This problem is reasonably easy to solve. This is because there is a straightforward mapping from the mouse movement to the desired movement. At each time-step, you rotate the camera to point along whatever ray is currently underneath the mouse. (You'll see in the next chapter how to rotate an object to point in a particular direction.) To accomplish this, you must decide whether to keep rotating if the mouse is held still but off-center. You must also decide whether to rotate only when the mouse is moved. In the case of mouse movement, you need to reset the cursor position to the center of the screen each time you move. (With this approach, it is best to hide the cursor.)

When using the mouse to rotate an object in the camera view, things get a little trickier. There is no hard-and-fast translation from one to the other. You can make a start, however. The most natural assumption for someone rotating an object is that the point of the object clicked on will remain under the mouse as it rotates. You can do this as long as you know the intersection point of the ray. The difficulty is knowing which way should be up. As will be discussed in Chapter 18, you can specify an up-vector for a point-at operation. In this case, there's no obvious winner.

As an example of how to apply such observations, consider a case in which the object to be rotated has position vector $\mathbf{p}$, and the point on its clicked surface has position vector $\mathbf{q}$. Now the mouse is moved so that it defines a ray $\mathbf{o} + t\mathbf{v}$ from the observer. You want to know which direction to point the object so that it points toward the mouse position. In other words, you want to point the object toward the ray.

To find the correct direction, you need to find the point of intersection of the ray with the sphere centered on $\mathbf{p}$ whose radius is the magnitude of $\mathbf{q} - \mathbf{p}$. If there is such an intersection, then this tells you the new position toward which the object should point. If there is no intersection, then the mouse is outside the range of the object, in which case you can either continue to rotate or point it as closely as possible toward the mouse. Another way to put it is to say that you point it along a vector perpendicular to the vector $\mathbf{v}$ through the plane containing $\mathbf{v}$ and $\mathbf{p} - \mathbf{o}$.

But what about the up-vector? One option is to use the camera's up-vector. This works reasonably well, but it leads to problems when you want to rotate the object to align with this vector. Another approach is to use the axis of rotation, but this causes the object to rotate rather erratically. A good compromise is to use the cross-product of the camera's direction vector and the movement vector of the point.

Exercise

EXERCISE 17.1

Create a function that will draw a three-dimensional cube, culling the back faces. While you can determine which faces of a cube are visible by using the normal of the plane, this is a task that is better left for later. For the moment, concentrate on the projection. See if you can work out how to use the cross product to determine if a particular face of the cube is visible. Use the function to make a cube that spins around its center. Look at the effect of using different projection techniques and fields of view.

Summary

In this chapter, you've had a brief introduction to three-dimensional space and how it works. As you've seen, the third dimension can be understood using the concepts used to discuss 2-D objects. What happens, however, is that calculations become more complex due to the extra freedom of movement and because you have to work with an observer who can't see the whole space.

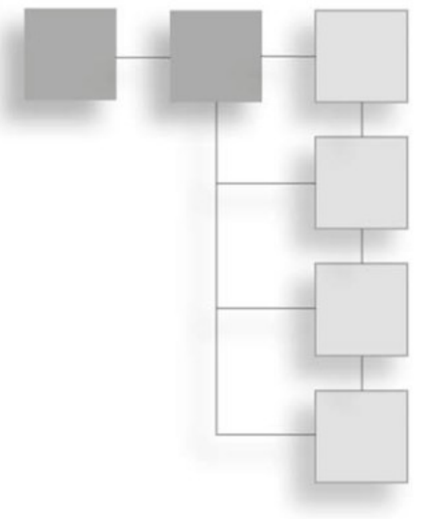
In the next chapter, you'll look further into how the space works and extend the matrix math you met in Chapter 5 to deal with the much more complex motions and transformations available to you.

You Should Now Know

- How to extend vectors into three dimensions
- The meaning and use of the *cross* (*vector*) product
- How to find points and lines of intersection between *lines* and *planes*
- The meaning of the term *homogeneous coordinates* and how to use them to calculate intersections
- How to use different kinds of *projection* to create your own 3-D engine
- How to use *raycasting* to create user interaction in 3-D space

CHAPTER 18

TRANSFORMS



In This Chapter

- Overview
- Describing Locations in Space
- Applying Transforms

Overview

You've already seen how a 2-D matrix can be used to describe a sequence of transformations in 2-D space. In this chapter, you'll look at the 3-D equivalent of this, the *transform*. You'll also see how transforms can be used to create objects with relationships to each other.

Describing Locations in Space

The 3-D world is populated by objects called *models*. Models are sets of vertices joined together in triangles to make a *mesh*. In order to work out where these models are, the 3-D engine treats them as a single object called a *node*. The node is associated with a particular location and orientation. The 3-D engine works out the positions of the vertices relative to the node. The same method is also used to describe the location of lights, cameras, and other members of 3-D space.

Position, Rotation, and Scale

To describe a node, you must know three things: its position, its rotation, and its scale. Rotation and scale can be handled by a transformation matrix. Position is a simple vector. The simplest way to visualize this combination of transformations is as a single process acting on the "raw" model. The first action is scaling. The second is rotating about the origin. The final is translating to the correct point.

All of these transformations are *affine*, meaning that if two lines are parallel before transformation, then they remain parallel afterward. Shears and reflections are also affine transformations. In fact, any transformation that can be performed by a matrix is affine. Rotations, translations, and reflections are slightly stricter. They are rigid-body transformations because, as well as affinity, they preserve angles between lines in space. In other words, while the relative positions of vertices may change, the angles between them remain the same. As illustrated by Figure 18.1, this is not true of scales in general.

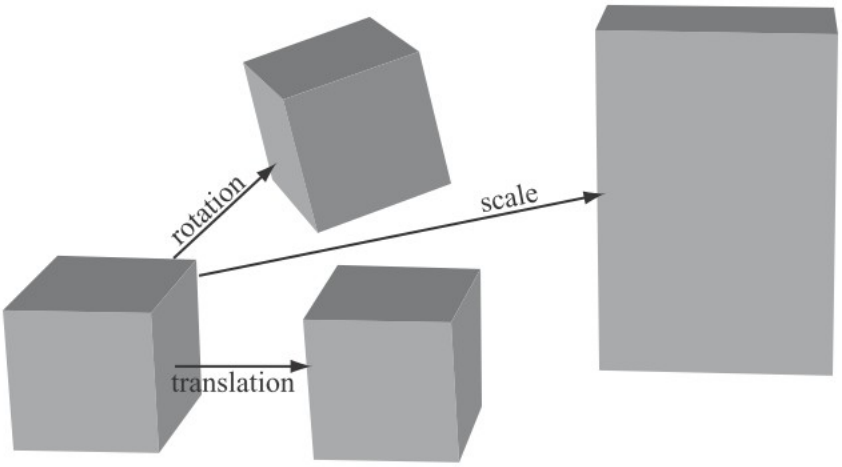


Figure 18.1
The three basic transformations.

Scale is the transformation that is easiest to visualize. Scaling an object by a constant factor involves multiplying each position vector by the scale factor. In terms of matrix mathematics, the matrix is multiplied the matrix $n\mathbf{I}$, where $\mathbf{I}$ is the identity matrix. More generally, you can scale by different amounts in each direction. To accomplish this, you multiply the vectors by the following matrix:

$$\begin{pmatrix} a & 0 & 0 \\ 0 & b & 0 \\ 0 & 0 & c \end{pmatrix}$$

Any scale transformation can be calculated in this way. For example, a scale factor of 2 in the direction (1 1 0) is equivalent to the scale

$$\begin{pmatrix} \sqrt{2} & 0 & 0 \\ 0 & \sqrt{2} & 0 \\ 0 & 0 & 1 \end{pmatrix}$$

Rotation is more complicated than scaling. In two dimensions, rotation about the origin is relatively straightforward. It is described by a single angle. When a third dimension is added, however, you must specify an axis of rotation. Any vector in space can act as an axis, but as with the pool balls you looked at in previous chapters, due to topspin and sidespin, any rotation can be decomposed into simpler rotations about the basis vectors.

A rotation about one of the basis vectors can be described by a matrix like this:

$$\mathbf{R}_x = \begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{pmatrix}$$

Combining all three such matrices gives you a generic rotation:

$$\mathbf{R} \equiv \mathbf{R}_z\mathbf{R}_y\mathbf{R}_x = \begin{pmatrix} \cos\xi & \sin\xi & 0 \\ -\sin\xi & \cos\xi & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} \cos\phi & 0 & \sin\phi \\ 0 & 1 & 0 \\ -\sin\phi & 0 & \cos\phi \end{pmatrix}\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{pmatrix}$$

Note

> The triple bar symbol (≡) here means "is defined as" or "is identical to." It's like a stronger kind of equals sign.

Multiplying out all these matrices is an extremely involved process, but it's not as bad as it might seem. Suppose you transform the vectors **i**, **j**, and **k** under **R**. You end up with the column vectors **u**, **v**, and **w** of the matrix. One feature of a rotation is that the vector between a point and its image must always be perpendicular to the axis of rotation. As a result, if you now take the cross product (**u** – **i**) × (**v** – **j**), you find a new vector **a** perpendicular to both. This vector **a** is the overall axis of rotation.

What's more, you can calculate the angle of rotation α by finding the components of **i** and **v** perpendicular to **a**. In other words, you find the result of projecting vectors **i** and **v** to a plane normal to **a**. Here is how this can be accomplished:

$$\begin{aligned}\mathbf{i}_N &= \mathbf{i} - (\mathbf{a} \cdot \mathbf{i})\,\mathbf{a} \\ \mathbf{v}_N &= \mathbf{v} - (\mathbf{a} \cdot \mathbf{v})\,\mathbf{a} \\ \mathbf{i}_N \cdot \mathbf{v}_\mathrm{N} &= (\mathbf{i} - (\mathbf{a} \cdot \mathbf{i})\,\mathbf{a}) \cdot (\mathbf{v} - (\mathbf{a} \cdot \mathbf{v})\,\mathbf{a}) \\ &= \mathbf{i} \cdot \mathbf{v} - (\mathbf{a} \cdot \mathbf{i})\,(\mathbf{a} \cdot \mathbf{v})\,(2 - \mathbf{a} \cdot \mathbf{a})\end{aligned}$$

Note

This only works if **i** (and therefore **v**) is not parallel to **a**. If it is parallel to **a**, you must use a different basis vector for comparison.

Assuming **a** is a unit vector (if it is not, you can normalize it), and given the definition of rotation, noting that the dot product with **i** and **v** must be equal, you arrive at this equation:

$$\cos \alpha = \mathbf{i} \cdot \mathbf{v} - (\mathbf{a} \cdot \mathbf{i})^2$$

This process can always be used to combine two or more transformations into one. Conversely, since you can decompose a rotation **R** into primitive rotations about the basis vectors, a rotation is often described by means of a rotation vector giving the angle of rotation about the three axes. You'll be coming back to this issue several times over the course of this section.

While the notions proposed in this section work fine, you still eventually hit a snag. How can you represent translations? It would be good to be able to perform a complete transformation in one step, including translations. Otherwise, among other things, any combination of transformations would require first translating back to the origin, performing rotations and scales, re-adding the position, and then translating again. Since position information is additive, however, and not multiplicative, such activity becomes seemingly impossible.

The Transformation Matrix

The solution to this problem is to use the homogeneous coordinates introduced in the previous chapter. With the aid of the fourth dimension, you can perform translations using a 4 × 4 matrix. Here is how this is done:

$$\begin{pmatrix} 1 & 0 & 0 & a \\ 0 & 1 & 0 & b \\ 0 & 0 & 1 & c \\ 0 & 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} x \\ y \\ z \\ 1 \end{pmatrix} = \begin{pmatrix} x+a \\ y+b \\ z+c \\ 1 \end{pmatrix}$$

Notice that the last row of the calculation is almost irrelevant. It serves largely as a piece of bookkeeping. Also, notice that if you perform a translation on a direction vector instead of a position vector, so that the w-coordinate is zero, the vector is unaffected by the transformation.

If you combine the resultant matrix with the scaling and rotation matrices mentioned previously, you end up with a generic transform

$$\mathbf{T} = \mathbf{P}\mathbf{R}_z\mathbf{R}_y\mathbf{R}_x\mathbf{S}$$

where **P** is a translation, and **S** is a scale that appears like this

$$\begin{pmatrix} a & 0 & 0 & 0 \\ 0 & b & 0 & 0 \\ 0 & 0 & c & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

and

$$\mathbf{R}_z = \begin{pmatrix} \cos\theta & \sin\theta & 0 & 0 \\ -\sin\theta & \cos\theta & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}$$

A similar relationship applies for $\mathbf{R}_y$ and $\mathbf{R}_x$. The non-translation matrices are created simply by replacing the 3 × 3 matrix at the top-left of the 4 × 4 matrix with the appropriate 3-D matrix.

Because its bottom row is always $(0 \quad 0 \quad 0 \quad 1)$, **T** has 12 unknown entries. However, not all such matrices are valid transforms. Those with a determinant of zero are invalid. Of the rest, exactly half would perform a reflection and most others would create some form of shear. It's easy to see that there are nine degrees of freedom in creating a valid transform. Three are rotation angles, three are scale factors, and three are translation values.

Each of the matrices that make up a transform can be inverted fairly easily. For a translation, replace each value with its negation. For a rotation, negate the rotation angle. For a scale, replace the scale factors by their reciprocals. In fact, as it happens, inverting translations and rotations is even easier than that. Their inverse is actually their transpose. In such situations, you say the matrices are *orthogonal*, which is equivalent to the rigid-body nature of the transformation. This means that you can invert the whole transform. When you do this, it is important to remember that you must apply the inverses in the opposite order:

$$\mathbf{T}^{-1} = \mathbf{S}^{-1}\mathbf{R}_x^{\mathrm{T}}\mathbf{R}_y^{\mathrm{T}}\mathbf{R}_z^{\mathrm{T}}\mathbf{P}^{\mathrm{T}}$$

This process is straightforward providing that you keep track of the primitive transformations making up the transform. Otherwise, you have to either decompose the general transform into its component parts or invert it as it stands.

To decompose a transform into position, rotation, and scale information, you first strip off the translation element from the last column of the matrix. To calculate the scale and rotation, notice first that when you multiply **S** by the basis vectors, you multiply the basis vectors by the scale factors a, b, and c. For example, $\mathbf{RSi} = \mathbf{R}(a\mathbf{i}) = a(\mathbf{Ri})$. Also, since **R** is a rigid rotation, **Ri** is a unit vector.

A further point is that **Ri** is also the first column of **R**. Given this information, a must be the magnitude of the first column of **RS**, and the first column of **R** is the normalized version of this vector. Since the case is similar for b and c, you can split the transform into the three underlying transformations.

Further decomposing **R** into rotations about the three axes is also possible, although not always necessary. You're looking for θ, ϕ, and ξ such that

$$\begin{pmatrix} \cos\xi & \sin\xi & 0 \\ -\sin\xi & \cos\xi & 0 \\ 0 & 0 & 1 \end{pmatrix}\begin{pmatrix} \cos\phi & 0 & \sin\phi \\ 0 & 1 & 0 \\ -\sin\phi & 0 & \cos\phi \end{pmatrix}\begin{pmatrix} 1 & 0 & 0 \\ 0 & \cos\theta & \sin\theta \\ 0 & -\sin\theta & \cos\theta \end{pmatrix} = \begin{pmatrix} x_1 & x_2 & x_3 \\ y_1 & y_2 & y_3 \\ z_1 & z_2 & z_3 \end{pmatrix}$$

(Since it is not involved in this transformation, you ignore the w-coordinate.)

Since the z rotation doesn't affect the z-coordinate and the x rotation doesn't affect the x-coordinate, you can see that $z_1 = -\sin\phi$. This tells you the value of ϕ. Having done that, you can see that $z_2 = -\cos\phi\ \sin\theta$, which gives you θ and $x_1 = \cos\phi\ \cos\xi$, which gives you ξ. The only problem is that there is more than one set of solutions to this system, so different sets of rotations will combine to give the right answer. This might seem trivial, but it does cause problems, particularly when interpolating transforms.

One advantage to working with the raw transformations underlying a transform is that they provide you with a validation system against rounding errors. Because of the redundancy in the transform matrix, small errors can accumulate to give a transform that is not valid if a small sheer factor is introduced. You can counteract this by checking a transform against its underlying transformations and ensuring that the two are true to one another. To some extent, this decreases the value of combining transforms into a single matrix. In this respect, it is important to remember that the main value occurs when applying a transform to multiple objects in a scene. In such cases, a validation isn't necessary. You need only to validate the transform when modifying it in some way.

Applying Transforms

Transforms simplify 3-D calculations enormously. This section provides a few examples of how this can be accomplished.

Creating Motion with Transforms

In practice, it's easiest to work with transforms by ignoring the full transform matrix and concentrating on the underlying raw transformations. In general, you'll have some node with a transform **T**, and you'll want to move it somewhere else. The only time you need to use the full transform is when calculating the actual position of the vertices of a model. For example, the basic unit cube has eight vertices at the eight permutations of the homogeneous vector $(\pm 0.5 \ \ \pm 0.5 \ \ \pm 0.5 \ \ 1)^T$. You can use a transform to move this cube to any other position or size in space. Once you have calculated the appropriate transform, you multiply it by each of the vertices to determine the new location of the cube.

The same process also works for direction vectors. As a result, the vector along one side of the cube will be unaffected. However, you do need to be careful about normal vectors. Because the scale transform does not preserve angles between lines, a direction vector that is normal to a line or plane before transforming is unlikely to still be normal afterward if the transform includes a scaling element.

If you know that **n** and **v** are perpendicular vectors, to find a vector normal to the transformed vector **Tv**, you must find some new transform $\mathbf{T}_n$, such that $\mathbf{T}_n\mathbf{n}\mathbf{T}\mathbf{v} = 0$. Recall from the definition of the dot product that since $\mathbf{n} \cdot \mathbf{v} = \mathbf{u}^T\mathbf{v}$, $(\mathbf{T}_n\mathbf{n})^T (\mathbf{T}\mathbf{v}) = 0$. Likewise, $\mathbf{n}^T\mathbf{T}_n^T\mathbf{T}\mathbf{v} = 0$. Since **n** and **v** are perpendicular by definition, if $\mathbf{T}_n^T\mathbf{T} = \mathbf{I}$, then the equation is solved. You can conclude, then, that $\mathbf{T}_n = (\mathbf{T}^{-1})^T$, the inverse transpose of **T**.

Yet again, it should be stressed that since such calculations are mostly handled behind the scenes by a decent real-time 3-D program, you don't need to worry about them. Still, it is worth keeping them in mind. They become more relevant as you work more deeply into the details of collision detection.

To consider examples of how you can use transforms to perform a common task, consider the action of aligning an arrow to point at a particular position vector. Suppose the arrow is a model whose root position (its appearance under the identity transform) is as shown in Figure 18.2. Notice that it is pointing along the positive *z*-axis.

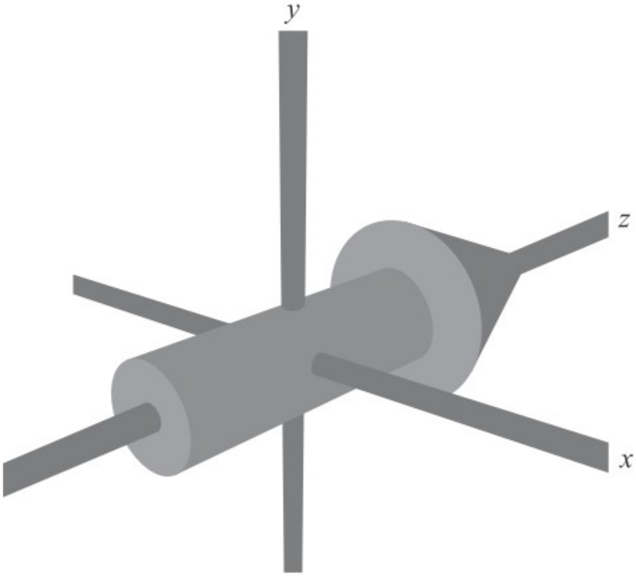

Figure 18.2
An arrow model in its untransformed state.

Imagine that the arrow in Figure 18.2 is located at position **p**, pointing along the vector **v**. To calculate **v**, you start with the transform of the arrow. If you know the transform of the arrow, then **v** is the normalized third column of the transform matrix. You want the arrow to point at a point **q** instead along the vector **v**, so you rotate it appropriately. To do this, you can first calculate the vector $\mathbf{q} - \mathbf{p}$. This is the new direction for the transform's *z*-axis. Normalized, you call this **u**. Taking the cross product $\mathbf{u} \times \mathbf{v}$, you can find the axis around which you would like the arrow to rotate. By taking the dot product $\mathbf{u} \cdot \mathbf{v}$, you can find the cosine of the rotation angle.

Now all you need to do is to perform the rotation. The general matrix for rotating around an arbitrary axis is a little ugly. It appears as follows:

$$\mathbf{R} = \begin{pmatrix} c_+ + a_1^2 c_- & a_1 a_2 c_- - a_3 s & a_1 a_3 c_- + a_2 s \\ a_1 a_2 c_- + a_3 s & c_+ + a_2^2 c_- & a_2 a_3 c_- - a_1 s \\ a_1 a_3 c_- - a_2 s & a_2 a_3 c_- + a_1 s & c_+ + a_3^2 c_- \end{pmatrix}$$

where the axis is given by the vector $(a_1 \quad a_2 \quad a_3)^T$. If the angle is θ, then s, c_+, and c_- are defined as $s = \sin\theta$, $c_+ = \cos\theta$, and $c_- = 1 - c_+$.

If you were working with non-homogeneous coordinates, you'd have to combine this with a translation to the origin, the rotation, and then the translation back. In this case you don't need to worry, however. Since translation is applied last, the translation and rotation parts of the homogeneous matrix are essentially independent. As a result, you can create a transform **S** that has **R** in the top-left portion and an identity position element.

Given this progress, all you need to do is to combine the matrix **S** with the original transform **T** to apply the rotation. While in most instances this might be done readily, however, there is one potential problem. You must decide whether you should right- or left-multiply the transforms. To solve this problem, consider that since **S** is to be applied after **T**, you need to combine it on the left as **ST**, not as **TS**.

Note

> In contrast, since it's generally more useful to apply the scale to the object in its unrotated form before applying rotations, consider that a scale transform is more likely to be applied before **T**, and therefore right-multiplied with it.

Everything seems to be in order at this point, but still there is another complication. What happens if the node you are interested in is not symmetrical? For example, if the node is not an arrow model but a camera, then it's not enough to point at a particular location. You must also specify which way is up. Otherwise, your camera will spin in strange directions.

To resolve this problem, you perform not just one rotation, but two. First, you rotate the object, as before, to point in a particular direction. This might be along its local *z*-axis. You then rotate again around this direction vector to keep the preferred up-vector (usually the local *y*-axis) pointing as close to upward as possible. Figure 18.3 shows this process.

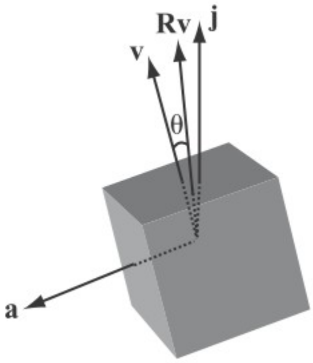

Figure 18.3

Keeping a preferred up-vector.

Note

> There's nothing special about the up direction. You could just as easily align it to keep a preferred left side. In a gravitational world, however, it's often sensible to single out the vertical direction.

Determining the angle of rotation requires calculus. You are seeking an angle that maximizes **Rv** · **j**, where **R** is a rotation matrix around the (normalized) pointing direction **a** = **q** – **p**, and **v** is the current direction of the up-vector. Plugging this into the matrix for **R**, you are trying to find θ that maximizes

$$(a_1a_2v_1 + a_2a_3v_3 + a_2^2v_2)(1 - \cos\theta) + v_2\cos\theta - (a_3v_1 + a_1v_3)\sin\theta$$

Differentiating, you see that θ must solve as

$$\tan\theta = \frac{(a_3v_1 + a_1v_3)}{(a_1a_2v_1 + a_2a_3v_3 + (a_2^2 - 1)v_2)}$$

This yields two possible values for θ. One gives the angle to point down. The other gives an angle to point up. Also, if the numerator and denominator are both zero, you are in a situation in which the pointing vector **a** is parallel to **j**, so all directions are equally far from pointing upward.

Interpolation

One of the most powerful features of transforms is the ability to create smooth motion by *interpolating* between two matrices. For example, you might want to create a camera that automatically follows a race car. If you place the camera at a constant distance relative to the car, the result is that the camera provides a view that makes it appear that it is tied on the back of the car. Instead of this, you want it to appear as though the camera is mounted on a helicopter smoothly following along behind the car.

To do this, you can calculate two transforms. The first is the current transform **C** of the camera. This is something that you are likely to already know. The second is the target transform **T**, which is at a set position relative to the moving car. At this point, instead of moving the camera to the new transform, you move it part way along, to some transform $t\mathbf{C} + (1 - t)\mathbf{T}$.

The effect of this change is to make the camera ease into position. This strategy works particularly well when following an object that is moving continually, like a car. A similar process can be used for following a third-person perspective character in a game like *Super Mario World* or *Tomb Raider*. In such cases, however, calculating the target transform is more complicated, since you have to deal with the possibility that other objects or landscape features are in the way. Generally, camera controls are one of the most difficult aspects of game design and can often make or break the game in terms of playability.

Quaternions

As mentioned previously, there are simple ways to handle rotations. The key concept is the *quaternion*. The quaternion is a special kind of 4-D vector. A quaternion $\mathbf{q}$ can be written as $(w \;\; x \;\; y \;\; z)^T$. Alternatively, it can be written as $w + xi + yj + zk$, where the numbers i, j, and k are related to the imaginary number i. The imaginary number i is defined to be the square root of -1.

In this case, i, j, and k are *orthogonal imaginary numbers*, in the sense that squaring any of them gives -1, and together they satisfy the following equations: $ij = -ji = k$; $jk = -kj = i$; $ki = -ik = j$. No real numbers satisfy these equations. They are not numbers in that sense. Instead, they are mathematical abstractions that do what you want them to do. What they generate is a kind of imaginary vector.

The quaternion $\mathbf{q}$ may also be written in the form $w + \mathbf{v}$, where $\mathbf{v}$ is the vector $(x \;\; y \;\; z)^{\mathrm{T}}$. You also define the conjugate of $\mathbf{q}$ to be the quaternion $w - \mathbf{v}$. Having defined your strange imaginary basis, you can calculate the product of two quaternions:

$$\begin{aligned}
&(w_1 + x_1 i + y_1 j + z_1 k)\,(w_2 + x_2 i + y_2 j + z_2 k) = w_1\,(w_2 + x_2 i + y_2 j + z_2 k)\\
&\quad + x_1 i\,(w_2 + x_2 i + y_2 j + z_2 k) + y_1 j\,(w_2 + x_2 i + y_2 j + z_2 k) + z_1 k\,(w_2 + x_2 i + y_2 j + z_2 k)\\
&\quad = (w_1 w_2 + w_1 x_2 i + w_1 y_2 j + w_1 z_2 k) + (x_1 w_2 i - x_1 x_2 + x_1 y_2 k + x_1 z_2 j)\\
&\quad + (y_1 w_2 j - y_1 x_2 k - y_1 y_2 + y_1 z_2 i) + (z_1 w_2 k - z_1 x_2 j - z_1 y_2 i - z_1 z_2)\\
&\quad = (w_1 w_2 - x_1 x_2 - y_1 y_2 - z_1 z_2) + (w_1 x_2 + x_1 w_2 + y_1 z_2 - z_1 y_2)\, i\\
&\quad + (w_1 y_2 + y_1 w_2 - z_1 x_2 + x_1 z_2)\, j + (w_1 z_2 + z_1 w_2 + x_1 y_2 - y_1 x_2)\, k
\end{aligned}$$

As unpleasant as this product might appear, it can be simplified if you use the vector form. If you say $\mathbf{q}_1 = w_1 + \mathbf{v}_1$ and $\mathbf{q}_2 = w_2 + \mathbf{v}_2$, then the product is given by

$$\mathbf{q}_1\mathbf{q}_2 = w_1 w_2 + \mathbf{v}_1 \cdot \mathbf{v}_2 + w_1\mathbf{v}_2 + w_2\mathbf{v}_1 + \mathbf{v}_1 \times \mathbf{v}_2$$

Notice that because of the cross-product component, the product of quaternions is not commutative.

Armed with this result, you can take the product of a quaternion with its conjugate:

$$\mathbf{q}\overline{\mathbf{q}} = w^2 - \mathrm{v}\cdot\mathrm{v} - \mathrm{v}\times\mathrm{v}$$

Since for any vector, $\mathbf{v} \times \mathbf{v} = 0$, you can reason that

$$\mathbf{q}\overline{\mathbf{q}} = w^2 - \mathrm{v}\cdot\mathrm{v}$$

And because $i^2 = j^2 = k^2 = -1$, you find that $\mathbf{q}\overline{\mathbf{q}} = \mathbf{q}\cdot\mathbf{q} = |\mathbf{q}|^2$. The inverse (both left and right) of a quaternion can be given by $\mathbf{q}^{-1} = \dfrac{\overline{\mathbf{q}}}{|\mathbf{q}|^2}$, or in particular for a unit quaternion, $\mathbf{q}^{-1} = \overline{\mathbf{q}}$. The product of a quaternion with its inverse is the quaternion $(1 \;\; 0 \;\; 0 \;\; 0)^{\mathrm{T}}$, which is equal to the scalar 1.

What does all this mathematical work have to do with rotations? It turns out that if you consider the vector $\mathbf{u}$ to be a quaternion with a zero scalar part, and if you calculate the product $\mathbf{quq}^{-1}$ for some quaternion $\mathbf{q}$, you arrive at the rotation of $\mathbf{v}$ about a particular axis.

Notice first that since the product $\mathbf{quq}^{-1}$ is the same for any scalar multiple of **q**, you can consider **q** to be a unit quaternion **s** + **v**, whose inverse is $\overline{\mathbf{q}} = \mathbf{s} - \mathbf{v}$. This gives the product as

$$\begin{aligned}\mathbf{quq}^{-1} &= (-\mathbf{v}\cdot\mathbf{u} + s\mathbf{u} + \mathbf{v}\times\mathbf{u})\overline{\mathbf{q}} \\ &= -s\mathbf{v}\cdot\mathbf{u} + (s\mathbf{u} + \mathbf{v}\times\mathbf{u})\cdot\mathbf{v} + s(s\mathbf{u} + \mathbf{v}\times\mathbf{u}) + (\mathbf{v}\cdot\mathbf{u})\mathbf{v} - (s\mathbf{u} + \mathbf{v}\times\mathbf{u})\times\mathbf{v} \\ &= \mathbf{v}\cdot(\mathbf{v}\times\mathbf{u}) + s^2\mathbf{u} + 2s(\mathbf{v}\times\mathbf{u}) + (\mathbf{v}\cdot\mathbf{u})\mathbf{v} - (\mathbf{v}\times\mathbf{u})\times\mathbf{v}\end{aligned}$$

By the identities of the dot and cross products, the first term is zero and the last term is $|\mathbf{v}|^2 - \mathbf{u}(\mathbf{v}\cdot\mathbf{u})\mathbf{v}$, so you have

$$\mathbf{quq}^{-1} = (s^2 - |\mathbf{v}|^2)\,\mathbf{u} + 2s(\mathbf{v}\times\mathbf{u}) + 2(\mathbf{v}\cdot\mathbf{u})\,\mathbf{v}$$

If you say $t = |\mathbf{v}|$ and set **a** to the normalized vector $\frac{\mathbf{v}}{t}$, then you can rewrite this as

$$\mathbf{quq}^{-1} = (s^2 - t^2)\,\mathbf{u} + 2st(\mathbf{a}\times\mathbf{u}) + 2t^2(\mathbf{a}\cdot\mathbf{u})\,\mathbf{a}$$

This represents a rotation about the axis **a**, with an angle θ given by $\cos\theta - s^2 = t^2$, $\sin\theta = 2st$, and $1 - \cos\theta = 2t^2$. Of these, you need only the last, since the first two together confirm that $1 - \cos\theta = 2t^2$, which you know because **q** is of unit length. The last is equivalent to saying that $s^2 + t^2 = 1$, which implies that $s = \cos\left(\frac{\theta}{2}\right)$. You can sum all this up by saying that a rotation around an axis **a** with angle θ can be calculated as follows using the quaternion:

$$\mathbf{q} = \cos\left(\frac{\theta}{2}\right) + \sin\left(\frac{\theta}{2}\right)\mathbf{a}$$

This is a fairly significant improvement on the matrix form. One reason is that far fewer calculations are involved in the transformation. Another reason is that it's much easier to see the relationship between the rotation and the quaternion than it is with the matrix. Also, just as with matrices, you can interpolate between two quaternions by taking a linear combination of them, although the rate at which the interpolation occurs is not the same as the rate at which the angle varies.

Parents and Children

In addition to combining transforms to move objects from one place to another, you can use them to define relationships between different nodes. This allows you to move whole groups of nodes together by varying a single transform, just as varying a node's transform can affect all the vertices of its model mesh.

You arrange all the nodes of the 3-D world in the form of a tree. In the tree, each node has exactly one parent and any number of children. The topmost node is the world itself, and each of the world node's children has its own transform relative to the world. But the transform of a child node is applied relative to its parent. In other words, if the child's relative transform is **C** and the parent's transform is **P**, then the child's transform relative to the world's coordinate system is **CP**.

For example, suppose one model is sitting in the world with a world transform consisting of a rotation about the *x*-axis and a uniform scale. Any child of this model will be rotated and scaled before its own transform is applied. As a result, the model and its children act as a group. If the parent model is translated, rotated or scaled, its children, grandchildren, and so on will move along with it.

Note

In this section, what applies to translation in most cases can be applied to rotation and scaling.

Such movement means that there is a potential ambiguity when transforming an object. Say that you want to move an object 5 units along the *z*-axis. Which *z*-axis does that mean? It could be the node's "local" *z*-axis, or its *z*-axis relative to its parent. It could also be the actual *z*-axis of the world. Figure 18.4 illustrates this situation.

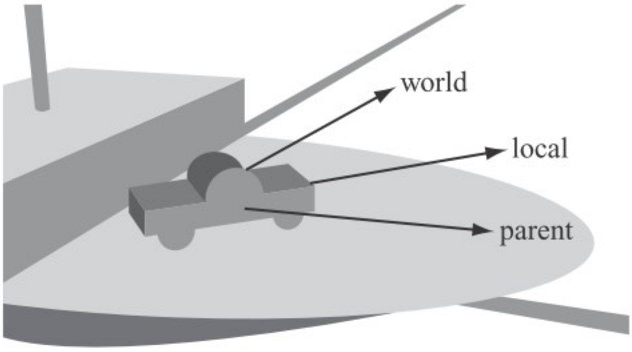

Figure 18.4
Relative motion in 3-D space.

Figure 18.4 represents a model of a car. The parent of the car is a ship on which the car is sitting. The car was modeled with its *z*-axis pointing along the body of the car. If you want to translate the car by 5 units along a *z*-axis, this could mean any of the directions indicated. The first is the car's own *z*-axis, which is pointing along the world vector $(1\ \ 0\ \ 1)^T$. The second is the ship's *z*-axis, which is pointing along the world's *x*-axis. The third is the world's *z*-axis. Ultimately, you might want to use the *z*-axis of any other node in the scene.

Fortunately, each of these is easy to calculate. The *z*-axis of the node is given by the last column of its complete world transform matrix. In general, any direction vector can be found simply by transforming it with the node's world transform. Similarly, while with a little work you can determine the direction of the parent's *z*-axis or any other model's, working out the world's *z*-axis is even easier.

Commonly, you want to go the other way around. You need to know how to change the node's personal transform in order to make it move along a particular vector. In this case, the simplest situation involves transforming the object in its local reference frame. Transforming locally is a matter of altering the transform of the object.

To alter the transform relative to the object's parent's transform is a little harder. To understand how this is so, suppose you want to move the object 5 pixels relative to the parent's *z*-axis. You must first calculate the vector in the child's reference frame. Expressed differently, you need a vector $\mathbf{v}$ such that $\mathbf{Cv} = \mathbf{k}$, which is given by $\mathbf{v} = \mathbf{C}^{-1}\mathbf{k}$. In English, this means that the vector $\mathbf{v}$, when "untransformed" into parent-space, is equal to the *z*-vector $\mathbf{k}$. Notice that this is the same independent of the parent's own transform. Similarly, to translate relative to a world-vector, you must invert the complete world transform of the child node.

Note

The vector **v** does not need to be of unit length, since any of the transforms involved may include a scaling element. Actually, this is convenient, for it means you can perform your translation of 5 units without worrying about scale. To do so, you multiply by the already scaled vector **v**. But for rotations you need to remember to normalize the axis vector before performing the rotation.

Exercise

Exercise 18.1

Create functions that will apply a translation, scale, or rotation for a particular node relative to the world, the node's parent, or the node itself. You should think about which method of storing transform information is most useful: as a single matrix or as three transformation vectors? Using quaternions for rotations?

Summary

In this chapter you have seen how homogeneous coordinates and mathematical gizmos like quaternions can be used to create a simple representation of a node's disposition in 3-D space. In the process, you've also learned how to create smooth motion incorporating simultaneous rotation, translation, and scale transformations by interpolating between transforms.

In the next chapter, you'll take one final look at collision detection by extending your previous work into the third dimension.

You Should Now Know

- The meaning of the term *transform* and how it is represented in various forms: as a single matrix, as a combination of separate matrices, and as three vectors
- How *quaternions* can be used to create a simpler representation of rotations
- How transforms can be combined to move objects from place to place, and to create groups of objects with a fixed position relative to one another

+// " 6 , $ /"
(4 " 8 / 4

of the string; deflections with a small (large) slope are (Subsection 2.1.3) linear (nonlinear). The elastic string is the one-dimensional analogue of an elastic membrane (Subsection 2.1.4) in two dimensions (Sections II.6.1 and II.6.2).

2.1.1 Tangential and Normal Components of the Tension

In the absence of transverse loading, the string is straight, and the x-axis can be taken along it; in the presence of transverse loads (Figure 2.1a), the string is deflected (2.1a), and the arc length is given by (2.1b)

$$y = \zeta(x): \quad (\mathrm{d}s)^2 = (\mathrm{d}y)^2 + (\mathrm{d}x)^2 = \left(1 + \zeta'^2\right)(\mathrm{d}x)^2, \quad \zeta' \equiv \frac{\mathrm{d}\zeta}{\mathrm{d}x}, \tag{2.1a–c}$$

where prime denotes the derivative with regard to x; for example, (2.1c) is the slope of the shape (2.1a) of the string. Since the tension T is tangent to the string, its horizontal (T_x) and vertical (T_y) components are given (Figure 2.1a) by

$$T_x = T\frac{\mathrm{d}x}{\mathrm{d}s} = T\left|1 + \zeta'^2\right|^{-1/2}, \quad T_y = T\frac{\mathrm{d}y}{\mathrm{d}s} = T\frac{\mathrm{d}y}{\mathrm{d}x}\frac{\mathrm{d}x}{\mathrm{d}s} = T_x\zeta' = T\zeta'\left|1 + \zeta'^2\right|^{-1/2}, \tag{2.2a,b}$$

where (2.1a through c) is used. The exact horizontal (2.2a) and vertical (2.2b) tensions are a nonlinear function of the slope, which can be linearized for small slopes (2.3a):

$$\zeta'^2 \ll 1 \Leftrightarrow \mathrm{d}s = \mathrm{d}x \Rightarrow \left(y_{\max}\right)^2 \ll L^2, \tag{2.3a–c}$$

and (1) this is equivalent to the statement (2.3b) that the length of the string is equal to its horizontal projection (Figure 2.1b); (2) it implies that (2.3c) the maximum transverse deflection $y_{\max}$ is small relative to the length L of the string (Figure 2.2a); and (3) the latter condition is necessary but not sufficient, that is, the relative total deflection may be small, yet the slope could be locally large if the string has steep ripples (Figure 2.2b), and in this case the deformation is nonlinear. For a small slope (2.4a) everywhere,

$$\zeta'^2 \ll 1: \quad T_x = T, \quad T_y = T\zeta', \tag{2.4a–c}$$

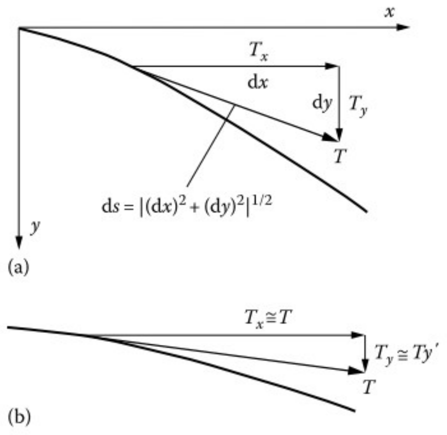

FIGURE 2.1 The tension along the tangent to an elastic string has vertical and horizontal components (a) that simplify in the linear case of small slope (b).

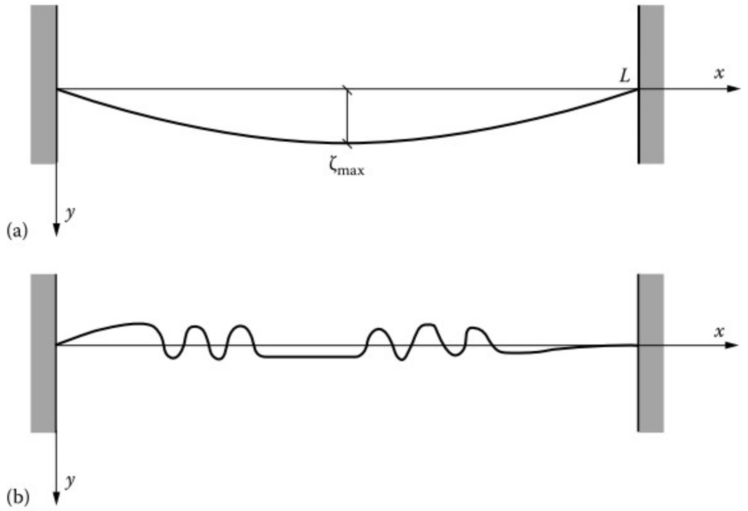

FIGURE 2.2 A linear deflection is defined by a small slope, and implies that the maximum deflection is small compared with the distance between the supports (a). The converse may not be true, for example, if the maximum deflection is small but the slope is large due to the presence of steep "ripples" (b) the deflection of the string is nonlinear.

the horizontal tension (2.4b) coincides with the tension T along the string, and the vertical tension (2.4c) is small but nonnegligible by comparison. Hence, *for an elastic string of shape (2.1a), under uniform or nonuniform tension T, the horizontal and vertical components are given exactly in the nonlinear case by (2.2a and b) and are approximated by (2.4b and c) in the linear case of a small slope everywhere by (2.4a)* ≡ *(2.3a through c).*

2.1.2 Transverse Force and Shear Stress

If a transverse force $F(x)$ is applied to the string, then the latter will deflect to an equilibrium shape such that, along each segment dx, the variation of the **transverse force** dF is balanced by the variation of the vertical component of the tension (2.5a):

$$\mathrm{d}F + \mathrm{d}T_y = 0, \quad F(x) = -T_y(x), \tag{2.5a,b}$$

where the constant of integration in (2.5b) is zero because the two terms must balance at the supported ends of the string, $x = 0, L$. Substituting (2.2b) into (2.5b) leads to the differential equation of first order (2.6) specifying the shape of the string:

$$-F(x) = T\zeta'\left|1+\zeta'^2\right|^{-1/2}, \tag{2.6}$$

under an arbitrary transverse force $F(x)$. The **shear stress** $f(x)$ is defined as the transverse force per unit length (2.7a):

$$f(x) \equiv \frac{\mathrm{d}F}{\mathrm{d}x}, \quad F(x) = F(0) + \int_0^x f(\xi)\,\mathrm{d}\xi, \tag{2.7a,b}$$

Addition, Product, and Inverses

An operation upon complex numbers is a relation between two ordered pairs of real numbers and a third ordered pair, and it can be represented graphically on the complex plane. The sum (Sections 3.1 and 3.2) is most conveniently performed in the Cartesian representation, and the product (Sections 3.3 and 3.4) in the polar representation. The operations sum and product, and their inverses subtraction and division, can be used (Sections 3.5 and 3.6) together with the conjugate operator to determine the real and imaginary parts, and the modulus and argument, of complex expressions. The algebra of complex numbers is related to the geometry of the Cartesian plane (Sections 3.8 and 3.9), and implies a number of trigonometrical relations (Section 3.7). The algebra of complex numbers extends to functions of one or more variables, and thus to complex spaces whose real dimension is twice the number of complex variables.

3.1 Complex Addition and Rule of the Parallelogram

Starting with two complex numbers in the Cartesian representation:

$$u = a + ib, \quad v = c + id, \tag{3.1a,b}$$

the operator addition is defined by the sum of each element of the pair,

$$u + v \equiv (a + c) + i\,(b + d), \tag{3.2}$$

and corresponds (Figure 3.1) to the addition of u and v as vectors, according to the **rule of the parallelogram**. Hence, the real (imaginary) part is the sum of the real (imaginary) parts:

$$\operatorname{Re}(u + v) = \operatorname{Re}(u) + \operatorname{Re}(v), \quad \operatorname{Im}(u + v) = \operatorname{Im}(u) + \operatorname{Im}(v). \tag{3.3a,b}$$

The addition of complex numbers has the following properties: (i) it is closed because the sum of complex numbers is a complex number, that is, (1.1) holds for the operation + in $|C$; (ii) it is commutative (3.4a) and associative (3.4b):

$$u + v = v + u, \quad (u + v) + w = u + (v + w); \tag{3.4a,b}$$

(iii) it has a neutral element, namely, zero $0 + 0i$; (iv) each complex number $u = a + ib$ has a symmetric $-u = -a - ib$, given by (1.18). Hence, the ordered pair $(|C, +)$, where $|C$ is the set of complex numbers and + the operation addition defined by (3.1a,b; 3.2), is a **commutative group**.

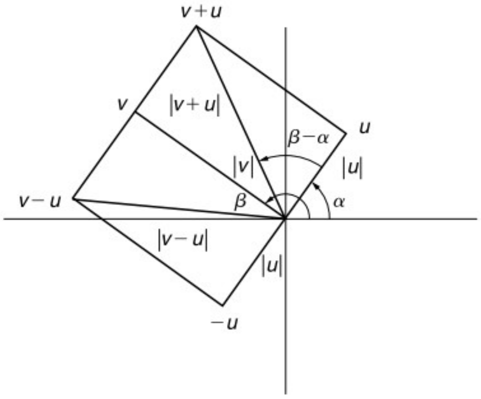

FIGURE 3.1
Taking two complex numbers u, v as the sides of a rectangle their sum is the diagonal. Their difference $u - v$ is the diagonal of the rectangle obtained by reflection on the v-direction.

3.2 Modulus, Argument, and Triangular Equalities (Pythagoras, VI b.c.)

The modulus (1.11) of the sum (3.2) is given by

$$\begin{aligned} |u+v|^2 &= (a+c)^2 + (b+d)^2 = \left(a^2+d^2\right) + 2\,(ac+bd) \\ &= |u|^2 + |v|^2 + 2\,|u|\,|v|\,(\cos\alpha\cos\beta + \sin\alpha\sin\beta)\,, \end{aligned} \tag{3.5}$$

where α, β are the arguments of u,v. The expression (3.5) simplifies

$$\alpha \equiv \arg(u)\,, \beta \equiv \arg(v): \quad |u+v| = \left| |u|^2 + |v|^2 + 2\,|u|\,|v|\cos(\alpha-\beta)\right|^{1/2}, \tag{3.6}$$

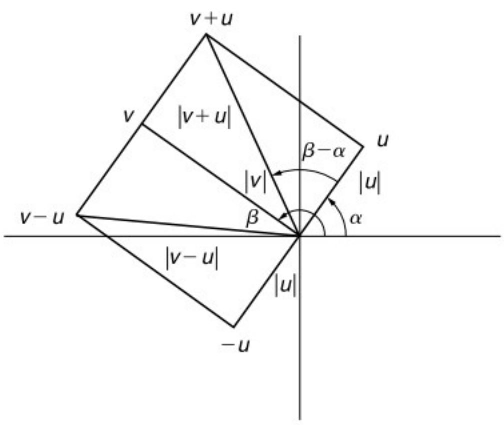
which *specifies the length* $|u+v|$ *of one side of a triangle, from the lengths* $|u|, |v|$ *of the other two sides, and the angle* $\alpha - \beta$ *between them* (Figure 3.2a). In the case $\alpha - \beta = \pm\pi/2$, the two perpendicular sides lead to **Pythagoras theorem (VI b.c.)** *for the rectangular triangle (Figure 3.2b):*

$$\arg(u) - \arg(v) = \pm\frac{\pi}{2}: \quad |u+v|^2 = |u|^2 + |v|^2\,. \tag{3.7}$$

From (1.12a) and (3.2) follows the expression:

$$\begin{aligned} \arg(u+v) &= \text{arc }\tan\left(\frac{b+d}{a+c}\right) \\ &= \text{arc}\tan\left(\frac{|u|\sin\alpha + |v|\sin\beta}{|u|\cos\alpha + |v|\cos\beta}\right), \end{aligned} \tag{3.8}$$

for *the argument of the sum of complex numbers (3.8);* other alternative expressions are given in Example 10.6.



6 !

3.2 Modulus, Argument, and Triangular Equalities (Pythagoras, VI b.c.)

The modulus (1.11) of the sum (3.2) is given by

$$\begin{aligned}|u+v|^2 &= (a+c)^2 + (b+d)^2 = \left(a^2+d^2\right) + 2\,(ac+bd)\\ &= |u|^2 + |v|^2 + 2\,|u|\,|v|\,(\cos\alpha\cos\beta + \sin\alpha\sin\beta)\,,\end{aligned} \tag{3.5}$$

where α, β are the arguments of u,v. The expression (3.5) simplifies

$$\alpha \equiv \arg(u)\,, \beta \equiv \arg(v): \quad |u+v| = \left|\,|u|^2 + |v|^2 + 2\,|u|\,|v|\cos(\alpha-\beta)\right|^{1/2}, \tag{3.6}$$

which *specifies the length* $|u+v|$ *of one side of a triangle, from the lengths* $|u|, |v|$ *of the other two sides, and the angle* $\alpha-\beta$ *between them* (Figure 3.2a). In the case $\alpha-\beta = \pm\pi/2$, the two perpendicular sides lead to **Pythagoras theorem (VI b.c.)** *for the rectangular triangle (Figure 3.2b):*

$$\arg(u) - \arg(v) = \pm\frac{\pi}{2}: \quad |u+v|^2 = |u|^2 + |v|^2\,. \tag{3.7}$$

From (1.12a) and (3.2) follows the expression:

$$\begin{aligned}\arg(u+v) &= \text{arc }\tan\left(\frac{b+d}{a+c}\right)\\ &= \text{arc }\tan\left(\frac{|u|\sin\alpha + |v|\sin\beta}{|u|\cos\alpha + |v|\cos\beta}\right),\end{aligned} \tag{3.8}$$

for *the argument of the sum of complex numbers (3.8);* other alternative expressions are given in Example 10.6.

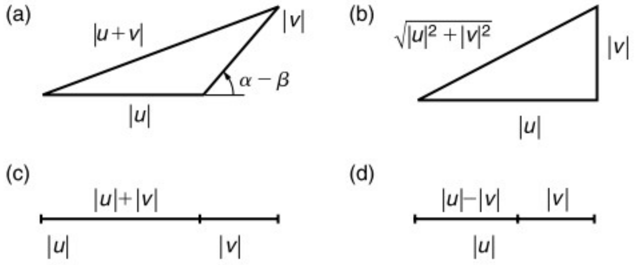


FIGURE 3.2
The sum of complex numbers by the rule of the diagonal of the rectangle (Figure 3.1) is equivalent to summing complex numbers as the sides of a triangle (a). A particular case is a rectangular triangle (b) with orthogonal sides for which holds the Pythagoras theorem. The degenerate cases are collapsed triangles with parallel (c) or antiparallel (d) sides.

1 — DOMÍNIO COMPLEXO

Os primeiros números usados pelo homem foram os naturais (entiers positifs; positive integers) que permitiam fazer somas sem restrições; a diferença de dois naturais $n-m$ só é um natural se $n>m$. Para poder realizar a subtracção sem restrições introduziram-se os inteiros (entiers; integers); o produto de inteiros não tem restrições, mas a divisão de dois inteiros n/m só é um inteiro se n é múltiplo de m. Para poder realizar a divisão noutros casos introduziram-se os racionais (rationels; rationals); estes não são compactos, visto que entre dois racionais existem outros números (por exemplo π, e) que são os irracionais (irrationels; irrationals). O conjunto dos reais (réels; reals), que consiste dos racionais e irracionais é compacto; permite a operação potência mas a raíz $\sqrt[n]{a}$ nem sempre tem n soluções reais. Introduzem-se então os complexos (complexes, complex), para os quais tanto as operações directas (soma, produto e potência), como as operações inversas (subtracção, divisão e radiação) não tem restrições.

os racionais são densos mas não são compactos

1.1 — REPRESENTAÇÃO CARTESIANA E POLAR

Um número complexo é um par ordenado de números reais e o conjunto dos complexos está em correspondência com os pontos do plano, o que permite a sua representação gráfica.

1.1.1 — **Parte real e parte imaginária**

Um número *complexo z é um par ordenado (x,y) de números reais*, para o qual se usa vulgarmente a notação

$$z = x + iy \tag{1}$$

em que x e y se designam respectivamente de parte real e imaginária (partie réelle et imaginaire; real and imaginary part):

$$x \equiv \mathrm{Re}(z), \qquad y \equiv \mathrm{Im}(z). \tag{2a,b}$$

As partes real e imaginária podem ser tomadas como coordenadas x,y num referencial cartesiano (Descartes 1637), sendo **z** representado por um ponto no plano de Argand (1806; aliás introduzido por Gauss em 1799). Logo existe uma correspondência biunívoca entre o conjunto S dos complexos **z**, o conjunto R^2 dos pares ordenados (x,y) reais e os pontos P do plano complexo (plan complexe; complex plane).

Caspar Wessel

1.1.2 — Coordenadas polares: módulo e argumento

A distância do ponto P (Figura 1) representativo do complexo **z** à origem define o módulo (module, modulus):

$$\rho \equiv |z| = |x^2 + y^2|^{1/2} \tag{3}$$

em que $|\dots|^{1/2}$ significa que se toma a raíz quadrada com sinal positivo. O ângulo do segmento OP com o eixo Ox, medido a partir do eixo Ox, no sentido positivo, que é o contrário ao dos ponteiros do relógio (counter-clockwise), define o argumento (argument):

$$\theta \equiv \arg(z) = \begin{cases} \operatorname{arc\,tan}(y/x) & x > 0, \\ \operatorname{arc\,tan}(y/x) + \pi & x < 0, \end{cases} \tag{4}$$

em que $-\pi/2 < \theta < \pi/2$ para $x > 0$ (semi-plano direito) e $\pi/2 < \theta < 3\pi/2$ para $x < 0$ (semi-plano esquerdo). Um *número complexo é representado univocamente pelo seu módulo (3)* $\rho \geqslant 0$ *e argumento (4)* $0 \leqslant \theta < 2\pi$; o argumento é indeterminado na origem $\rho = 0$, já que (4) depende da forma como $x,y \to 0$.

1.1.3 — Fórmula de Moivre (1730; Euler 1749)

Entre as partes real e imaginária, e o módulo e argumento de um complexo existem as seguintes relações (vide Figura 1):

$$x = \rho\cos\theta, \qquad y = \rho\sin\theta. \tag{5a,b}$$

Substituindo em (l):

$$z = \rho(\cos\theta + i\sin\theta) = \rho\, e^{i\theta} \tag{6}$$

em que usou a fórmula

$$\boxed{e^{i\theta} \equiv \cos\theta + i\sin\theta} \tag{7}$$

que será justificada ulteriormente (§ 5.5.1). *As expressões (1) e (6) são respectivamente a representação cartesiana* (cartesienne; cartesian) *e polar* (polaire; polar) *do complexo.* A passagem de representação cartesiana à polar é feita por (3,4), e a transformação inversa é (5a,b). O Jacobiano respectivo

$$\begin{vmatrix} \partial x/\partial\rho & \partial y/\partial\rho \\ \partial x/\partial\theta & \partial y/\partial\theta \end{vmatrix} = \begin{vmatrix} \cos\theta & \sin\theta \\ -\rho\sin\theta & \rho\cos\theta \end{vmatrix} = \rho \neq (0, \infty) \tag{8}$$

mostra que a transformação é *invertível excepto na origem (§ 1.1.2) e no infinito (§ 1.9), onde* θ *é indeterminado.*

1.1.4 — Conjugado e simetria na origem e eixos

O ponto simétrico de P em relação ao eixo real (axe réel; real axis) define o complexo conjugado:

$$z^* = x - iy = \rho\, e^{-i\theta}\,. \tag{9}$$

Note-se que a dupla aplicação do conjugado é idempotente:

$$(z^*)^* = z\,. \tag{10}$$

O simétrico de P em relação à origem (origine; origin) é o simétrico algébrico:

$$-z = -x - iy = \rho\, e^{i(\pi+\theta)}. \tag{11}$$

O simétrico em relação ao eixo imaginário (axe imaginaire; imaginary axis) é o conjugado do simétrico:

$$-z^* = -x + iy = \rho\, e^{i(\pi-\theta)}. \tag{12}$$

Convencionando que o primeiro quadrante se segue ao quarto conclui-se que (Figura 1) *os complexos z* (1,6), $-z^*$ (12), $-z$ (11) e z^* (9) *estão em quadrantes sucessivos.*

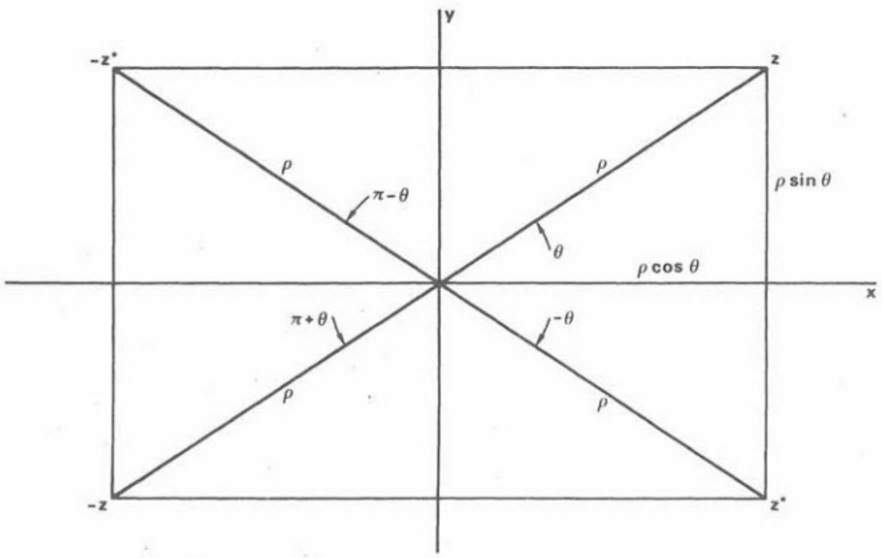

Fig. 1 — Representação de complexos no plano.

.A + / / "

1.2 — ESTABILIDADE DE UMA POSIÇÃO DE EQUILÍBRIO

Quando um corpo (ou sistema) se encontra numa posição (ou estado) de equilíbrio, e é perturbado podem verificar-se três casos: (i) o corpo permanece na posição perturbada, e o equilíbrio diz-se indiferente (indifferent); (ii) o corpo regressa à posição de equilíbrio que se diz estável (stable); (iii) o corpo afasta-se mais da posição de equilíbrio, que se diz instável (unstable). O afastamento ou aproximação da posição de equilíbrio, após a perturbação, pode ser monótono (monotone; monotonic) ou oscilatório (oscillatoire; oscilatory). Estes vários casos de movimento estão incluídos numa só expressão complexa.

1.2.1 — **Trajectória após afastamento da posição de equilíbrio**

Um corpo encontra-se na posição de equilíbrio caracterizada pela coordenada $x=0$. No instante $t=0$ é afastado para a posição x_o, e o seu movimento ulterior é dado pela lei:

$$\zeta = \omega + i\lambda : \; x(t) = \mathrm{Re}(x_o \, e^{i\zeta t}), \tag{1}$$

em que ζ é em geral complexo. Visto que **x** tem que ser real, tomou-se a parte real da expressão entre parêntesis; (1) é um exemplo de representação complexa de uma grandeza real. A representação complexa também pode ser usada para calcular a velocidade **v** e a aceleração **a**,

$$v(t) \equiv dx/dt = \mathrm{Re}(i\zeta x_o \, e^{i\zeta t}), \tag{2a}$$

$$a(t) \equiv dv/dt = d^2x/dt^2 = \mathrm{Re}(-\zeta^2 x_o \, e^{i\zeta t}). \tag{2b}$$

1.2.2 — **Corpo em repouso e equilíbrio indiferente**

Pretende-se agora analisar o movimento para todos os valores possíveis de ζ, e concluir da estabilidade da posição de equilíbrio $x=0$. O caso trivial (I) é $\zeta=0$, em que:

$$\zeta = 0; \quad x(t) = x_o, \quad v(t) = 0 = a(t), \tag{3a,b}$$

isto é *se $\zeta=0$, a posição de equilíbrio $x=0$ é indiferente, visto que o corpo uma vez afastado para x_o mantém-se em repouso na nova posição* (Figura 2a).

( )

1.3 — OPERAÇÕES ADIÇÃO E PRODUTO

As operações sobre números complexos são relações de dois pares ordenados de reais com um terceiro par ordenado de reais e são representáveis graficamente no plano complexo. Para a adição é mais conveniente a representação cartesiana, ao passo que a representação polar simplifica o cálculo do produto. As operações adição e produto, e as suas inversas subtracção e divisão podem ser usadas com o conjugado para determinar a parte real, imaginária, módulo ou argumento de expressões complexas.

1.3.1 — **Adição de complexos e regra do paralelogramo**

Dados dois números complexos na representação cartesiana:

$$u = a + ib, \qquad v = c + id \tag{1a,b}$$

define-se o resultado da operação adição como o complexo:

$$u + v = (a + c) + i\,(b + d) \tag{2}$$

obtido (Figura 3a) adicionando **u** e **v** como vectores, segundo a regra do paralelogramo. Logo, a parte real/imaginária da soma é a soma das respectivas partes real/imaginária:

$$\operatorname{Re}(u + v) = \operatorname{Re}(u) + \operatorname{Re}(v), \qquad \operatorname{Im}(u + v) = \operatorname{Im}(u) + \operatorname{Im}(v). \tag{3}$$

A operação adição de complexos tem as seguintes propriedades: (i) é fechada visto a soma de dois complexos ser um complexo; (ii) é comutativa e associativa:

$$u + v = v + u, \qquad (u + v) + w = u + (v + w); \tag{4}$$

(iii) tem elemento neutro, que é $0 + 0i$; (iv) todo o complexo $u = a + ib$, tem simétrico $-u = -a - ib$. Logo o *par ordenado (S, +) em que S é o conjunto dos complexos, e + a operação adição definida por (1a, b; 2) é um grupo abeliano.*

1.3.2 — **Módulo da soma e teorema de Pitágoras**

Calculando o módulo de $u + v$ (2), usando (1.1.3):

$$\begin{aligned}|u + v|^2 &= (a + c)^2 + (b + d)^2 = (a^2 + b^2) + (c^2 + d^2) + 2\,(ac + bd) = \\ &= |u|^2 + |v|^2 + 2\,|u|\,|v|\,(\cos\alpha\,\cos\beta + \sin\alpha\,\sin\beta),\end{aligned} \tag{5}$$

em que $\alpha = \arg(u)$, $\beta = \arg(v)$. Logo *o módulo da soma é dado pela fórmula:*

$$|u+v| = \{|u|^2 + |v|^2 + 2|u|\,|v| \cos(\alpha - \beta)\}^{1/2}, \tag{6}$$

que exprime (Figura 3c) o comprimento de um lado do triângulo em termos do comprimento dos outros dois lados, e do ângulo $\alpha - \beta$ entre eles. No caso de dois lados serem perpendiculares $\alpha - \beta = \pi/2$, e obtém-se:

$$\alpha - \beta = \pi/2: \quad |u+v|^2 = |u|^2 + |v|^2, \tag{7}$$

que é o *Teorema de Pitágoras para o triângulo rectângulo.*

1.3.3 — Produto de complexos, homotetia e rotação

Dados dois complexos na forma polar:

$$u = |u|\, e^{i\alpha}, \quad v = |v|\, e^{i\beta} \tag{8a,b}$$

define-se o produto como o complexo:

$$uv = |u|\,|v|\, e^{i(\alpha+\beta)}. \tag{9}$$

Logo, multiplicar o complexo **u** pelo complexo **v**, corresponde (Figura 3b) a: (i) multiplicar o módulo de **u** pelo de **v**, o que corresponde a uma extensão se $|v| > 1$, ou contracção se $|v| < 1$; (ii) adicionar ao argumento de **u** ao de **v**, o que corresponde a uma rotação no sentido positivo se $\beta > 0$, e negativo se $\beta < 0$:

$$|uv| = |u|\,|v|, \quad \arg(uv) = \arg(u) + \arg(v), \tag{10a,b}$$

Atendendo a que $|uv|/|v| = |u|/1$, e $\arg(u) = \arg(uv) - \arg(v)$, os triângulos de vértices (0, 1, u) e (0, v, uv) são semelhantes, isto é, têm ângulos internos iguais dois a dois e lados todos na mesma proporção. *O par ordenado (S, x), em que S é o conjunto dos complexos e x a operação produto definida por (8a,b; 9) é um grupo abeliano.* O elemento neutro é 1, e o inverso de u é 1/u (§ 1.3.5).

1.3.4 — Significado do símbolo imaginário

As partes real e imaginária (9) são dadas respectivamente por:

$$\begin{aligned} \mathrm{Re}(uv) = |u|\,|v| \cos(\alpha+\beta) &= |u| \cos\alpha\, |v| \cos\beta - \\ &- |u| \sin\alpha\, |v| \sin\beta = ac - bd, \end{aligned} \tag{11a}$$

$$\operatorname{Im}(uv) = |u|\,|v|\,\sin(\alpha+\beta) = |u|\,\sin\alpha\,|v|\,\cos\beta + {} + |u|\,\cos\alpha\,|v|\,\sin\beta = bc - ad; \tag{11b}$$

Logo o produto de complexos na forma cartesiana é:

$$(a+ib)\,(c+id) = (ac-bd) + i\,(ad+bc), \tag{12}$$

que corresponde à regra vulgar do produto desde que:

$$i^2 = -1, \quad \sqrt{-1} = \pm i\,. \tag{13a,b}$$

A condição (13a,b) a que satisfaz o símbolo imaginário i pode ser deduzida de $i \equiv e^{i\pi/2}$ logo $i^2 = e^{i\pi} = -1$.

1.3.5 — **Conjugado da soma, produto e inversão**

A partir de (2) e (12) verifica-se que o conjugado da soma/produto é a soma/produto dos conjugados:

$$(u+v)^* = u^* + v^*, \quad (uv)^* = u^*\,v^*. \tag{14a,b}$$

De (1.1.1,9) deduzem-se as seguintes fórmulas para a parte real e imaginária dum complexo:

$$x \equiv \operatorname{Re}(z) = (z+z^*)/2, \quad y \equiv \operatorname{Im}(z) = (z-z^*)/2i\,. \tag{15a,b}$$

De (1.1.6,9) deduzem-se fórmulas para o módulo e argumento:

$$\rho \equiv |z| \equiv (z\,z^*)^{1/2}, \quad \theta \equiv \arg(z) = \frac{1}{2}\arg(z/z^*)\,. \tag{16a,b}$$

O conjugado permite obter uma fórmula para o inverso de um complexo:

$$1/z = \rho^{-1}\,e^{-i\theta} = z^*/zz^* = z^*\,|z|^{-2}, \tag{17}$$

cujas partes real e imaginária são respectivamente:

$$\operatorname{Re}(1/z) = \rho^{-1}\cos\theta = x\,(x^2+y^2)^{-1/2}, \tag{18a}$$

$$\operatorname{Im}(1/z) = -\,\rho^{-1}\sin\theta = -\,y\,(x^2+y^2)^{-1/2}. \tag{18b}$$

1.3.6 — Representação complexa de grandezas reais

As fórmulas (15a,b) são o exemplo da representação de reais por meio de complexos. As representações complexas adicionam-se, por exemplo $x + iy = z$, mas o produto simplifica-se:

$$\frac{1}{2}(u + u^*)\,\frac{1}{2}(v + v^*) = \frac{1}{4}\{(uv + uv^*) + (uv + uv^*)^*\},$$

que corresponde a:

$$\mathrm{Re}(u)\,\mathrm{Re}(v) = \frac{1}{2}\,\mathrm{Re}(uv + uv^*). \tag{19}$$

Analogamente se demonstra que:

$$\mathrm{Im}(u)\,\mathrm{Im}(v) = \frac{1}{2}\,\mathrm{Re}(uv^* - uv), \tag{20}$$

$$\mathrm{Re}(u)\,\mathrm{Im}(v) = \frac{1}{2}\,\mathrm{Im}(uv - uv^*). \tag{21}$$

1.3.7 — Desigualdades incluindo a triangular de Schwartz

Elevando (15a,b) ao quadrado deduzem-se as desigualdades:

$$(z + z^*)^2 \geqslant 0 \geqslant (z - z^*)^2, \tag{22}$$

em que a primeira igualdade só se verifica **para z imaginário** puro e a **segunda para z** real. Atendendo a que $-1 \leqslant \cos(\alpha - \beta) \leqslant 1$, deduz-se de (6):

$$|u|^2 + |v|^2 - 2|u|\,|v| \leqslant |u + v|^2 \leqslant |u|^2 + |v|^2 + 2|u||v|,$$

que é a *desigualdade de Schwartz:*

$$|u| - |v| \leqslant |u + v| \leqslant |u| + |v|, \tag{23}$$

em que a *segunda igualdade se verifica se* $\arg(u) = \arg(v)$*, e a primeira se* $\arg(u) = \arg(v) + \pi$*. A interpretação geométrica (Figura 3c) é que o comprimento de um lado de um triângulo não excede a soma dos comprimentos dos outros dois, nem é inferior à sua diferença; a igualdade corresponde ao triângulo degenerado em segmento.*

This famous differential equation is called Bessel's equation. It has two linearly independent solutions, which we will study in some detail later:

$$R = G\,J_m(\rho) + H\,N_m(\rho) = G\,J_m(\alpha r) + H\,N_m(\alpha r). \qquad (2.4.10)$$

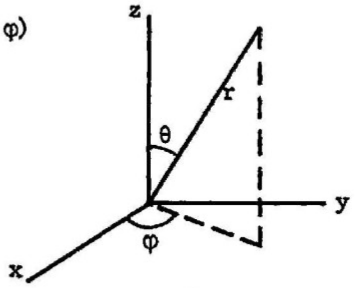
The special case $\alpha = 0$ deserves special mention. This arises in the case of z independent solutions of Laplace's equation, for which $\alpha = k = 0$. The equation for $R(r)$ reduces to

$$\frac{d^2R}{dr^2} + \frac{1}{r}\frac{dR}{dr} - \frac{m^2}{r^2} R = 0. \qquad (2.4.11)$$

One can easily find the elementary solutions of this equation:

$$R(r) = \begin{cases} Gr^m + Hr^{-m}, & m \neq 0, \\ G + H \ln r, & m = 0. \end{cases} \qquad (2.4.12)$$

2.5 SPHERICAL COORDINATES (r, θ, φ)



In spherical coordinates Helmholtz' equation assumes the form

$$\frac{1}{r}\frac{\partial^2}{\partial r^2}(ru) + \frac{1}{r^2 \sin\theta}\left[\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial u}{\partial\theta}\right) + \frac{1}{\sin\theta}\frac{\partial^2 u}{\partial\varphi^2}\right] + k^2 u = 0. \qquad (2.5.1)$$

We assume a separated solution of the form

$$u = R(r)\ Y(\theta,\varphi), \tag{2.5.2}$$

substitute in (2.5.1), divide by $u = RY$, and find

$$\frac{1}{R}\frac{1}{r}\frac{d^2}{dr^2}(rR) + \frac{1}{r^2}\frac{1}{Y\sin\theta}\left[\frac{\partial}{\partial\theta}(\sin\theta\frac{\partial Y}{\partial\theta}) + \frac{1}{\sin\theta}\frac{\partial^2 Y}{\partial\varphi^2}\right]$$
$$+ k^2 = 0. \tag{2.5.3}$$

The form of this equation implies

$$\frac{1}{Y}\frac{1}{\sin\theta}\left[\frac{\partial}{\partial\theta}(\sin\theta\frac{\partial Y}{\partial\theta}) + \frac{1}{\sin\theta}\frac{\partial^2 Y}{\partial\varphi^2}\right] = -\lambda \tag{2.5.4}$$

and

$$\frac{1}{R}\frac{1}{r}\frac{d^2}{dr^2}(rR) + k^2 - \frac{\lambda}{r^2} = 0, \tag{2.5.5}$$

where λ is a constant.

Consider first the radial equation (2.5.5). If $k^2 \neq 0$, let $r = \rho/k$ and rewrite the equation in the form

$$\frac{d^2R}{d\rho^2} + \frac{2}{\rho}\frac{dR}{d\rho} + (1 - \frac{\lambda}{\rho^2})R = 0. \tag{2.5.6}$$

This is almost Bessel's equation (2.4.9). To reduce it to the form of Bessel's equation, make the substitution

$$R = \frac{1}{\sqrt{\rho}}S. \tag{2.5.7}$$

After a short calculation one finds Bessel's equation for S:

$$\frac{d^2S}{d\rho^2} + \frac{1}{\rho}\frac{dS}{d\rho} + \left(1 - \frac{\lambda+\frac{1}{4}}{\rho^2}\right)S = 0. \tag{2.5.8}$$

Comparing with (2.4.9), (2.4.10) we see that this has the solution

$$S = A\,J_\beta(\rho) + B\,N_\beta(\rho) \quad , \quad \beta = \sqrt{\lambda+\tfrac{1}{4}}\,, \tag{2.5.9}$$

or equivalently

$$R = A\frac{1}{\sqrt{kr}}J_\beta(kr) + B\frac{1}{\sqrt{kr}}N_\beta(kr)\,. \tag{2.5.10}$$

For Laplace's equation, with $k^2 = 0$, the radial equation (2.5.5) is much simpler:

$$\frac{1}{r}\frac{d^2}{dr^2}(rR) - \frac{\lambda}{r^2}R = 0\,. \tag{2.5.11}$$

Assuming a solution of the form

$$R = r^\alpha, \tag{2.5.12}$$

one finds a quadratic equation for α with roots

$$\alpha = \frac{1}{2}\left(-1 \pm \sqrt{1+4\lambda}\right). \tag{2.5.13}$$

The general solution of (2.5.11) is then

$$R = Ar^{\alpha_1} + Br^{\alpha_2}, \tag{2.5.14}$$

where α_1, α_2 are the two roots (2.5.13).

Returning now to the angular equation (2.5.4), we separate again,

$$Y = P(\theta)\ \Phi(\varphi), \tag{2.5.15}$$

and obtain

$$\frac{1}{P}\frac{1}{\sin\theta}\frac{d}{d\theta}(\sin\theta\frac{dP}{d\theta}) + \frac{1}{\sin^2\theta}\frac{1}{\Phi}\frac{d^2\Phi}{d\varphi^2} + \lambda = 0, \tag{2.5.16}$$

which implies

$$\frac{1}{\Phi}\frac{d^2\Phi}{d\varphi^2} = -m^2 \tag{2.5.17}$$

and

$$\frac{1}{\sin\theta}\frac{d}{d\theta}(\sin\theta\frac{dP}{d\theta}) + (\lambda - \frac{m^2}{\sin^2\theta})P = 0. \tag{2.5.18}$$

The φ equation (2.5.17) has a simple solution

$$\Phi = Ae^{im\varphi} + Be^{-im\varphi}. \tag{2.5.19}$$

The θ equation (2.5.18) is Legendre's equation. To eliminate the trigonometric functions let $x = \cos\theta$. Equation (2.5.18) then assumes the form

$$\frac{d}{dx}\left[(1-x^2)\frac{dP}{dx}\right] + \left[\lambda - \frac{m^2}{1-x^2}\right]P = 0 \tag{2.5.20}$$

or

$$\frac{d^2P}{dx^2} - \frac{2x}{1-x^2}\frac{dP}{dx} + \frac{1}{1-x^2}\left[\lambda - \frac{m^2}{1-x^2}\right]P = 0, \tag{2.5.21}$$

which has two linearly independent solutions to be studied in detail later:

$$P = CP_\ell^m(x) + DQ_\ell^m(x) \quad , \quad \ell(\ell+1) = \lambda . \tag{2.5.22}$$

We have considered here only the three most common coordinate systems. Evidently the method can be employed in the case of the more exotic coordinate systems such as elliptic coordinates.

2.6 SERIES SOLUTIONS OF ORDINARY DIFFERENTIAL EQUATIONS: PRELIMINARIES

We have seen that the separation of variables procedure reduces a partial differential equation to ordinary differential equations. In some cases the ordinary differential equations were trivial. In sections 2.2 - 2.5 we came across two nontrivial cases: Bessel's equation (2.4.9) and Legendre's equation (2.5.21). For these and other cases we need a more general method of obtaining a solution.

We shall study the general class of second order linear differential equations of the form

$$\frac{d^2u}{dx^2} + p(x)\frac{du}{dx} + q(x)\,u = 0\,. \tag{2.6.1}$$

We restrict ourselves to the case of a real variable x and assume that in some region in x of interest p(x) and q(x) are analytic functions except for isolated poles. When we say that a function f(x) is analytic at a point x_o we shall mean that it can be expanded in a Taylor series

$$f(x) = \sum_{n=0}^{\infty} \frac{1}{n!} f^{(n)}(x)(x - x_o)^n \tag{2.6.2}$$

7.2 The Euler Equation in Streamline Coordinates

Consider a two-dimensional ideal-fluid flow on the (y, z)-plane shown in Fig. 7.1a, in which the solid lines with arrows represent streamlines. At a specific point of a stream line, the direction $\boldsymbol{s}$ is defined as the tangential direction of the streamline at that point. The direction $\boldsymbol{n}$ is perpendicular to $\boldsymbol{s}$ and points outward. The coordinate system spanned by $\{\boldsymbol{s}, \boldsymbol{n}\}$ is termed the *streamline coordinate system*. Taking inner product of the Euler equation with two infinitesimal vectors $\mathrm{d}\boldsymbol{s}$ and $\mathrm{d}\boldsymbol{n}$ yields

$$\begin{aligned} \mathrm{d}\boldsymbol{s} \cdot \left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla p + \rho \boldsymbol{b} \right), &\quad \longrightarrow \quad u_s \frac{\partial u_s}{\partial s} = -\frac{1}{\rho}\frac{\partial p}{\partial s} - g\frac{\partial z}{\partial s}, \\ \mathrm{d}\boldsymbol{n} \cdot \left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla p + \rho \boldsymbol{b} \right), &\quad \longrightarrow \quad \frac{u_s^2}{R} = \frac{1}{\rho}\frac{\partial p}{\partial n} + g\frac{\partial z}{\partial n}, \end{aligned} \tag{7.2.1}$$

if the gravitational acceleration g is the only body force, and the steady-flow assumption is used, where u_s and u_n are respectively the velocity components in the s- and n-directions, and R denotes the radius of curvature at the evaluation point on the streamline. Equation $(7.2.1)_2$ is obtained by the fact that the acceleration a_n that is experienced by a fluid element at the point is the inverse of centrifugal acceleration given by $a_n = -u_s^2/R$.

---

[2] Daniel Bernoulli, 1700–1782, a Swiss mathematician and physicist, who was one of the many prominent mathematicians in the *Bernoulli family*, with his main contributions in mathematics, mechanics, fluid mechanics, probability, and statistics.

[3] Although the term $\nabla\phi \cdot \nabla\phi$ in Eq. (7.1.4) is nonlinear, it places no difficulty in the analysis.

equally be determined in a simpler manner. The *Bernoulli equation*,[2] to be discussed in Sect. 7.3, is an integration form of the Euler equation give by

$$\frac{\partial \phi}{\partial t} + \frac{p}{\rho} + \frac{1}{2}\nabla\phi \cdot \nabla\phi - G = F(t), \tag{7.1.4}$$

which is shown here to demonstrate the solving procedure, where G is the potential function of the conservative body forces and $F(t)$ represents the *unsteady Bernoulli constant*. The pressure field can be determined by using this equation if ϕ is determined. Consequently, for ideal-fluid flows, instead of solving the equations of hydrodynamics directly, the pressure and velocity fields can be obtained in a simpler manner by using Eqs. (7.1.3) and (7.1.4). The study of ideal-fluid flows by using this simpler solving procedure is termed the *potential-flow theory*. When compared to the hydrodynamic equations, the features of potential-flow theory are twofold: First, Eq. (7.1.4) is linear, whereas Eq. $(7.1.1)_2$ is nonlinear.[3] Second, the *principle of superposition* can be used for linear equations to superimpose simple solutions to obtain solutions to complex circumstances. This latter feature will be used extensively in the analyses of two- and three-dimensional potential flows.

7.2 The Euler Equation in Streamline Coordinates

Consider a two-dimensional ideal-fluid flow on the (y, z)-plane shown in Fig. 7.1a, in which the solid lines with arrows represent streamlines. At a specific point of a stream line, the direction $\boldsymbol{s}$ is defined as the tangential direction of the streamline at that point. The direction $\boldsymbol{n}$ is perpendicular to $\boldsymbol{s}$ and points outward. The coordinate system spanned by $\{\boldsymbol{s}, \boldsymbol{n}\}$ is termed the *streamline coordinate system*. Taking inner product of the Euler equation with two infinitesimal vectors $\mathrm{d}\boldsymbol{s}$ and $\mathrm{d}\boldsymbol{n}$ yields

$$\begin{aligned} &\mathrm{d}\boldsymbol{s} \cdot \left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla p + \rho\boldsymbol{b}\right), \quad \longrightarrow \quad u_s\frac{\partial u_s}{\partial s} = -\frac{1}{\rho}\frac{\partial p}{\partial s} - g\frac{\partial z}{\partial s}, \\ &\mathrm{d}\boldsymbol{n} \cdot \left(\frac{\partial \boldsymbol{u}}{\partial t} + (\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\frac{1}{\rho}\nabla p + \rho\boldsymbol{b}\right), \quad \longrightarrow \quad \frac{u_s^2}{R} = \frac{1}{\rho}\frac{\partial p}{\partial n} + g\frac{\partial z}{\partial n}, \end{aligned} \tag{7.2.1}$$

if the gravitational acceleration g is the only body force, and the steady-flow assumption is used, where u_s and u_n are respectively the velocity components in the s- and n-directions, and R denotes the radius of curvature at the evaluation point on the streamline. Equation $(7.2.1)_2$ is obtained by the fact that the acceleration a_n that is experienced by a fluid element at the point is the inverse of centrifugal acceleration given by $a_n = -u_s^2/R$.

---

[2] Daniel Bernoulli, 1700–1782, a Swiss mathematician and physicist, who was one of the many prominent mathematicians in the *Bernoulli family*, with his main contributions in mathematics, mechanics, fluid mechanics, probability, and statistics.

[3] Although the term $\nabla\phi \cdot \nabla\phi$ in Eq. (7.1.4) is nonlinear, it places no difficulty in the analysis.

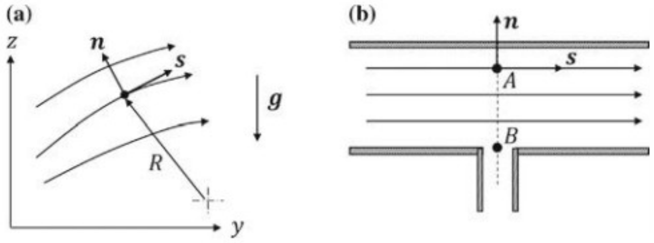

Fig. 7.1 Euler equation in a streamline coordinate system. **a** Illustration of the streamline coordinates. **b** Equivalence between the pressures at point A and point B in view of the Euler equation

The implications of Eq. (7.2.1) are straightforward. For example, consider a steady ideal-fluid flow along a horizontal streamline, for which the Euler equation in the s-direction reduces to

$$u_s \frac{\partial u_s}{\partial s} = -\frac{1}{\rho} \frac{\partial p}{\partial s}. \tag{7.2.2}$$

This equation indicates that a negative pressure gradient in the s-direction is required to have a positive velocity increase and vice versa. On the other hand, if the pressure is maintained as a constant along a streamline which has an elevation difference (i.e., z is not a constant), Eq. $(7.2.1)_1$ reduces to

$$u_s \frac{\partial u_s}{\partial s} = -\frac{\partial z}{\partial s}. \tag{7.2.3}$$

Similarly, in order to have a positive velocity increase, a negative elevation gradient in the s-direction is required. Without solving the Euler equation directly, Eqs. (7.2.2) and (7.2.3) deliver the important physical features of ideal-fluid flows which are summarized as follows:

- A fluid tends to flow locally from a high-pressure region to a low-pressure region.
- A fluid tends to flow locally from a high-elevation region to a low-elevation region.

For circumstances in which both elevation and pressure gradients present, the flow direction is determined by the relative significance between the pressure and gravitation forces. Although the above conclusions are obtained for ideal-fluid flows, they can equally be extended *qualitatively* for viscous fluid flows, except that the influence of viscous force needs to be taken into account.

For a steady horizontal streamline, the Euler equation in the n-direction reduces to

$$\frac{\partial p}{\partial n} = -g \frac{\partial z}{\partial n}, \tag{7.2.4}$$

which corresponds exactly to the hydrostatic equation given in Sect. 3.1. If the gravitational acceleration is further assumed to point in the x-direction (i.e., the direction perpendicular to the page), this equation is simplified to

$$\frac{\partial p}{\partial n} = 0, \tag{7.2.5}$$

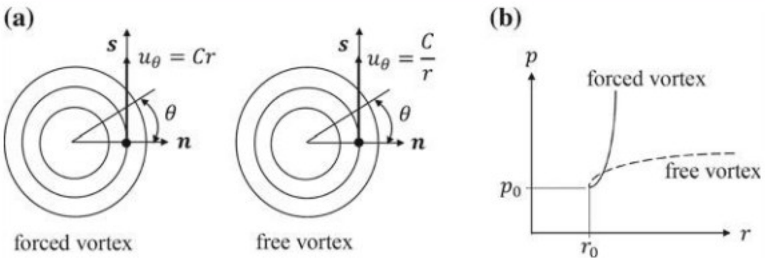

Fig. 7.2 Applications of the Euler equation in a streamline coordinate system. **a** Two-dimensional forced and free vortices. **b** The radial pressure distributions of two vortices

indicating that there exists no pressure variation in the n-direction. This equation provides the theoretical foundation of pressure measurement. For example, consider a two-dimensional flow shown in Fig. 7.1b, in which the gravitational acceleration points perpendicularly to the page. The pressure at point A is exactly the same as that at point B, which can be measured by using e.g. a manometer connected to the wall. However, caution must be made to ensure that the tube of manometer should strictly be perpendicular to the wall with completely flat connecting surfaces. If it is not the case, then at the connection region there exists a non-vanishing R, giving rise to a non-vanishing value of u_s^2/R on the left-hand-side of Eq. $(7.2.1)_2$. In this case, the pressure at point A is no longer the same as the pressure at point B.

Applications of the Euler equation in a streamline coordinate system are demonstrated in Fig. 7.2a by studying e.g. the pressure distributions of a two-dimensional forced and a free vortices, in which the gravitational acceleration points perpendicularly to the page. The pressure variations in the forced and free vortices are described by using the Euler equation in the radial direction given respectively by

$$\frac{\partial p}{\partial r} = \rho C^2 r, \qquad \frac{\partial p}{\partial r} = \frac{\rho C^2}{r^3}, \tag{7.2.6}$$

showing that the pressure variation in a forced vortex is proportional to r, while that in a free vortex is proportional to r^{-3}. Integrating these equations yields

$$p - p_0 = \frac{1}{2}\rho C^2 (r - r_0^2), \qquad p - p_0 = \frac{1}{2}\rho C^2 \left(\frac{1}{r_0^2} - \frac{1}{r^2} \right), \tag{7.2.7}$$

where the reference point is taken at $r = r_0$ with $p = p_0$, i.e., the atmospheric pressure. These results are illustrated graphically in Fig. 7.2b. Applying Eq. (7.2.7) to the free surfaces of two vortices gives rise respectively to

$$\frac{1}{2}\rho C^2 (r - r_0^2) = 0, \qquad \frac{1}{2}\rho C^2 \left(\frac{1}{r_0^2} - \frac{1}{r^2} \right) = 0, \tag{7.2.8}$$

which are the equations of free surfaces. The first equation corresponds to the free surface of a fluid in rigid rotational motion described in Sect. 3.5. Although these two equations have singular points, they serve as the simplest models to demonstrate qualitatively the features of forced and free vortices.[4]

---

[4] The singular point of a forced vortex occurs at $r \to \infty$, while that of a free vortex occurs at $r \to 0$.

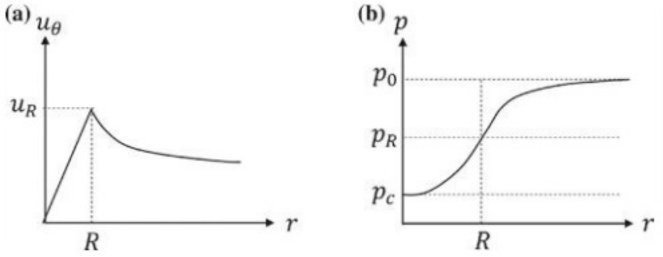

Fig. 7.3 Characteristics of a Rankine vortex in the radial direction. **a** Distribution of the tangential velocity. **b** Distribution of the thermodynamic pressure

A *Rankine vortex* is a combination of a forced vortex in the inner part and a free vortex in the outer part,[5] with the distributions of tangential velocity and pressure shown in Fig. 7.3, where p_c is the pressure at the vortex center, u_R represents the maximum tangential velocity with pressure p_R, and p_0 denotes the surrounding (atmospheric) pressure. The Rankine vortex is the simplest model to describe the features of a typhoon and can be used as a first engineering approximation to estimate the wind loads on structures due to the occurrence of a typhoon. In this circumstance, u_R is used to estimate the typhoon intensity, and R corresponds nearly to the edge of typhoon eye. It follows from the Euler equation that moist air flows from the surrounding toward the center of a typhoon, with the flow direction deflected to the right by the Coriolis force in the Northern Hemisphere, causing a typhoon to rotate counterclockwise. On the contrary, the flow direction is deflected to the left in the Southern Hemisphere, and a typhoon rotates clockwise. During the inward motion, the moist air experiences equally an upward motion to reach the top of a typhoon. Since the atmospheric temperature in high elevation is lower than that near the sea surface, it is likely possible that condensation of water vapor contained in the moist air takes place. The latent heat released by the condensation process provides an energy supply to maintain or even enhance the rotational motion of a typhoon, until all supplied energies are dissipated by the viscous and other effects.

7.3 The Bernoulli Equation

7.3.1 General Formulation

For the Newtonian fluids with constant density and dynamic viscosity, the Navier-Stokes equation with vanishing viscous force reads

$$\rho\frac{\partial \boldsymbol{u}}{\partial t} + \rho(\boldsymbol{u}\cdot\nabla)\boldsymbol{u} = -\nabla p + \rho\nabla G, \tag{7.3.1}$$

---

[5] William John Macquorn Rankine, 1820–1872, a Scottish mechanical engineer, who made contributions to various fields, and together with Rudolf Clausius and William Thomson, founded first law of thermodynamics.

where the body force per unit mass is considered a *conservative field* with its corresponding scalar potential given by G, i.e., $\boldsymbol{b} = \nabla G$. For example, the gravitational acceleration is a conservative force field, which can be determined by the gradient of gravitational potential energy per unit mass. Since

$$(\boldsymbol{u} \cdot \nabla)\boldsymbol{u} = \nabla\left(\frac{1}{2}\boldsymbol{u} \cdot \boldsymbol{u}\right) - \boldsymbol{u} \times \boldsymbol{\omega}, \tag{7.3.2}$$

where $\boldsymbol{\omega} = \nabla \times \boldsymbol{u}$, substituting this expression into Eq. (7.3.1) yields

$$\frac{\partial \boldsymbol{u}}{\partial t} + \nabla\left(\frac{1}{2}\boldsymbol{u} \cdot \boldsymbol{u}\right) - \boldsymbol{u} \times \boldsymbol{\omega} = -\frac{1}{\rho}\nabla p + \nabla G. \tag{7.3.3}$$

Taking inner product of this equation with a line element of a space curve, $\mathrm{d}\boldsymbol{\ell}$, gives

$$\frac{\partial \boldsymbol{u}}{\partial t} \cdot \mathrm{d}\boldsymbol{\ell} + \mathrm{d}\left(\frac{1}{2}\boldsymbol{u} \cdot \boldsymbol{u}\right) + \frac{\mathrm{d}p}{\rho} - \mathrm{d}G = (\boldsymbol{u} \times \boldsymbol{\omega}) \cdot \mathrm{d}\boldsymbol{\ell}, \tag{7.3.4}$$

along the tangential direction at a specific point on the space curve ℓ, where $\mathrm{d}\alpha$ denotes the total derivative of any quantity α. This equation is referred to as the *differential Bernoulli equation* or the *differential Bernoulli integral* for frictionless flow. Although Eq. (7.3.4) originates from the Euler equation, it is in fact a scalar equation denoting an energy balance, for each term represents a kind of energy. Integrating Eq. (7.3.4) results in

$$\int \frac{\partial \boldsymbol{u}}{\partial t} \cdot \mathrm{d}\boldsymbol{\ell} + \frac{1}{2}\boldsymbol{u} \cdot \boldsymbol{u} + \int \frac{\mathrm{d}p}{\rho} - G = \int (\boldsymbol{u} \times \boldsymbol{\omega}) \cdot \mathrm{d}\boldsymbol{\ell}, \tag{7.3.5}$$

which is termed the *Bernoulli equation* or the *Bernoulli integral* for frictionless flows along an arbitrary curve in space.

Several important simplifications to Eq. (7.3.5) can be made, which are explored in the following.

- For steady and incompressible flows along a streamline, Eq. (7.3.5) reduces to

  $$\frac{u^2}{2} + \frac{p}{\rho} - G = \mathcal{C}, \qquad u = \|\boldsymbol{u}\|, \tag{7.3.6}$$

  for $\boldsymbol{u}$ is in parallel with $\mathrm{d}\boldsymbol{\ell}$, giving rise to a vanishing value of $(\boldsymbol{u} \times \boldsymbol{\omega}) \cdot \mathrm{d}\boldsymbol{\ell}$. The term $\mathcal{C}$ is an integration constant, called the *Bernoulli constant*, which is different in different streamlines. Obviously, the right-hand-side of Eq. (7.3.5) vanishes equally if the flow is irrotational. For such a circumstance, $\mathrm{d}\boldsymbol{\ell}$ represents then a line element of any curve in space, which is not necessary a streamline. If the flow experiences both the gravitational acceleration $\boldsymbol{g} = \|g\|$ and a concentric acceleration $r\omega^2$ with r the radius and ω the angular speed, the scalar potential G is then given by

  $$G = -gz + \frac{r^2\omega^2}{2}, \tag{7.3.7}$$

  with which Eq. (7.3.6) becomes

  $$\frac{u^2 - r^2\omega^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}, \tag{7.3.8}$$

where z is the elevation. If the fluid experiences no rotational motion, the above equation is simplified to

$$\frac{u^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}, \tag{7.3.9}$$

which is the most common form of the Bernoulli equation, being valid for every point on a streamline. This equation indicates that the total mechanical energy, including the kinetic energy $u^2/2$, pressure energy p/ρ, and potential energy gz per unit mass, should be a constant through the entire streamline. From this perspective, Eq. (7.3.9) represents the simplest conservation of energy of fluid flows and provides a transformation rule for mechanical energy of steady, ideal-fluid flows along a streamline. The equivalent expressions of Eq. (7.3.9) are given by

$$\frac{u^2}{2g} + \frac{p}{\gamma} + z = \mathcal{C}, \qquad \frac{\rho u^2}{2} + p + \rho g z = \mathcal{C}. \tag{7.3.10}$$

- For steady and compressible flows along a streamline, Eq. (7.3.5) reduces to

$$\frac{u^2 - r^2\omega^2}{2} + \int \frac{\mathrm{d}p}{\rho} + gz = \mathcal{C}. \tag{7.3.11}$$

Further simplifications to this equation become possible if the relations between ρ and p are prescribed. For example, consider an ideal gas characterized by $p = C\rho^\gamma$, where C is a constant and γ denotes the specific-heat ratio. Substituting this expression into the above equation yields

$$\frac{u^2 - r^2\omega^2}{2} + \frac{\gamma}{\gamma - 1}\frac{p}{\rho} + gz = \mathcal{C}, \tag{7.3.12}$$

which is different from Eq. (7.3.8) for incompressible flows due to the amount of energy stored in pressure form. The difference becomes more obvious if Eqs. (7.3.8) and (7.3.12) are expressed in terms of the Mach number $\mathcal{M}_a$ given respectively by[6]

$$\frac{p_2 - p_1}{p_1} = \frac{\gamma(\mathcal{M}_a)_1^2}{2}; \quad \frac{p_2 - p_1}{p_1} = \frac{\gamma(\mathcal{M}_a)_1^2}{2}\left(1 + \frac{1}{4}(\mathcal{M}_a)_1^2 + \frac{2-\gamma}{24}(\mathcal{M}_a)_1^4 + \cdots\right), \tag{7.3.13}$$

between any two points 1 and 2 on a streamline without the contributions of concentric acceleration, where $(\mathcal{M}_a)_1$ represents the Mach number at point 1. For air, $\gamma = 1.4$, and it is ready to verify that the pressure energy stored in a compressible flow is larger than that in an incompressible flow. However, the difference is nearly 2% when $(\mathcal{M}_a)_1 = 0.3$. For larger values of $(\mathcal{M}_a)_1$, the disagreement between Eqs. $(7.3.13)_1$ and $(7.3.13)_2$ becomes obvious. These results imply that compressible flows can be approximated by using the theory of incompressible flows if the Mach number does not exceed 0.3.

---

[6] A more detailed discussion will be provided in Sect. 9.3.4.

Table 7.1 Different forms of the Bernoulli equation with the corresponding restrictions under conservative body forces

Form	Restrictions
$\int \frac{\partial \boldsymbol{u}}{\partial t} \cdot \mathrm{d}\boldsymbol{\ell} + \frac{1}{2}\boldsymbol{u} \cdot \boldsymbol{u} + \int \frac{\mathrm{d}p}{\rho} - G = \int (\boldsymbol{u} \times \boldsymbol{\omega}) \cdot \mathrm{d}\boldsymbol{\ell}$	F
$\frac{u^2 - r^2\omega^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}$	F + I + S + L
$\frac{u^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}$	F + I + S + L (gravitational field)
$\frac{u^2 - r^2\omega^2}{2} + \int \frac{\mathrm{d}p}{\rho} + gz = \mathcal{C}$	F + S + L
$\int \frac{\partial u}{\partial t}\mathrm{d}\ell + \frac{u^2 - r^2\omega^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}$	F + I + L
$\frac{\partial \phi}{\partial t} + \int \frac{\mathrm{d}p}{\rho} + \frac{1}{2}\nabla\phi \cdot \nabla\phi - G = F(t)$	F + IR

F: frictionless flows, I: incompressible flows, IR: irrotational flows, S: steady flows, L: along a streamline

- For unsteady and incompressible flows along a stream line, Eq. (7.3.5) reduces to

$$\begin{aligned} &\int \frac{\partial u}{\partial t}\mathrm{d}\ell + \frac{u^2 - r^2\omega^2}{2} + \frac{p}{\rho} + gz = \mathcal{C}, \\ &\int_1^2 \frac{\partial u}{\partial t}\mathrm{d}\ell + \frac{(u_2^2 - r_2^2\omega^2) - (u_1^2 - r_1^2\omega^2)}{2} + \frac{p_2 - p_1}{\rho} + g(z_2 - z_1) = 0, \end{aligned} \tag{7.3.14}$$

  which should be evaluated between any two points 1 and 2 on a streamline.
- For unsteady and irrotational flows, the right-hand-side of Eq. (7.3.5) vanishes identically, and the equation reduces to

$$\frac{\partial \phi}{\partial t} + \int \frac{\mathrm{d}p}{\rho} + \frac{1}{2}\nabla\phi \cdot \nabla\phi - G = F(t), \tag{7.3.15}$$

  where $\boldsymbol{u} = \nabla\phi$ is used for irrotational flows with ϕ the velocity potential function, and $F(t)$ is termed the unsteady Bernoulli constant, even though it is not strictly a constant.

Table 7.1 summarizes different forms of the Bernoulli equation with the corresponding restrictions. The restriction “along a streamline” can be removed if the flow is irrotational. In that circumstance, the Bernoulli equation can be used between any two points on any curve in space.

The Bernoulli equation is frequently used to estimate the energy loss between any two points of a flow. The difference in total mechanical energies between any two points is defined as the energy loss in-between. For example, consider water flowing through a valve. Let point 1 be located before the valve and point 2 be located after the valve. The energy loss of water passing the valve per unit mass, ΔE, is then obtained as

$$\Delta E = \left(\frac{p_1}{\rho} + \frac{u_1^2}{2} + gz_1\right) - \left(\frac{p_2}{\rho} + \frac{u_2^2}{2} + gz_2\right), \tag{7.3.16}$$

for a steady, incompressible flow along a streamline with the gravitational field. It is noted that this equation only provides the general concept of energy loss. For viscous flows, it should be revised to take into account the influence of non-uniform velocity distributions in laminar and turbulent flows on the estimations on the kinetic energy. The topic will be discussed in Sect. 8.6.8.

7.3.2 Static, Dynamic, and Stagnation Pressures

The pressure in the Bernoulli equation is termed the thermodynamic pressure or static pressure. Instead of expressing the pressure as a gage one in determining the hydrostatic force on a submerged surface described in Sect. 3.2, in applying the Bernoulli equation the pressure needs to be expressed as an absolute value, for it represents a kind of energy stored in the fluid. The term $\rho u^2/2$ is called the *dynamic pressure*, which is an equivalent pressure due to the presence of fluid velocity. The sum of static and dynamic pressures is called the *stagnation pressure* p_s given by

$$p_s = p + \frac{1}{2}\rho u^2. \tag{7.3.17}$$

The stagnation pressure is interpreted as the pressure that a fluid element, initially associated with a velocity in an ideal fluid, experiences if it is brought to rest *isentropically*, in which the entropy of fluid remains unchanged. In such a process, the kinetic energy of a fluid element is converted completely to a form of pressure. For viscous-fluid flows, a moving fluid element experiences equally a pressure which is larger than the static pressure when it is brought to rest. However, this larger pressure is not the stagnation pressure, for the process is not isentropic, and only a part of the kinetic energy is converted to a form of pressure, while the other part is converted to heat due to the dissipative viscous effects.

The static and stagnation pressures of a fluid can be measured by e.g. a *Pitot tube* shown in Fig. 7.4a, which is a combination of two concentric circular tubes with the inner tube open in the front and outer tube having small open holes on the sides. The static pressure is measured at point B, while the stagnation pressure is measured at point A. It is possible to connect these two points with a regular manometer, with which the fluid velocity can be determined by

Maths

Elusive mystery of the number 42 solved

IT MIGHT not tell us the meaning of life, the universe and everything, but mathematicians have cracked a tricky problem involving the number 42.

The origins of this puzzle go back a long way. In 1825, a mathematician known as S. Ryley proved that any fraction could be represented as the sum of three cubes of fractions. Then, in the 1950s, a mathematician named Louis Mordell asked whether the same could be done for integers, or whole numbers.

In other words, are there whole numbers k, x, y and z such that $k = x^3 + y^3 + z^3$ for each possible value of k? It is an example of a maths riddle that is easy to state but fiendishly difficult to solve.

Andrew Booker at the University of Bristol, UK, and Andrew Sutherland at the Massachusetts Institute of Technology have now solved the problem for 42, the only number under 100 for which a solution hadn't been found.

"It is an example of a maths riddle that is easy to state but fiendishly difficult to solve"

Some numbers have simple solutions. The number 3, for example, can be expressed as $1^3 + 1^3 + 1^3$ and $4^3 + 4^3 + (-5)^3$. But solving the problem for other numbers requires vast strings of digits and computing power.

The solution for 42, which Booker and Sutherland found using an algorithm, is:

$42 = (-80538738812075974)^3 + 80435758145817515^3 + 12602123297335631^3$.

They worked with software firm Charity Engine to run the program across more than 400,000 volunteers' idle computers, using processing power that would otherwise be wasted. It is equivalent to a single computer processor running continuously for more than 50 years, says Sutherland.

Earlier this year, Booker found a sum of cubes for the number 33, which was previously the lowest unsolved example.

We know for certain that some whole numbers, such as 4, 5 and 13, can't be expressed as the sum of three cubes. However, the problem is still unsolved for 10 numbers under 1000, the smallest of which is 114.

The team will next search for another solution to the number 3. "It's possible we'll find it in the next few months; it's possible it won't be for another 100 years," says Booker.

Those interested in aiding the search can volunteer computing power through Charity Engine, says Sutherland. ▮

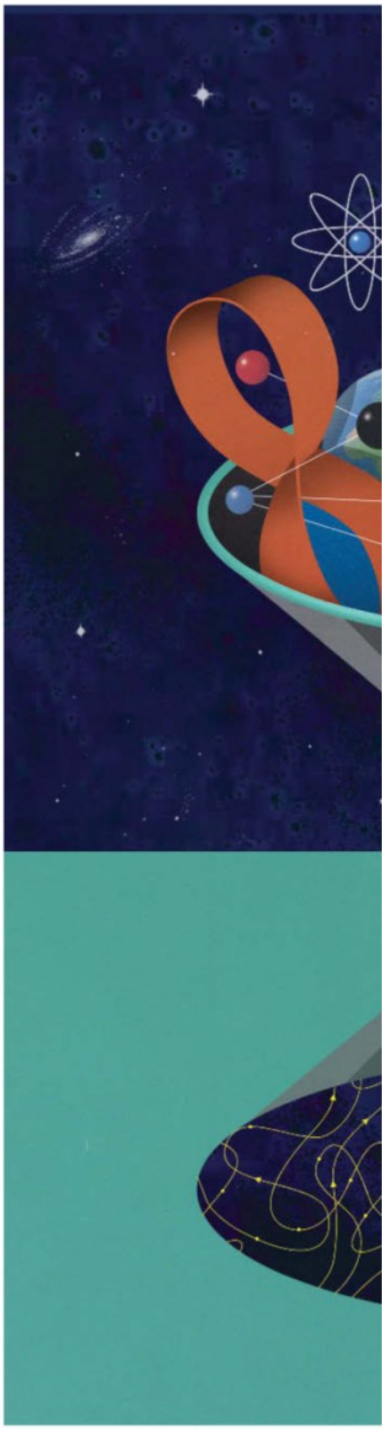
Woven from weirdness

The true origins of space-time, the backdrop to reality, are hidden in the quantum realm, writes physicist **Sean Carroll**



BRETT RYDER

LET'S say you want to meet a friend for coffee. You have to tell them where you are going to be – your location in space – but you also need to let them know when. Both bits of information are necessary because we live in a four-dimensional continuum: three-dimensional space and everything within it, from steaming coffee machines to stars exploding in faraway galaxies, all happening at different moments of one-dimensional time.

"Space-time" is simply the physical universe inside which we and everything else exists. And yet, even after millennia living in it, we still don't know what space-time actually is. Physicists have strived to work it out for more than a century. In recent years, many of us have been trying to figure out what might be the threads from which the fabric of reality is woven. We have ideas, each with its own selling points and shortcomings. But for my money, the most exciting one is the most surprising.

It is the idea that space-time emerges from a weird property of the quantum world that means particles and fields, those fundamental constituents of nature, can be connected even if they are at opposite ends of the universe. If that is correct, we might finally have found a bridge between the two irreconcilable totems of physics, placing us on the threshold of a theory of quantum gravity. We would also have the most startling demonstration yet that the world we see isn't the world as it is – that there is always "something deeply hidden", as Albert Einstein put it – and that the only way to understand the fundamental nature of reality is by confronting quantum mechanics head-on.

Space-time is a relatively new notion. Isaac Newton had no need for it. For him, space and time were individually real and absolute. Only when Einstein formulated his special theory of relativity in 1905 did the two start to come together. He showed that different observers will generally divide space-time into "space" and "time" in different, incompatible ways; what is "space" and what is "time" are relative to how an observer is moving.

Various thinkers had previously speculated that the two should be rolled together. In Edgar Allan Poe's 1848 prose poem *Eureka*, for instance, he wrote that "space and duration are one." But it wasn't until 1908 that mathematician Hermann Minkowski unified them in a scientific way. He dramatically proclaimed: "Henceforth, space for itself, and time for itself, shall completely reduce to a mere shadow, and only some sort of union of the two shall preserve independence."

Einstein was unimpressed, grumbling about "superfluous learnedness". But he eventually came round to the idea, putting the geometry

Hear the latest incredible ideas in Big Physics on the Cosmology stage at New Scientist Live, from 10 to 13 October

Sean Carroll is a physicist at the California Institute of Technology. His most recent book is *Something Deeply Hidden: Quantum Worlds and the Emergence of Spacetime*

"How in the world can space-time exist in a superposition of various possibilities?"

of space-time firmly at the heart of his general relativity. It said that space-time isn't merely a static background in which things happen. It is a dynamic entity, warping and stretching under the influence of mass and energy. The curvature of space-time manifests itself to us as the force of gravity.

Still, it would seem weird to ask what space-time is "made of" in classical physics. In general relativity, space-time changes over time in response to other stuff. But it is still a background, and a fundamental constituent of nature. It isn't made of anything; it just "is".

The problems with that view started with the discovery of quantum mechanics, the rules that govern the behaviour of subatomic particles and fields. Scientists haven't been able to construct a quantum-mechanical theory of gravity as they have for the three other fundamental forces of nature. Part of the issue is technical: when we try to make classical general relativity into a quantum-mechanical theory using standard techniques, our equations blow up and we get nonsensical answers. But part of it is conceptual.

Quantum mechanics tells us that systems exist in superpositions of different measurable quantities like position and velocity. There is no such thing as "the position" of a quantum particle; there are many possible positions, ›

ENTANGLED TIME

In the quest to figure out what lies behind the backdrop to reality we call space-time, we have begun to grasp how the space part can emerge from quantum entanglement (see main story). Time is a different story. But there is one way to derive the fourth dimension from the same phenomenon.

It was suggested back in 1983 by Don Page, now at the University of Alberta in Canada, and William Wootters at Williams College in Williamstown, Massachusetts. In quantum mechanics, if a system can be in various different states, we can add those states together in any combination to create new states, superpositions of the originals. An electron, for example, can be spinning clockwise or counterclockwise, but it can also be in a superposition of both.

With that in mind, consider a quantum system consisting of two subsystems: one is a clock and the other is everything else. Let the system as a whole evolve through time, so that the clock reads differently at each moment. Now take a series of such moments, say one per second, and add together all the specific quantum states at all the moments—all the ways the world actually was at each reading of the clock.

This gives you a new super-state, a superposition of individual states with specific clock readings and specific configurations of everything else. It doesn't evolve with time. But because this is a quantum system, the clock is entangled with the rest of the world. And if we were to measure the clock to see what it read, the rest of the system would instantly snap into whatever quantum state the original system had at that corresponding time.

In this way, time can appear to emerge even in an unchanging quantum state. The key is entanglement; all we need is a clock subsystem that is entangled with the rest of the universe in the right way. Time is just what your clock reads.

which take on definite values only when we observe them. How in the world can space-time exist in a superposition of different possibilities? That would make it impossible to say for sure that a certain event happened at a definite location in space and time.

Physicists of different persuasions have taken different approaches to constructing a solution in the form of a theory of quantum gravity. The most popular is string theory, which replaces particles with loops and segments of vibrating string. String theory successfully produces a quantum version of gravity, but not one that connects with our world in an obvious way. Nor does it resolve those fundamental conceptual problems. String theory's leading rival, loop quantum gravity, is an attempt to directly quantise general relativity. Loop proponents typically take the conceptual challenges of quantum gravity more seriously than their stringy colleagues, but the challenges remain.

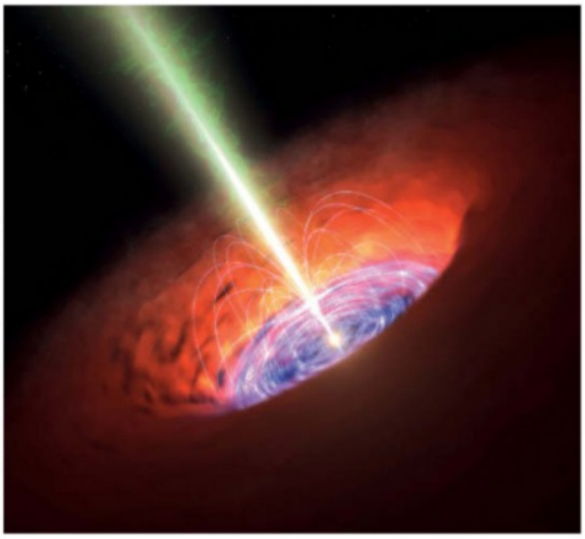
This has led some physicists to take a step back and ask the question in a different way. The standard approach to developing a quantum description of some phenomenon, like the electromagnetic field or a collection of atoms, is to start with a classical description and then "quantise" it. That approach has failed again and again when it comes to gravity and space-time. It also isn't how nature works. The real world doesn't start classically and then somehow quantise. It is quantum from the start, and the classical world emerges as an approximation.

So maybe we shouldn't be trying to quantise gravity at all. Perhaps we should instead formulate a quantum theory from the start, and then show how classical space-time emerges from that. It is a new approach that has dramatic consequences for how we think about what space-time itself is made of.

Spooky action

To make progress in this direction, it is helpful to start with our current best physical theory, which is quantum field theory. According to this theory, the fundamental ingredients of the world are fields, such as the electric and magnetic fields. Even particles like electrons and quarks are simply vibrations

"Maybe it was a mistake to quantise gravity, and space-time was lurking in quantum mechanics all along"



L. CALCADA/EUROPEAN SOUTHERN OBSERVATORY/SCIENCE PHOTO LIBRARY

Black holes give us reason to think space can emerge like a hologram

in fields that stretch through space.

Classically, we can specify the value of a field in an approximate fashion by dividing space into tiny regions, then listing the value of the field in each region. Once we graduate to quantum field theory, an extra feature comes into the game: the values of the field in different regions can be entangled with each other. Due to quantum uncertainty, we don't know exactly what answer we will get if we measure the field at some location, but entanglement means the answer we get at one point will affect what we would measure at any other point.

In the vacuum state of an ordinary quantum field theory – empty space, no particles flying around – the entanglement between fields in different regions is directly tied to the distance between them, and therefore to the geometry of space-time. Nearby regions are highly entangled with each other, while faraway regions share little entanglement.

This suggests an intriguing way to reverse our normal way of thinking and so find space-time within quantum theory. Let us imagine starting with just a quantum state, no pre-existing notion of space-time. Now we can try to work backwards, to extract space-time from entanglement.

If in ordinary physics the entanglement between two regions goes down as the regions get further apart, let us imagine defining the distance as (inversely) related to the entanglement. In that case, having a quantum state automatically gives us the "distance" between any two parts of it, and therefore defines a geometry on this emergent space.

So far so good. But a quantum state exists at each moment of time, so at best it can define the geometry of space at that moment. We want to extend this to four-dimensional space-time.

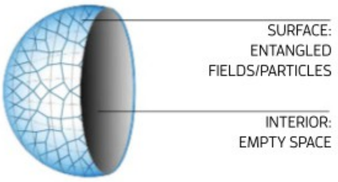
Thankfully, here we can borrow a trick from physicist Ted Jacobson at the University of Maryland, who, in 1995, showed how we could derive Einstein's equation for general relativity from simple assumptions about the relationship between entropy and geometry.

Entropy, a measure of disorder, is directly related to entanglement: the more entangled a region is with the rest of the world, the more entropy it contains. Einstein said that it is adding matter or energy to a region that causes space-time to curve. Jacobson showed that increasing the entanglement of a region can have the same effect, if we insist that the amount of entropy must be proportional to the area bounding that region. That is automatically true in empty space, but Jacobson suggested that it remains true even when space isn't empty. You can try to add more entanglement, but space-time will bend to compensate, so that entropy always remains proportional to area.

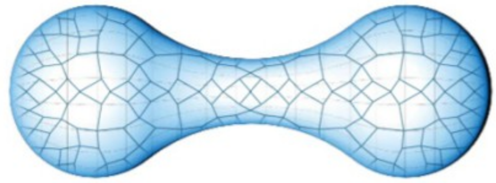
Quantum gum

Space-time might be woven from quantum entanglement

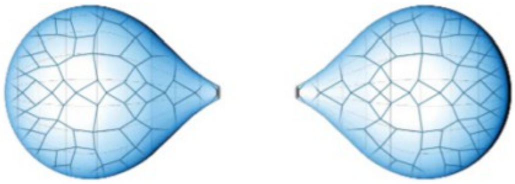
In a model universe, the equations describing gravity in a volume of space are equivalent to those describing the surface of that volume, which don't include gravity. This suggests space on the inside somehow emerges from the properties of the outside, namely entanglement



Sure enough, when you reduce the entanglement connecting two regions of the outside surface, the space inside pulls apart as if pulling at two ends of a piece of chewing gum



If you eliminate all entanglement, the space inside splits in two, suggesting that entanglement is the thread that binds space-time



Essence of reality

So Einstein says that energy causes curvature, while Jacobson says entanglement does. But Jacobson also argued that it is really the same thing: whenever you add entanglement, energy necessarily follows. From this logic, he was able to derive that the curvature of space-time in his approach obeyed the same equation that Einstein first wrote down for general relativity. Gravity, it appears, can arise from entanglement, rather than directly from mass and energy. This remarkable result was the beginning of what is now called "thermodynamic" or "entropic" gravity.

But it doesn't quite get us to where we need to be. In deriving his alternative picture of where gravity comes from, Jacobson assumed a classical space-time and imagined that there were quantum fields living within it. Ideally, we would like to keep everything quantum from the start and derive the existence of space-time itself. This is something I recently attempted with my collaborators, ChunJun (Charles) Cao and Spiros Michalakis at the California Institute of Technology. Rather than starting with vibrating quantum fields living in space-time, we started with completely abstract quantum "degrees of freedom".

This is just some quantity that can take on different values, independently of other quantities. In Newtonian mechanics, the degrees of freedom are positions and velocities of particles; in field theory, they are the values and rates of change of the fields. In our approach, the degrees of freedom don't have any direct physical interpretation. They are the basic stuff of reality, the essence out of which everything else is made – a kind of "quantumness" that pre-exists everything. Most importantly, these quantum degrees ›

> **"Only with massive amounts of entanglement do we see large-scale distortions in the fabric of space"**

of freedom are entangled with each other.

With that in mind, we flip around Jacobson's idea. Now we can define the area surrounding a region as the entanglement of its degrees of freedom with the outside world. And sure enough, the corresponding geometry obeys Einstein's equation of general relativity. Gravity, in other words, can emerge directly from the quantum essence of reality, without quantising any assumed classical stuff.

That might sound like a conclusion, but it is more like a promising beginning. Many assumptions went into our derivation, and whether these assumptions hold true in nature remains to be seen. Most importantly, our derivation of Einstein's equation from entanglement only works when gravity is weak and spacetime is nearly flat. Once gravity becomes strong and space-time is curved, as in the Big Bang or near a black hole, radically new phenomena become important.

The most dramatic of these is the "holographic principle," the idea that the degrees of freedom describing a black hole can be thought of as living on its edge, the event horizon, rather than the interior. Juan Maldacena of the Institute for Advanced Study in Princeton used the holographic principle to show an equivalence between two very different theories: quantum field theory without gravity in four-dimensional space-time, and quantum gravity with a negative vacuum energy in five dimensions.

The wormhole connection

Subsequent work by Mark van Raamsdonk at the University of British Columbia in Canada and others has shown that the space-time geometry on the quantum-gravity side of this correspondence is directly tied to quantum entanglement on the field-theory side. As we decrease entanglement in the field theory, space-time on the quantum-gravity side grows apart (see "Quantum gum", page 37).

Maldacena and Leonard Susskind at Stanford University in California have taken this connection to extremes with a bold idea they dubbed "ER=EPR." ER stands for Albert Einstein and Nathan Rosen, who wrote a paper in 1935 proposing the existence of wormholes, or shortcuts through space-time. EPR, meanwhile, stands for Einstein, Boris Podolsky and Rosen, who collaborated on another paper emphasising the role of entanglement in quantum theory. The ER=EPR conjecture therefore posits that whenever you have two entangled particles, there is a tiny wormhole connecting them.

Don't take this too literally. The wormholes that purportedly connect pairs of particles would be microscopically small and impossible for anything to pass through. It is only when massive amounts of entanglement become involved that we begin to see a macroscopic distortion in the fabric of space.

Moreover, our universe has a positive vacuum energy, not a negative one, so the implications of the equivalence revealed in Maldacena's negative-vacuum-energy thought experiment don't translate directly to an actionable strategy for dealing with quantum gravity in the real world. They do, however, serve as another strong hint that quantum entanglement is at the heart of it all.

All of these ideas are, at present, somewhere between promising conjectures and optimistic dreams. We don't know the best way to think about these supposed fundamental degrees of freedom that entangle together to make space-time, nor do we know how they interact with each other in any detailed way. We can't yet derive the emergence of quantum fields living within space-time, obeying the rules of relativity. And we certainly can't answer important questions like why the energy of empty space is so small, or why space has four macroscopic dimensions.

Even so, imagining that space-time emerges from quantum entanglement is a promising way to think about the basic nature of reality. It may be that it was a mistake to start with general relativity and try to quantise it; maybe space-time was lurking within quantum mechanics all along.

And even if formulating a complete theory of quantum gravity isn't your thing, thinking about space-time this way should at least put a new slant on the familiar four-dimensional continuum in which we live, rushing around in space to be on time for coffee. ∎

have real propagation speeds. A complication that is always present in alternative theories of gravity is that the extra degrees of freedom are always non-minimally coupled to gravity (else there would be matter fields by definition). So, when constructing an action for a theory with a given field content it is nontrivial to judge whether it will satisfy the stability criteria mentioned above. As a result, one of the first calculations one does in every alternative theory of gravity is to check if all excitations satisfy these criteria around flat space (or some maximally symmetric space—the vacuum solution of the theory).

In Sect. 1.2.2 we mentioned that theories that lead to higher-order equations are generically plagued by instabilities. These instabilities are essentially due to the presence of ghosts. It has been shown by Ostrogradski in 1850 that non-degenerate Lagrangians with higher-order derivatives generically lead to Hamiltonians that are linear in at least one of the momenta [11]. Such Hamiltonians are not bound from below. A detailed discussion can be found in [12]. Obviously, Ostragradski's instabilities make higher-order theories particularly unappealing. However, higher-order theories which can be explicitly re-written as second-order theories with more fields evade such instabilities. We will see an example of such a theory below.

Once stability issues have been addressed, and the behaviour of the new degrees of freedom has been tamed, the next step is to find a mechanism that hides them in regimes where general relativity is well tested and no extra degrees of freedom have been seen, but still allows them to be present and lead to different phenomenology in other regimes. How challenging a task this is and how inventive we have been in order to circumvent the difficulties will be demonstrated by the examples from scalar-tensor gravity presented in the next section.

It should be mentioned that a road less taken is to consider alternative theories with non-dynamical extra degrees of freedom. In fact, one could circumvent Lovelock's theorem by considering a gravity theory where fields other than the metric are present, but they are auxiliary fields, so that they do not satisfy dynamical equation but can be instead algebraically eliminated. This way ones has the same degrees of freedom as in general relativity and does not have to worry about instabilities associated with new dynamical fields. However, such an approach is not without serious shortcomings, see [13] for a discussion and references therein. For the rest of these notes we will focus one theories with dynamical new degrees of freedom, as most popular alternative theories of gravity fall under this category.

1.3 Scalar-Tensor Gravity

1.3.1 The Prototype: Brans–Dicke Theory

The action for Brans–Dicke theory is

$$S_{\mathrm{BD}} = \frac{1}{16\pi G}\int d^4x\sqrt{-g}\left(\varphi R - \frac{\omega_0}{\varphi}\nabla^\mu\varphi\nabla_\mu\varphi - V(\varphi)\right) + S_m(g_{\mu\nu},\psi), \qquad (1.8)$$

where φ is a scalar field and ω_0 is known as the Brans–Dicke parameter. After some manipulations, the corresponding field equations can take the form

$$\begin{aligned} R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = {} & \frac{8\pi G}{\varphi} T_{\mu\nu} + \frac{\omega_0}{\varphi^2} \left(\nabla_\mu \varphi \nabla_\nu \varphi - \frac{1}{2} g_{\mu\nu} \nabla^\lambda \varphi \nabla_\lambda \varphi \right) \\ & + \frac{1}{\varphi} \left(\nabla_\mu \nabla_\nu \varphi - g_{\mu\nu} \Box \varphi \right) - \frac{V(\varphi)}{2\varphi} g_{\mu\nu} \,, \qquad (1.9) \end{aligned}$$

$$(2\omega_0 + 3) \Box \varphi = \varphi \, V' - 2V + 8\pi G \, T \,, \qquad (1.10)$$

where $\Box = \nabla^\lambda \nabla_\lambda$ and a prime denotes differentiation with respect to the argument. In its original formulation Brans–Dicke theory did not have a potential.

It is straightforward to see that in vacuo, where $T_{\mu\nu} = 0$, the theory admits solutions where with $\varphi = \varphi_0 =$ constant, provided that $\varphi_0 \, V'(\varphi_0) - 2V(\varphi_0) = 0$. For such solutions the metric actually satisfies Einstein's equations with an effective cosmological constant $V(\phi_0)$. So, one could be misled to think that, as long as $V(\varphi_0)$ has the right value, the predictions of the theory could be the same as those of general relativity. For instant, the space-time around the Sun could be described by such a solution, and then solar system constraints would be automatically satisfied. What invalidates this logic is that the $\varphi = \varphi_0$ solutions are not unique. φ could actually have a nontrivial configuration, which would also force the metric to deviate for the corresponding solution of general relativity.

This is indeed the case for spherically symmetric solution that describe the exterior of stars, and in particular the Sun. Consider for concreteness the case where $V = m^2(\varphi - \varphi_0)^2$. Performing a newtonian expansion one can calculate the newtonian limit of the metric. The perturbations of the metric are

$$h_{00} = \frac{GM_s}{\varphi_0 r} \left(1 - \frac{1}{2\omega_0 + 3} exp \left[-\sqrt{\frac{2\varphi_0}{2\omega_0 + 3}} mr \right] \right) \,, \qquad (1.11)$$

$$h_{ij} = \frac{GM_s}{\varphi_0 r} \delta_{ij} \left(1 + \frac{1}{2\omega_0 + 3} exp \left[-\sqrt{\frac{2\varphi_0}{2\omega_0 + 3}} mr \right] \right) \,, \qquad (1.12)$$

where M_s is the mass of the Sun. There is a Yukawa-like correction to the standard $1/r$ potential, with effective mass $m_{\text{eff}} = \sqrt{\frac{2\varphi_0}{2\omega_0+3}} m$ and range m_{eff}^{-1}. The ratio of the perturbations of the time-time component h_{00} over any space-space diagonal component $h_{ij}|_{i=j}$, which is also known as the γ (Eddington) parameter is then given by [14]

$$\gamma \equiv \frac{h_{ij}|_{i=j}}{h_{00}} = \frac{2\omega_0 + 3 - exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0+3}} mr \right]}{2\omega_0 + 3 + exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0+3}} mr \right]} \,. \qquad (1.13)$$

It is clear that in order for γ to be close to 1, which is the value it has in general relativity, either ω_0 or $m_{\rm eff}$ should be very large. Indeed, in the limit where $\omega_0 \to \infty$ or $m \to \infty$ the equation imply that $\varphi \to \varphi_0$ and the constant φ solutions with $g_{\mu\nu}$ satisfying Einstein's equation become unique. Current constraints on γ require that $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ [15]. For $m = 0$, this constraint would require ω_0 to be larger than 40,000, which would make the theory indistinguishable from general relativity at all scales. For $\omega_0 = O(1)$, the range of the Yukawa correction would have to be below the smaller scale we have currently tested the inverse square law, i.e. a few microns. But if this is indeed the case, then this correction will never play a role at large scales.

The main message here is that weak gravity constraints are very powerful. It seems very hard to satisfy them and still have a theory whose phenomenology differs from that of general relativity at scales where we currently test gravity. One would have to circumvent this problem in order to construct a theory which is phenomenologically interesting.

1.3.2 *Scalar-Tensor Theories*

Scalar-tensor theories are straightforward generalisations of Brans–Dicke theory in which ω_0 is promoted to a general function of φ. Their action is

$$S_{\rm st} = \frac{1}{16\pi G}\int d^4x\sqrt{-g}\Big(\varphi R - \frac{\omega(\varphi)}{\varphi}\nabla^{\mu}\varphi\nabla_{\mu}\varphi - V(\varphi)\Big) + S_m(g_{\mu\nu},\psi)\,. \tag{1.14}$$

This is the most general action one can write for a scalar field non-minimally coupled to gravity which is second order in derivatives of the scalar. It can, therefore, be thought of as an effective field theory which captures, at some appropriate limit, the phenomenology of a more fundamental theory that contains a scalar field. The corresponding field equations are, after some manipulations

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} = \frac{8\pi G}{\varphi}T_{\mu\nu} + \frac{\omega(\varphi)}{\varphi^2}\left(\nabla_{\mu}\varphi\nabla_{\nu}\varphi - \frac{1}{2}g_{\mu\nu}\,\nabla^{\lambda}\varphi\nabla_{\lambda}\varphi\right)$$

$$+\frac{1}{\varphi}\left(\nabla_{\mu}\nabla_{\nu}\varphi - g_{\mu\nu}\Box\varphi\right) - \frac{V(\varphi)}{2\varphi}g_{\mu\nu}\,, \tag{1.15}$$

$$[2\omega(\varphi) + 3]\,\Box\varphi = -\omega'(\varphi)\,\nabla^{\lambda}\varphi\nabla_{\lambda}\varphi + \varphi\,V' - 2V + 8\pi G\,T\,. \tag{1.16}$$

Scalar-tensor theories have been extensively studied and we will not review them here. See [16, 17] for detailed reviews. The behaviour of the theories in the weak field limit will be no different than that of Brans–Dicke theory, though allowing ω

0. Introduction

A pseudo-Riemannian metric g on a (connected) manifold M is called an *Einstein metric* if its Ricci tensor Ric and scalar curvature s satisfy the relations

$$\mathrm{Ric} = \frac{\mathrm{s}}{n} g, \quad d\mathrm{s} = 0, \quad n = \dim M. \tag{0.1}$$

0. Introduction

A pseudo-Riemannian metric g on a (connected) manifold M is called an *Einstein metric* if its Ricci tensor Ric and scalar curvature s satisfy the relations

$$\mathrm{Ric} = \frac{\mathrm{s}}{n} g, \quad d\mathrm{s} = 0, \quad n = \dim M. \tag{0.1}$$

One then also refers to the pair (M, g) as an *Einstein manifold*. Note that, since M is assumed connected, condition $d\mathrm{s} = 0$ means here that s is constant.

This chapter is an exposition of selected results concerning Einstein metrics on four-manifolds. The focus of our discussion on dimension four, with other dimensions mentioned only in passing, follows what has consistently, with relatively few exceptions, seemed to be the main areas of interest for Einstein metrics both in differential geometry and mathematical physics.

We address two main topics concerning four-dimensional Einstein metrics, often treated as completely separate. One is the question of global properties of compact Einstein 4-manifolds which are *Riemannian* in the sense that their metrics are positive definite. The other topic pertains to local properties of Einstein metrics on 4-dimensional manifolds in Riemannian as well as *Lorentzian* and *neutral* cases; the italicized terms refer to the sign patterns $-+++$ and $--++$, of which the former characterizes spacetime metrics in general relativity.

As a result, the material presented here can naturally be divided into *local* and *global* topics. The former are dealt with in most of Part I and Part IV. As for the latter, they are discussed, usually in the context of compact Riemannian manifolds, in Parts II and III.

Here is a brief outline of the contents of this article. Part I covers a variety of elementary topics, ranging from preliminary material on curvature, flatness, submanifolds, and conformal changes of metrics, through local classification theorems for curvature-homogeneous Riemannian Einstein metrics of dimension four (along with the special cases of metrics which are locally homogeneous, or locally symmetric), and also including topics such as Einstein hypersurfaces in pseudo-Euclidean spaces, Einstein metrics conformal to Kähler metrics or to Riemannian-product metrics, mobility for Einstein metrics, and potentials for Kähler metrics. Parts II and III deal with topological conditions that guarantee nonexistence (or, in some rare cases, existence) of a Riemannian Einstein metric on a given compact four-manifold. Finally, Part IV is devoted to local properties of indefinite Einstein metrics in dimension four and contains Petrov's classification of curvature types and a local classification of locally symmetric pseudo-Riemannian Einstein 4-manifolds.

For more details, see the detailed summaries at the beginning of each of the four parts, and the table of contents.

Besides the local-global distinction, another division in the material reflects four different levels involved in the presentation. One, which might be termed *basic and self-contained*, appears in Part I, and is both easily accessible to nonexperts and accompanied by full proofs. A 'nonexpert' means here someone whose background includes, but does not reach far beyond, the contents of a typical introductory graduate course in modern differential geometry offered at large US universities. Accordingly, the reader is assumed to have some familiarity with objects such as manifolds, differentiable mappings, tensors, pseudo-Riemannian metrics, and vector bundles (along with differentiable sections of, connections in, and fibrewise algebraic operations on the latter); the notions just listed will not be defined. Other concepts, although expected to be known to the reader, are briefly defined here; these include the Levi-Civita connection, the curvature and Ricci tensors, the Lie bracket of vector fields, etc.

As for Part II, it contains material which is still *basic*, but this time relies on several nonelementary results that are quoted without proofs (but, once taken for granted, make the rest of the discussion in Part II quite easy). In Part IV, the presentation level is *intermediate*, which here means that it is elementary and self-contained, but involves lengthy technical details that a nonexpert might not be willing to go into. Finally, Part III contains material on an *advanced* level in the form of brief summaries of results relying on repeated uses of techniques the details of which cannot be presented in a text of this size.

As another consequence of its limited size, the present chapter does not and cannot address all facts concerning four-dimensional Einstein metrics that are deemed important by large groups of experts. The topics left out include:

- techniques of global complex analysis used to prove existence and uniqueness results of the Calabi–Yau–Aubin type;
- moduli spaces of Einstein metrics on compact manifolds;
- the whole subject of cohomogeneity-one Einstein 4-manifolds, with the example of a U(2)-invariant Einstein metric on a compact 4-manifold discovered by Page [53], and Bérard Bergery's classification theorem [4] stating that no further examples of this type are possible;
- further topological obstructions to the existence of specific types of Einstein metrics on compact 4-manifolds, such as a theorem due to Hitchin [36] for nonpositively or nonnegatively curved Riemannian metrics, or results of Law [44] for indefinite metrics of the *neutral* sign pattern $--++$;
- a result of DeTurck and Kazdan [26] which says that every Riemannian Einstein metric is analytic in suitable local coordinates;
- an approach to Einstein metrics using normal coordinates and power-series solutions to (0.1);
- a result of Gasqui [30] stating that any "Einsteinian" algebraic curvature tensor at a point x in a manifold M is realized as the curvature at x of an Einstein metric g defined on a neighborhood of x in M, with the prescribed value $g(x)$ at x;

and many more.

This paper benefited from correspondence and conversations with many people. Some of those discussions go back more than a decade. I am particularly obliged to Andrea Sambusetti for numerous comments and helpful criticism of Section 27. I also greatly appreciate conversations I had in the mid-1980s with Richard Palais and Chuu-Lian Terng, concerning warped-product Einstein metrics, a topic mentioned in Sections 16 and 19 of this text.

PART I: BASICS

Throughout the following twenty-three sections we will usually assume that the metrics in question are both *Riemannian* (positive definite) and *four-dimensional*, unless a generhave real propagation speeds. A complication that is always present in alternative theories of gravity is that the extra degrees of freedom are always non-minimally coupled to gravity (else there would be matter fields by definition). So, when constructing an action for a theory with a given field content it is nontrivial to judge whether it will satisfy the stability criteria mentioned above. As a result, one of the first calculations one does in every alternative theory of gravity is to check if all excitations satisfy these criteria around flat space (or some maximally symmetric space—the vacuum solution of the theory).

In Sect. 1.2.2 we mentioned that theories that lead to higher-order equations are generically plagued by instabilities. These instabilities are essentially due to the presence of ghosts. It has been shown by Ostrogradski in 1850 that non-degenerate Lagrangians with higher-order derivatives generically lead to Hamiltonians that are linear in at least one of the momenta [11]. Such Hamiltonians are not bound from below. A detailed discussion can be found in [12]. Obviously, Ostragradski's instabilities make higher-order theories particularly unappealing. However, higher-order theories which can be explicitly re-written as second-order theories with more fields evade such instabilities. We will see an example of such a theory below.

Once stability issues have been addressed, and the behaviour of the new degrees of freedom has been tamed, the next step is to find a mechanism that hides them in regimes where general relativity is well tested and no extra degrees of freedom have been seen, but still allows them to be present and lead to different phenomenology in other regimes. How challenging a task this is and how inventive we have been in order to circumvent the difficulties will be demonstrated by the examples from scalar-tensor gravity presented in the next section.

It should be mentioned that a road less taken is to consider alternative theories with non-dynamical extra degrees of freedom. In fact, one could circumvent Lovelock's theorem by considering a gravity theory where fields other than the metric are present, but they are auxiliary fields, so that they do not satisfy dynamical equation but can be instead algebraically eliminated. This way ones has the same degrees of freedom as in general relativity and does not have to worry about instabilities associated with new dynamical fields. However, such an approach is not without serious shortcomings, see [13] for a discussion and references therein. For the rest of these notes we will focus one theories with dynamical new degrees of freedom, as most popular alternative theories of gravity fall under this category.

1.3 Scalar-Tensor Gravity

1.3.1 The Prototype: Brans–Dicke Theory

The action for Brans–Dicke theory is

$$S_{\mathrm{BD}} = \frac{1}{16\pi G}\int d^4x\sqrt{-g}\left(\varphi R - \frac{\omega_0}{\varphi}\nabla^{\mu}\varphi\nabla_{\mu}\varphi - V(\varphi)\right) + S_m(g_{\mu\nu},\psi), \quad (1.8)$$

where φ is a scalar field and ω_0 is known as the Brans–Dicke parameter. After some manipulations, the corresponding field equations can take the form

$$R_{\mu\nu} - \frac{1}{2}Rg_{\mu\nu} = \frac{8\pi G}{\varphi}T_{\mu\nu} + \frac{\omega_0}{\varphi^2}\left(\nabla_\mu\varphi\nabla_\nu\varphi - \frac{1}{2}g_{\mu\nu}\,\nabla^\lambda\varphi\nabla_\lambda\varphi\right)$$
$$+\frac{1}{\varphi}\left(\nabla_\mu\nabla_\nu\varphi - g_{\mu\nu}\Box\varphi\right) - \frac{V(\varphi)}{2\varphi}g_{\mu\nu}\,, \tag{1.9}$$
$$(2\omega_0 + 3)\Box\varphi = \varphi\, V' - 2V + 8\pi G\, T\,, \tag{1.10}$$

where $\Box = \nabla^\lambda\nabla_\lambda$ and a prime denotes differentiation with respect to the argument. In its original formulation Brans–Dicke theory did not have a potential.

It is straightforward to see that in vacuo, where $T_{\mu\nu} = 0$, the theory admits solutions where with $\varphi = \varphi_0 =$ constant, provided that $\varphi_0\, V'(\varphi_0) - 2V(\varphi_0) = 0$. For such solutions the metric actually satisfies Einstein's equations with an effective cosmological constant $V(\phi_0)$. So, one could be misled to think that, as long as $V(\varphi_0)$ has the right value, the predictions of the theory could be the same as those of general relativity. For instant, the space-time around the Sun could be described by such a solution, and then solar system constraints would be automatically satisfied. What invalidates this logic is that the $\varphi = \varphi_0$ solutions are not unique. φ could actually have a nontrivial configuration, which would also force the metric to deviate for the corresponding solution of general relativity.

This is indeed the case for spherically symmetric solution that describe the exterior of stars, and in particular the Sun. Consider for concreteness the case where $V = m^2(\varphi - \varphi_0)^2$. Performing a newtonian expansion one can calculate the newtonian limit of the metric. The perturbations of the metric are

$$h_{00} = \frac{GM_s}{\varphi_0 r}\left(1 - \frac{1}{2\omega_0 + 3}exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0 + 3}}mr\right]\right)\,, \tag{1.11}$$

$$h_{ij} = \frac{GM_s}{\varphi_0 r}\delta_{ij}\left(1 + \frac{1}{2\omega_0 + 3}exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0 + 3}}mr\right]\right)\,, \tag{1.12}$$

where M_s is the mass of the Sun. There is a Yukawa-like correction to the standard $1/r$ potential, with effective mass $m_{\text{eff}} = \sqrt{\frac{2\varphi_0}{2\omega_0+3}}m$ and range m_{eff}^{-1}. The ratio of the perturbations of the time-time component h_{00} over any space-space diagonal component $h_{ij}|_{i=j}$, which is also known as the γ (Eddington) parameter is then given by [14]

$$\gamma \equiv \frac{h_{ij}|_{i=j}}{h_{00}} = \frac{2\omega_0 + 3 - exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0+3}}mr\right]}{2\omega_0 + 3 + exp\left[-\sqrt{\frac{2\varphi_0}{2\omega_0+3}}mr\right]}\,. \tag{1.13}$$

It is clear that in order for γ to be close to 1, which is the value it has in general relativity, either ω_0 or m_{eff} should be very large. Indeed, in the limit where $\omega_0 \to \infty$ or $m \to \infty$ the equation imply that $\varphi \to \varphi_0$ and the constant φ solutions with $g_{\mu\nu}$ satisfying Einstein's equation become unique. Current constraints on γ require that $\gamma - 1 = (2.1 \pm 2.3) \times 10^{-5}$ [15]. For $m = 0$, this constraint would require ω_0 to be larger than 40,000, which would make the theory indistinguishable from general relativity at all scales. For $\omega_0 = O(1)$, the range of the Yukawa correction would have to be below the smaller scale we have currently tested the inverse square law, i.e. a few microns. But if this is indeed the case, then this correction will never play a role at large scales.

The main message here is that weak gravity constraints are very powerful. It seems very hard to satisfy them and still have a theory whose phenomenology differs from that of general relativity at scales where we currently test gravity. One would have to circumvent this problem in order to construct a theory which is phenomenologically interesting.

1.3.2 Scalar-Tensor Theories

Scalar-tensor theories are straightforward generalisations of Brans–Dicke theory in which ω_0 is promoted to a general function of φ. Their action is

$$S_{\text{st}} = \frac{1}{16\pi G} \int d^4x \sqrt{-g}\Big(\varphi R - \frac{\omega(\varphi)}{\varphi} \nabla^\mu \varphi \nabla_\mu \varphi - V(\varphi)\Big) + S_m(g_{\mu\nu}, \psi)\,. \tag{1.14}$$

This is the most general action one can write for a scalar field non-minimally coupled to gravity which is second order in derivatives of the scalar. It can, therefore, be thought of as an effective field theory which captures, at some appropriate limit, the phenomenology of a more fundamental theory that contains a scalar field. The corresponding field equations are, after some manipulations

$$R_{\mu\nu} - \frac{1}{2} R g_{\mu\nu} = \frac{8\pi G}{\varphi} T_{\mu\nu} + \frac{\omega(\varphi)}{\varphi^2} \left(\nabla_\mu \varphi \nabla_\nu \varphi - \frac{1}{2} g_{\mu\nu}\, \nabla^\lambda \varphi \nabla_\lambda \varphi \right)$$

$$+ \frac{1}{\varphi} \left(\nabla_\mu \nabla_\nu \varphi - g_{\mu\nu} \Box \varphi \right) - \frac{V(\varphi)}{2\varphi} g_{\mu\nu}\,, \tag{1.15}$$

$$[2\omega(\varphi) + 3]\, \Box \varphi = -\omega'(\varphi)\, \nabla^\lambda \varphi \nabla_\lambda \varphi + \varphi\, V' - 2V + 8\pi G\, T\,. \tag{1.16}$$

Scalar-tensor theories have been extensively studied and we will not review them here. See [16, 17] for detailed reviews. The behaviour of the theories in the weak field limit will be no different than that of Brans–Dicke theory, though allowing ω

+,- * *. * $ < KD A H + % "

(@ $)

known from very precise experiments that the gravitational mass is for all material bodies proportional to the inertial mass, and the factor of proportionality is a universal constant (taken to be just 1). Hence, all bodies will experience the same acceleration in a given gravitational field. Consequently, the frame of reference connected with a body falling freely in a homogeneous gravitational field is inertial.

Homogeneous gravitational fields do not exist in Nature. However, along the trajectory of a body falling freely in any real gravitational field, the gravitational force and the inertial force cancel each other at every point. Hence, if the gravitational field is continuous (which is the case in all practical instances), then, in a *sufficiently small neighbourhood* of the falling body, the inertial forces will be arbitrarily small. Given the precision ε attainable in measurements, a falling body B will, at every point of its trajectory, determine a sphere of radius δ inside which the inertial force will be smaller than ε, i.e. unmeasurable. Inside that sphere the reference system defined by the body B will thus be 'practically' inertial. It is called the **local inertial frame** of the body B. (In fact, local inertial frames are defined not by individual bodies, but by their trajectories that do not depend on mass.) It is called 'local' because it differs from the universal inertial frame postulated in Newton's theory: there is an infinity of local inertial frames. It is easy to see that two different local inertial frames will in general move with acceleration relative to each other. For example, consider two local inertial frames connected with bodies falling freely towards the Earth from opposite directions. Thus, at a large distance from a freely falling body its local inertial frame ceases to be inertial.

12.3 Trajectories of free motion in Einstein's theory

Let us recall one more conclusion of Chapter 1: since no standard for a straight line exists in Nature, it will be simpler to assume that the geometry of our space is non-Euclidean, and in that geometry the trajectories of material bodies are free-motion trajectories. What was called 'gravitational field' in Newton's theory will be a consequence of the non-Euclidean geometry in which the free motions take place. By the argument of Section 12.1, the Riemann geometries should be appropriate. They do contain the Euclidean geometry as a special case and, because of the coordinate-independent formalism they use, are consistent with the postulate of equivalence of all reference systems.

The generalisation of the notion of a straight line that exists in a Riemann space is the geodesic line. If in a Riemann space the curvature goes to zero, the geometry goes over into the Euclidean geometry and the geodesic lines go over into straight lines. Hence, the geodesic line is a natural candidate for the trajectory of a free motion. In addition, the geodesic lines have the following property:

Theorem 12.1 *For a timelike geodesic* G, *the coordinates in a Riemann space can be chosen so that the Christoffel symbols vanish along* G.

This is an additional argument that the geodesics should be taken as the trajectories of free fall. The vanishing of the Christoffel symbols means that along G the local gravitational field will be approximately zero. (It is not exactly zero because the derivatives of the Christoffel symbols will not vanish, and so the curvature will be nonzero.)

Proof: (Latin indices will label vectors; the lower case ones will run through the values 0, 1, 2, 3, whereas the upper case ones will run through the values 1, 2, 3. Tensor indices running through the values 1, 2, 3 will also be denoted by latin letters. Wherever confusion might arise, vector indices will have a hat over them.)

At a point $p_0 \in G$, we choose such a basis in the tangent space that $e_{\hat{0}}{}^{\alpha}(p_0)$ is tangent to G, and the other vectors, $e_A{}^{\alpha}(p_0)$, $A = 1, 2, 3$ are orthogonal to $e_{\hat{0}}{}^{\alpha}(p_0)$, i.e. $g_{\alpha\beta} e_{\hat{0}}{}^{\alpha} e_A{}^{\alpha}\big|_{p_0} = 0$. Then we define the bases $e_i{}^{\alpha}(p)$ in a neighbourhood of G as follows:

1. For $p \in G$, we transport $e_i{}^{\alpha}(p_0)$ parallely from p_0 to p along G.
2. For $p \notin G$ we draw through p a geodesic G'_p that intersects G orthogonally (see Fig. 12.1). Let $p' \in G$ be the point of intersection of G'_p and G. Then we transport the basis $e_i{}^{\alpha}(p')$ (already defined in point 1) to p along G'_p.

This procedure works provided that there are no singular points on G'_p. It gives a unique result provided that p is not too distant from G, otherwise the geodesics orthogonal to G might intersect each other.

The following equations hold on G:

$$e_i{}^{\alpha}{}_{;\beta}\big|_G = 0, \qquad e^i{}_{\alpha;\beta}\big|_G = 0. \tag{12.1}$$

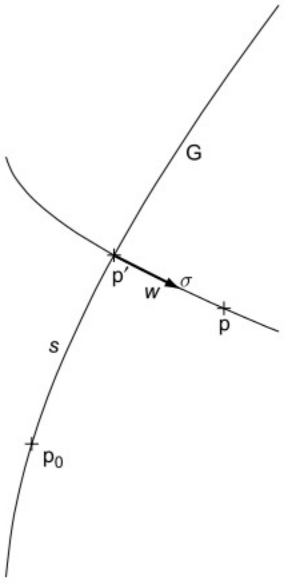

Fig. 12.1. Construction of the Fermi coordinates in which the Christoffel symbols vanish along a given timelike geodesic G. More explanation in the text.

The first equation follows because (i) $e_i{}^{\alpha}{}_{;\mu}\, e_{\widehat{0}}{}^{\mu}\big|_{\mathrm{G}} = 0$ in consequence of the basis $e_i{}^{\alpha}$ being transported parallely along G and $e_{\widehat{0}}{}^{\mu}$ being tangent to G and (ii) $e_i{}^{\alpha}{}_{;\mu} e_S{}^{\mu}\big|_{\mathrm{G}} = 0 (S = 1, 2, 3)$ in consequence of $e_S{}^{\mu}$ at G being tangent to one of the geodesics used to transplant the bases parallely to other points. The second of (12.1) follows from $e_i{}^{\alpha} e^i{}_{\beta} = \delta^{\alpha}{}_{\beta}$.

Now, using (12.1) in (4.19), we obtain

$$\left.\begin{Bmatrix} \alpha \\ \beta\gamma \end{Bmatrix}\right|_{\mathrm{G}} = e_s{}^{\alpha} e^s{}_{\beta,\gamma}\big|_{\mathrm{G}}\,. \tag{12.2}$$

Since the Christoffel symbols are symmetric, this implies at once that

$$e^i{}_{\beta,\gamma}\big|_{\mathrm{G}} = e^i{}_{\gamma,\beta}\big|_{\mathrm{G}}\,. \tag{12.3}$$

We have defined the basis (up to rotations of $e_A{}^{\alpha}(\mathrm{p}_0)$, $A = 1, 2, 3$), but we have not so far defined the coordinates. Let w^{α} be the tangent vector to G'_{p} of unit length (see Fig. 12.1), and let σ be the length of the segment of G'_{p} between p and G ($\sigma = 0$ for points on G). Let s be the length of the segment of G between p_0 and p'. For the point p we define the time coordinate $x^0 = s$ and the space coordinates

$$x^A = \sigma w^{\rho}(\mathrm{p}') e^{\widehat{A}}{}_{\rho}(\mathrm{p}'), \qquad A = 1, 2, 3. \tag{12.4}$$

In the coordinates (s, x^A) thus defined, called **Fermi coordinates**,

$$e_{\widehat{0}}{}^{\alpha}(\mathrm{p}') = \left.\frac{\partial x^{\alpha}}{\partial s}\right|_{\mathrm{G}} \underset{*}{=} \delta^{\alpha}{}_0, \tag{12.5}$$

since $e_{\widehat{0}}{}^{\alpha}$ is tangent to G, and

$$e_A{}^0(\mathrm{p}') \underset{*}{=} 0, \qquad A = 1, 2, 3, \qquad w^0 \underset{*}{=} 0 \tag{12.6}$$

because $e_A{}^{\alpha}(\mathrm{p}')$ and w^{α} lie in the subspace of the tangent space in which $x^0 = \text{constant}$. Equations (12.5) and (12.6) imply that the matrix $e_i{}^{\alpha}(\mathrm{p}')$ has a block form. Consequently, the inverse matrix $e^i{}_{\alpha}(\mathrm{p}')$ must have the same block form:

$$e^{\widehat{0}}{}_{\alpha}(\mathrm{p}') \underset{*}{=} \delta^0{}_{\alpha}, \qquad e^{\widehat{A}}_{0}(\mathrm{p}') \underset{*}{=} 0. \tag{12.7}$$

Now let us differentiate (12.4) by σ. Since $w^{\rho}(\mathrm{p}')$ and $e^{\widehat{A}}{}_{\rho}(\mathrm{p}')$ do not depend on σ, we have

$$w^A(\sigma) \overset{\mathrm{def}}{=} \frac{\mathrm{d}x^A}{\mathrm{d}\sigma} = w^{\rho}(\mathrm{p}') e^{\widehat{A}}{}_{\rho}(\mathrm{p}') \underset{*}{=} w^A(\mathrm{p}'), \tag{12.8}$$

which means that w^A does not depend on σ. In consequence of (12.6) and (12.7) this implies that $w^A(\mathrm{p}') \underset{*}{=} w^K(\mathrm{p}') e^{\widehat{A}}{}_K(\mathrm{p}')$, $K = 1, 2, 3$, so

$$e^{\widehat{A}}{}_K(\mathrm{p}') \underset{*}{=} \delta^{\widehat{A}}{}_K, \tag{12.9}$$

since $w^K(\mathrm{p}')$ is an arbitrary 3-vector at p'. From (12.7) and (12.9) we then obtain

$$e^i{}_{\alpha}(\mathrm{p}') \underset{*}{=} \delta^i{}_{\alpha}, \qquad e_i{}^{\alpha}(\mathrm{p}') \underset{*}{=} \delta^{\alpha}{}_i. \tag{12.10}$$

This implies that $e_i{}^{\alpha}(\mathrm{p}')$ is constant along G, so

$$e^i{}_{\alpha,\beta} e_{\widehat{0}}{}^{\beta}\big|_{\mathrm{G}} = \frac{\partial}{\partial s} e^i{}_{\alpha}(\mathrm{p}') \underset{*}{=} e^i{}_{\alpha,0}\big|_{\mathrm{G}} = 0, \qquad e^i{}_{0,\alpha}\big|_{\mathrm{G}} = 0. \tag{12.11}$$

(The last equation follows from the previous one by virtue of (12.3).)

Now note that

$$\frac{\mathrm{d}}{\mathrm{d}\sigma}\left(w^{\alpha} e^i{}_{\alpha}\right) \equiv \frac{\mathrm{D}}{\mathrm{d}\sigma}\left(w^{\alpha} e^i{}_{\alpha}\right) = 0, \tag{12.12}$$

because w^{α} is tangent to a geodesic on which σ is the affine parameter, while $e^i{}_{\alpha}$ is by definition parallely transported along that geodesic. Moreover, (12.8) implies that $\mathrm{d}w^{\alpha}/\mathrm{d}\sigma = 0$, hence

$$0 = \frac{\mathrm{d}}{\mathrm{d}\sigma}\left(w^{\alpha} e^i{}_{\alpha}\right) = w^{\alpha} \frac{\mathrm{d}e^i{}_{\alpha}}{\mathrm{d}\sigma} = w^{\alpha} w^{\beta} e^i{}_{\alpha,\beta} = w^A w^B e^i{}_{A,B}, \tag{12.13}$$

which means that $e^i{}_{(A,B)}\big|_{\mathrm{G}} = 0$, because along G w^A is an arbitrary vector orthogonal to G. Then, from (12.3),

$$e^i{}_{A,B}\big|_{\mathrm{G}} = 0. \tag{12.14}$$

Equations (12.11) and (12.14) imply that $e^i{}_{\alpha,\beta}\big|_{\mathrm{G}} = 0$, so, from (12.2),

$$\left.\begin{Bmatrix} \alpha \\ \beta\gamma \end{Bmatrix}\right|_{\mathrm{G}} \underset{*}{=} 0. \ \square \tag{12.15}$$

The physical meaning of (12.15) is that, in a sufficiently small neighbourhood of each $\mathrm{p}' \in \mathrm{G}$, other geodesics emanating from p′ are, up to first-order terms, approximated by straight lines. This neighbourhood is thus a local inertial frame. This is one more suggestion that geodesics should be the trajectories of free motion in relativity.

12.4 Special relativity versus gravitation theory

We have so far been dealing with the postulate that general relativity should reduce to the Newtonian kinematics of free motion in the limit of vanishing gravitational field. However, in between these extremes there is special relativity that describes the kinematics of free particles in the absence of gravitation, but takes into account velocities comparable to the velocity of light. In the previous sections we have thus been discussing a two-stage limiting transition: with the gravitational field to zero and with the velocity of light to infinity. When we switch off the gravitational field, but put no limits on the velocities, the geometric theory of gravitation should reproduce special relativity.

The spacetime of special relativity is a 4-dimensional flat Riemann space of signature $(+---)$. The Riemann space of general relativity should thus be of the same signature. This is because a change of signature means either a discontinuity in some metric components or at least one component of the metric passing through zero value, while we expect that the 'switching off' of the gravitational field can be done in a continuous way and does not lead through any singularities.

12.5 The Newtonian limit of relativity

We assumed that with the gravitational field switched off, general relativity should reproduce special relativity and, in addition, with the velocity of light becoming infinite it should reproduce the Newtonian kinematics of free motion. A logical consequence of these two postulates is the requirement that when the velocity of light is made infinite while the gravitational field is still there, general relativity should reproduce the Newtonian theory of gravitation. Hence, the field equations of relativity should, in the limit $c \to \infty$, reproduce the Poisson equation

$$\Delta\phi = 4\pi G\rho, \tag{12.16}$$

where ϕ is the gravitational potential and ρ is the density distribution of the matter generating the gravitational field.

12.6 Sources of the gravitational field

In the theory of gravitation that we are now constructing, the gravitational field should manifest its presence as non-flatness of the metric. Consequently, the metric tensor should be the device to describe gravitation. The metric tensor in four dimensions has in the most general case 10 components. Hence, we will need 10 equations to determine it.

The description of the sources in the equations should thus be correspondingly elaborate. The source in the equations generalising (12.16) should be a quantity that is a generalisation of mass-density. According to special relativity, the mass of a body depends on its energy. Hence, the energy of motion of a continuous medium should contribute to the gravitational field and so should the internal energy, e.g. pressure in a fluid and stresses in a solid.

In special relativity, the physical state of a continuous medium is described by the energy-momentum tensor $T_{\alpha\beta}$. In any chosen coordinate system, its component T_{00} is equal to the energy-density ρc^2, the components T_{0I}, $I = 1, 2, 3$, form the 3-dimensional vector of energy stream through a unit area of surface orthogonal to the direction of flow, and the components T_{ij} form the stress tensor. The tensor $T_{\alpha\beta}$ is symmetric, and so has in general 10 independent components. Consequently, it is a natural candidate for the source in the field equations of gravitation.

The description of motion of matter, i.e. the distribution of velocities inside matter, is part of the energy-momentum tensor. Consequently, the equations of motion are differential relations between various components of the energy-momentum tensor. In the Cartesian coordinates, the equations of motion are $T^{\alpha\beta}{}_{,\beta} \underset{*}{=} 0$. In any other coordinates then, these equations take the form

$$T^{\alpha\beta}{}_{;\beta} = 0. \tag{12.17}$$

The field equations determining the metric tensor in which the energy-momentum tensor should be the source must be consistent with (12.17).

The following equations hold on G:

$$e_i{}^{\alpha}{}_{;\beta}\big|_{\mathrm{G}} = 0, \qquad e^i{}_{\alpha;\beta}\big|_{\mathrm{G}} = 0. \tag{12.1}$$

As a result, the relation between the contravariant and covariant bases is given in the general curvilinear coordinate system $(u^1,\ldots,u^N)$.

$$\begin{cases} \mathbf{g}_i \cdot \mathbf{g}^k = \mathbf{g}^k \cdot \mathbf{g}_i = \delta_i^k \text{ for } i,k = 1,\ 2,\ \ldots,N \\ \mathbf{g}_i \cdot \mathbf{g}_k = \mathbf{g}_k \cdot \mathbf{g}_i \neq \delta_i^k \text{ for } i,k = 1,\ 2,\ \ldots,N \end{cases} \tag{2.21}$$

The basis $\mathbf{g}_i$ is called dual to the basis $\mathbf{g}^j$ [5] if

$$\mathbf{g}_i \cdot \mathbf{g}^j = \delta_i^j \text{ for } i,j = 1,\ 2,\ \ldots,N \tag{2.22}$$

where δ_i^j is the Kronecker delta.

Let $\{\mathbf{g}_1, \mathbf{g}_2,\ldots,\mathbf{g}_N\}$ be a covariant basis of the curvilinear coordinates $\{u^i\}$. The contravariant basis $\{\mathbf{g}^1, \mathbf{g}^2,\ldots,\mathbf{g}^N\}$, the dual basis to the covariant basis, can be written in the matrix formulation as

$$\mathbf{G} = \left[\mathbf{g}_1 \quad \mathbf{g}_2 \quad \cdot \quad \mathbf{g}_i \quad \mathbf{g}_N\right]; \ \mathbf{G}^{-1} = \begin{bmatrix} \mathbf{g}^1 \\ \mathbf{g}^2 \\ \cdot \\ \mathbf{g}^j \\ \mathbf{g}^N \end{bmatrix} \quad \Rightarrow \quad \mathbf{G}^{-1}\mathbf{G} = \mathbf{I} \tag{2.23}$$

where $\mathbf{g}^j$ is the j row vector of $\mathbf{G}^{-1}$; $\mathbf{g}_i$ is the i column vector of $\mathbf{G}$.

The covariant and contravariant bases (dual bases) of the orthogonal cylindrical and spherical coordinates are computed in the following section.

2.3.1.1 Orthogonal Cylindrical Coordinates

The cylindrical coordinates (r,θ,z) are orthogonal curvilinear coordinates in which the bases are mutually perpendicular but not unitary. Figure 2.3 shows a point P in the cylindrical coordinates (r,θ,z) embedded in the orthonormal Cartesian coordinates (x^1,x^2,x^3). However, the cylindrical coordinates change as the point P varies.

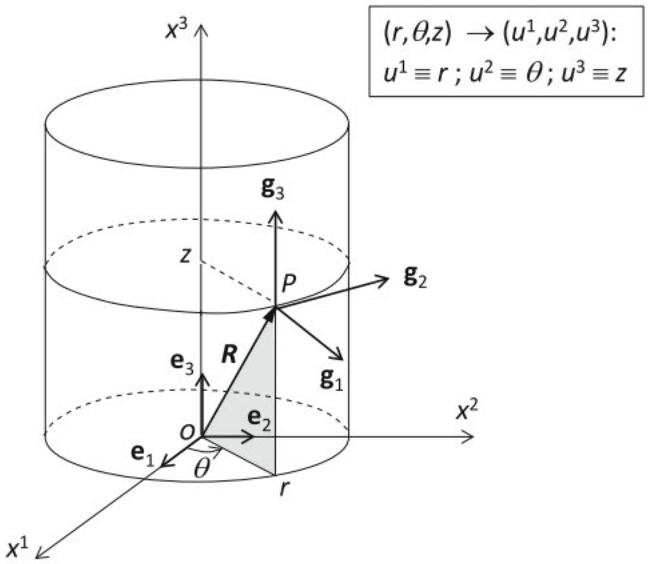
The vector **OP** can be written in Cartesian coordinates (x^1,x^2,x^3):

$$\begin{aligned} \mathbf{R} &= (r\cos\theta)\,\mathbf{e}_1 + (r\sin\theta)\,\mathbf{e}_2 + z\,\mathbf{e}_3 \\ &\equiv x^1\mathbf{e}_1 + x^2\mathbf{e}_2 + x^3\mathbf{e}_3 \end{aligned} \tag{2.24}$$

where

$\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$ are the orthonormal bases of Cartesian coordinates;

θ is the polar angle.



$(r,\theta,z) \rightarrow (u^1,u^2,u^3)$:

Fig. 2.3 Covariant bases of orthogonal cylindrical coordinates

To simplify the formulation with Einstein symbol, the coordinates of u^1, u^2, and u^3 are used for r, θ, and z, respectively. Therefore, the coordinates of $P(u^1,u^2,u^3)$ are given in Cartesian coordinates:

$$P\left(u^1,u^2,u^3\right)=\begin{Bmatrix} x^1 = \ r\cos\theta \equiv u^1\cos u^2 \\ x^2 = \ r\sin\theta \equiv u^1\sin u^2 \\ x^3 = z \equiv u^3 \end{Bmatrix} \tag{2.25}$$

The covariant bases of the curvilinear coordinates are computed from

$$\mathbf{g}_i = \frac{\partial \mathbf{R}}{\partial u^i} = \frac{\partial \mathbf{R}}{\partial x^j}\cdot\frac{\partial x^j}{\partial u^i} = \mathbf{e}_j\frac{\partial x^j}{\partial u^i}\ \text{for } j = 1,2,3 \tag{2.26}$$

The covariant basis matrix $\mathbf{G}$ yields from Eq. (2.26):

$$\begin{aligned}\mathbf{G} &= [\mathbf{g}_1 \quad \mathbf{g}_2 \quad \mathbf{g}_3] \\ &= \begin{pmatrix} \frac{\partial x^1}{\partial u^1} & \frac{\partial x^1}{\partial u^2} & \frac{\partial x^1}{\partial u^3} \\ \frac{\partial x^2}{\partial u^1} & \frac{\partial x^2}{\partial u^2} & \frac{\partial x^2}{\partial u^3} \\ \frac{\partial x^3}{\partial u^1} & \frac{\partial x^3}{\partial u^2} & \frac{\partial x^3}{\partial u^3} \end{pmatrix} = \begin{pmatrix} \cos\theta & -r\sin\theta & 0 \\ \sin\theta & r\cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix}\end{aligned} \tag{2.27}$$

The determinant of $\mathbf{G}$ is called the Jacobian J.

$$|\mathbf{G}| \equiv J = \begin{vmatrix} \dfrac{\partial x^1}{\partial u^1} & \dfrac{\partial x^1}{\partial u^2} & \dfrac{\partial x^1}{\partial u^3} \\ \dfrac{\partial x^2}{\partial u^1} & \dfrac{\partial x^2}{\partial u^2} & \dfrac{\partial x^2}{\partial u^3} \\ \dfrac{\partial x^3}{\partial u^1} & \dfrac{\partial x^3}{\partial u^2} & \dfrac{\partial x^3}{\partial u^3} \end{vmatrix} = \begin{vmatrix} \cos\theta & -r\sin\theta & 0 \\ \sin\theta & r\cos\theta & 0 \\ 0 & 0 & 1 \end{vmatrix} = r \tag{2.28}$$

The relation between the covariant and contravariant bases yields from Eq. (2.22):

$$\mathbf{g}^i \cdot \mathbf{g}_j = \delta^i_j \quad \text{(Kronecker delta)} \tag{2.29}$$

Thus, the contravariant basis matrix $\mathbf{G}^{-1}$ results from the inversion of the covariant basis matrix $\mathbf{G}$, as given in Eq. (2.27).

$$\mathbf{G}^{-1} = \begin{bmatrix} \mathbf{g}^1 \\ \mathbf{g}^2 \\ \mathbf{g}^3 \end{bmatrix} = \frac{1}{r} \begin{pmatrix} r\cos\theta & r\sin\theta & 0 \\ -\sin\theta & \cos\theta & 0 \\ 0 & 0 & r \end{pmatrix} \tag{2.30}$$

The calculation of the determinant and inversion matrix of $\mathbf{G}$ will be discussed in the following section.

According to Eq. (2.27), the covariant bases can be denoted as

$$\begin{cases} \mathbf{g}_1 = (\cos\theta)\,\mathbf{e}_1 + (\sin\theta)\,\mathbf{e}_2 + 0\cdot\,\mathbf{e}_3 \Rightarrow |\mathbf{g}_1| = 1 \\ \mathbf{g}_2 = -(r\sin\theta)\,\mathbf{e}_1 + (r\cos\theta)\,\mathbf{e}_2 + 0\cdot\,\mathbf{e}_3 \Rightarrow |\mathbf{g}_2| = r \\ \mathbf{g}_3 = 0\cdot\,\mathbf{e}_1 + 0\cdot\mathbf{e}_2 + 1\cdot\mathbf{e}_3 \Rightarrow |\mathbf{g}_3| = 1 \end{cases} \tag{2.31}$$

The contravariant bases result from Eq. (2.30).

$$\begin{cases} \mathbf{g}^1 = (\cos\theta)\,\mathbf{e}_1 + (\sin\theta)\,\mathbf{e}_2 + 0\cdot\,\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^1\right| = 1 \\ \mathbf{g}^2 = -\left(\dfrac{\sin\theta}{r}\right)\mathbf{e}_1 + \left(\dfrac{\cos\theta}{r}\right)\mathbf{e}_2 + 0\cdot\,\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^2\right| = \dfrac{1}{r} \\ \mathbf{g}^3 = 0\cdot\mathbf{e}_1 + 0\cdot\,\mathbf{e}_2 + 1\cdot\,\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^3\right| = 1 \end{cases} \tag{2.32}$$

Not only the covariant bases but also the contravariant bases of the cylindrical coordinates are orthogonal due to

$$\begin{aligned} &\mathbf{g}_i \cdot \mathbf{g}^j = \mathbf{g}^j \cdot \mathbf{g}_i = \delta^j_i \\ &\mathbf{g}_i \cdot\, \mathbf{g}_j = 0 \text{ for } i \neq j; \\ &\mathbf{g}^i \cdot\, \mathbf{g}^j = 0 \text{ for } i \neq j. \end{aligned}$$

2.3.1.2 Orthogonal Spherical Coordinates

The spherical coordinates (ρ,φ,θ) are orthogonal curvilinear coordinates in which the bases are mutually perpendicular but not unitary.

The spherical coordinates (ρ,φ,θ) are orthogonal curvilinear coordinates in which the bases are mutually perpendicular but not unitary. Figure 2.4 shows a point P in the spherical coordinates (r,θ,z) embedded in the orthonormal Cartesian coordinates (x^1,x^2,x^3). However, the spherical coordinates change as the point P varies.

The vector **OP** can be written in Cartesian coordinates (x^1,x^2,x^3):

$$\begin{aligned}\mathbf{R} &= (\rho \sin\varphi \cos\theta)\, \mathbf{e}_1 + (\rho \sin\varphi \sin\theta)\, \mathbf{e}_2 + \rho \cos\varphi\, \mathbf{e}_3 \\ &\equiv x^1\mathbf{e}_1 + x^2\mathbf{e}_2 + x^3\mathbf{e}_3\end{aligned} \tag{2.33}$$

where

$\mathbf{e}_1$, $\mathbf{e}_2$, and $\mathbf{e}_3$ are the orthonormal bases of Cartesian coordinates;

φ is the equatorial angle;

θ is the polar angle.

To simplify the formulation with Einstein symbol, the coordinates of u^1, u^2, and u^3 are used for ρ, φ, and θ, respectively. Therefore, the coordinates of $P(u^1,u^2,u^3)$ are given in Cartesian coordinates:

$$P\left(u^1,u^2,u^3\right)=\left\{\begin{array}{l} x^1 = \ \rho\sin\varphi\cos\theta \equiv u^1\sin u^2\cos u^3 \\ x^2 = \ \rho\sin\varphi\sin\theta \equiv u^1\sin u^2\cos u^3 \\ x^3 = \rho\cos\varphi \equiv u^1\cos u^2 \end{array}\right\} \tag{2.34}$$

The covariant bases of the curvilinear coordinates are computed from

$$\mathbf{g}_i=\frac{\partial\mathbf{R}}{\partial u^i}=\frac{\partial\mathbf{R}}{\partial x^j}\cdot\frac{\partial x^j}{\partial u^i}=\mathbf{e}_j\frac{\partial x^j}{\partial u^i}\text{ for } j=1,2,3 \tag{2.35}$$

Thus, the covariant basis matrix **G** can be calculated from Eq. (2.35).

$$\begin{aligned}\mathbf{G}=[\,\mathbf{g}_1\quad\mathbf{g}_2\quad\mathbf{g}_3\,]&=\begin{pmatrix}\dfrac{\partial x^1}{\partial u^1} & \dfrac{\partial x^1}{\partial u^2} & \dfrac{\partial x^1}{\partial u^3}\\ \dfrac{\partial x^2}{\partial u^1} & \dfrac{\partial x^2}{\partial u^2} & \dfrac{\partial x^2}{\partial u^3}\\ \dfrac{\partial x^3}{\partial u^1} & \dfrac{\partial x^3}{\partial u^2} & \dfrac{\partial x^3}{\partial u^3}\end{pmatrix}\\ &=\begin{pmatrix}\sin\varphi\cos\theta & \rho\cos\varphi\cos\theta & -\rho\sin\varphi\sin\theta\\ \sin\varphi\sin\theta & \rho\cos\varphi\sin\theta & \rho\sin\varphi\cos\theta\\ \cos\varphi & -\rho\sin\varphi & 0\end{pmatrix}\end{aligned} \tag{2.36}$$

The determinant of the covariant basis matrix **G** is called the Jacobian J.

$$\begin{aligned}|\mathbf{G}|\equiv J&=\begin{vmatrix}\sin\varphi\cos\theta & \rho\cos\varphi\cos\theta & -\rho\sin\varphi\sin\theta\\ \sin\varphi\sin\theta & \rho\cos\varphi\sin\theta & \rho\sin\varphi\cos\theta\\ \cos\varphi & -\rho\sin\varphi & 0\end{vmatrix}\\ &=\rho^2\sin\varphi\end{aligned} \tag{2.37}$$

Similarly, the contravariant basis matrix $\mathbf{G}^{-1}$ is the inversion of the covariant basis matrix **G**.

$$\mathbf{G}^{-1}=\begin{bmatrix}\mathbf{g}^1\\ \mathbf{g}^2\\ \mathbf{g}^3\end{bmatrix}=\frac{1}{\rho}\begin{pmatrix}\rho\sin\varphi\cos\theta & \rho\sin\varphi\sin\theta & \rho\cos\varphi\\ \cos\varphi\cos\theta & \cos\varphi\sin\theta & -\sin\varphi\\ -\left(\dfrac{\sin\theta}{\sin\varphi}\right) & \left(\dfrac{\cos\theta}{\sin\varphi}\right) & 0\end{pmatrix} \tag{2.38}$$

The matrix product $\mathbf{G}\mathbf{G}^{-1}$ must be an identity matrix according to Eq. (2.23).

$$\begin{aligned}\mathbf{G}^{-1}\mathbf{G} &= \frac{1}{\rho}\begin{pmatrix} \rho\sin\varphi\cos\theta & \rho\sin\varphi\sin\theta & \rho\cos\varphi \\ \cos\varphi\cos\theta & \cos\varphi\sin\theta & -\sin\varphi \\ -\left(\dfrac{\sin\theta}{\sin\varphi}\right) & \left(\dfrac{\cos\theta}{\sin\varphi}\right) & 0 \end{pmatrix} \\ &\cdot\begin{pmatrix} \sin\varphi\cos\theta & \rho\cos\varphi\cos\theta & -\rho\sin\varphi\sin\theta \\ \sin\varphi\sin\theta & \rho\cos\varphi\sin\theta & \rho\sin\varphi\cos\theta \\ \cos\varphi & -\rho\sin\varphi & 0 \end{pmatrix} = \begin{pmatrix} 1 & 0 & 0 \\ 0 & 1 & 0 \\ 0 & 0 & 1 \end{pmatrix} \equiv \mathbf{I}\end{aligned} \tag{2.39}$$

According to Eq. (2.36), the covariant bases can be written as

$$\begin{aligned}\mathbf{g}_1 &= (\sin\varphi\cos\theta)\,\mathbf{e}_1 + (\sin\varphi\sin\theta)\,\mathbf{e}_2 + \cos\varphi\,\mathbf{e}_3 \Rightarrow |\mathbf{g}_1| = 1 \\ \mathbf{g}_2 &= (\rho\cos\varphi\cos\theta)\,\mathbf{e}_1 + (\rho\cos\varphi\sin\theta)\,\mathbf{e}_2 - (\rho\sin\varphi)\,\mathbf{e}_3 \Rightarrow |\mathbf{g}_2| = \rho \\ \mathbf{g}_3 &= (-\rho\sin\varphi\sin\theta)\,\mathbf{e}_1 + (\rho\sin\varphi\cos\theta)\,\mathbf{e}_2 + 0\cdot\mathbf{e}_3 \Rightarrow |\mathbf{g}_3| = \rho\sin\varphi\end{aligned} \tag{2.40}$$

The contravariant bases result from Eq. (2.38).

$$\begin{aligned}\mathbf{g}^1 &= (\sin\varphi\cos\theta)\,\mathbf{e}_1 + (\sin\varphi\sin\theta)\,\mathbf{e}_2 + \cos\varphi\,\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^1\right| = 1 \\ \mathbf{g}^2 &= \left(\frac{1}{\rho}\cos\varphi\cos\theta\right)\mathbf{e}_1 + \left(\frac{1}{\rho}\cos\varphi\sin\theta\right)\mathbf{e}_2 - \left(\frac{1}{\rho}\sin\varphi\right)\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^2\right| = \frac{1}{\rho} \\ \mathbf{g}^3 &= -\left(\frac{1}{\rho}\frac{\sin\theta}{\sin\varphi}\right)\mathbf{e}_1 + \left(\frac{1}{\rho}\frac{\cos\theta}{\sin\varphi}\right)\mathbf{e}_2 + 0\cdot\mathbf{e}_3 \Rightarrow \left|\mathbf{g}^3\right| = \frac{1}{\rho\sin\varphi}\end{aligned} \tag{2.41}$$

Not only the covariant bases but also the contravariant bases of the spherical coordinates are orthogonal due to

$$\begin{aligned}&\mathbf{g}_i\cdot\mathbf{g}^j = \mathbf{g}^j\cdot\mathbf{g}_i = \delta_i^j; \\ &\mathbf{g}_i\cdot\mathbf{g}_j = 0 \quad \text{for } i\neq j; \\ &\mathbf{g}^i\cdot\,\mathbf{g}^j = 0 \quad \text{for } i\neq j.\end{aligned}$$

2.3.2 Metric Coefficients in General Curvilinear Coordinates

The covariant basis vectors $\mathbf{g}_1$, $\mathbf{g}_2$, and $\mathbf{g}_3$ to the general curvilinear coordinates (u^1, u^2,u^3) at the point P can be calculated from the orthonormal bases ($\mathbf{e}_1$,$\mathbf{e}_2$,$\mathbf{e}_3$) in Cartesian coordinates $x^j = x^j(u^i)$, as shown in Fig. 2.2.

$$\begin{aligned}\mathbf{g}_i &\equiv \frac{\partial \mathbf{r}}{\partial u^i} = \frac{\partial \mathbf{r}}{\partial x^k}\frac{\partial x^k}{\partial u^i} \\ &= \mathbf{e}_k \frac{\partial x^k}{\partial u^i} \text{ for } k = 1, 2, 3\end{aligned} \tag{2.42}$$

The covariant metric coefficients g_{ij} are defined as

$$\begin{aligned}g_{ij} &\equiv \mathbf{g}_i \cdot \mathbf{g}_j = \frac{\partial \mathbf{r}}{\partial u^i}\frac{\partial \mathbf{r}}{\partial u^j} = \mathbf{g}_j \cdot \mathbf{g}_i \equiv g_{ji} \\ &= \frac{\partial x^k}{\partial u^i}\frac{\partial x^l}{\partial u^j}\mathbf{e}_k \mathbf{e}_l = \frac{\partial x^k}{\partial u^i}\frac{\partial x^l}{\partial u^j}\delta_{kl} \\ &= \frac{\partial x^k}{\partial u^i}\frac{\partial x^k}{\partial u^j}\end{aligned} \tag{2.43}$$

Similarly, the contravariant metric coefficients g^{ij} can be denoted as

$$g^{ij} \equiv \mathbf{g}^i \cdot \mathbf{g}^j = \mathbf{g}^j \cdot \mathbf{g}^i = g^{ji} \tag{2.44}$$

Furthermore, the contravariant basis can be rewritten as a linear combination of the covariant bases.

$$\mathbf{g}^i = A^{ij}\mathbf{g}_j \tag{2.45}$$

According to Eq. (2.44) and using Eqs. (2.21) and (2.45), the contravariant metric coefficients can be expressed as

$$\begin{aligned}g^{ik} &\equiv \mathbf{g}^i \cdot \mathbf{g}^k = A^{ij}\mathbf{g}_j \cdot \mathbf{g}^k \\ &= A^{ij}\delta_j^k = A^{ik}\end{aligned} \tag{2.46}$$

Thus,

$$\mathbf{g}^i = g^{ij}\mathbf{g}_j \text{ for } j = 1, 2, 3 \tag{2.47}$$

Analogously, one obtains the covariant basis

$$\mathbf{g}_k = g_{kl}\mathbf{g}^l \text{ for } l = 1, 2, 3 \tag{2.48}$$

The mixed metric coefficients can be defined by

$$\begin{aligned} g_k^i \equiv \mathbf{g}^i \cdot \mathbf{g}_k &= \left(g^{ij}\mathbf{g}_j\right) \cdot \mathbf{g}_k \\ &= \left(g^{ij}\mathbf{g}_j\right) \cdot \left(g_{kl}\mathbf{g}^l\right) = g^{ij} g_{kl} \left(\mathbf{g}_j \cdot \mathbf{g}^l\right) \\ &= g^{ij} g_{kl} \delta_j^l = g^{ij} g_{kj} \\ &= \delta_k^i \end{aligned} \tag{2.49a}$$

Thus,

$$g^{ij} g_{kj} = g_{kj} g^{ij} = \delta_k^i \tag{2.49b}$$

Therefore, the contravariant metric tensor is the inverse of the covariant metric tensor.

$$g^{ij} g_{kj} = g_{kj} g^{ij} = \delta_k^i \ \Leftrightarrow \mathbf{M}^{-1}\mathbf{M} = \mathbf{M}\mathbf{M}^{-1} = \mathbf{I} \tag{2.50}$$

where $\mathbf{M}^{-1}$ and $\mathbf{M}$ are the contravariant and covariant metric tensors.

Thus,

$$\begin{aligned} \mathbf{M}^{-1}\mathbf{M} &= \begin{bmatrix} g^{11} & g^{12} & . & g^{1N} \\ g^{21} & g^{22} & . & g^{2N} \\ . & . & g^{ij} & . \\ g^{N1} & g^{N2} & . & g^{NN} \end{bmatrix} \cdot \begin{bmatrix} g_{11} & g_{12} & . & g_{1N} \\ g_{21} & g_{22} & . & g_{2N} \\ . & . & g_{ij} & . \\ g_{N1} & g_{N2} & . & g_{NN} \end{bmatrix} \\ &= \left(g^{ij} g_{kj}\right) = \left(\delta_k^i\right) = \begin{bmatrix} 1 & 0 & . & 0 \\ 0 & 1 & . & 0 \\ 0 & . & 1 & 0 \\ 0 & 0 & . & 1 \end{bmatrix} = \mathbf{I} \end{aligned} \tag{2.51}$$

According to Eqs. (2.42) and (2.49a), the contravariant bases of the curvilinear coordinates can be derived as

$$\begin{aligned} &\delta_i^k \equiv \mathbf{g}^k \cdot \mathbf{g}_i = \mathbf{g}^k \cdot \frac{\partial x^j}{\partial u^i} \mathbf{e}_j \Rightarrow \\ &\delta_i^k \cdot \mathbf{e}_j = \left(\mathbf{g}^k \cdot \frac{\partial x^j}{\partial u^i} \mathbf{e}_j\right) \cdot \mathbf{e}_j = \mathbf{g}^k \cdot \frac{\partial x^j}{\partial u^i} \Rightarrow \\ &\mathbf{g}^k = \delta_i^k \frac{\partial u^i}{\partial x^j} \mathbf{e}_j = \frac{\partial u^k}{\partial x^j} \mathbf{e}_j \end{aligned} \tag{2.52}$$

Thus,

$$\mathbf{g}^j = \frac{\partial u^j}{\partial x^i} \mathbf{e}_i \text{ for } i = 1, 2, 3 \tag{2.53}$$

Generally, the covariant and contravariant metric coefficients of the general curvilinear coordinates have the following properties:

$$\begin{cases} g_{ji} = g_{ij} = \mathbf{g}_i \cdot \mathbf{g}_j \neq \delta_i^j \text{ (cov. metric coefficient)} \\ g^{ji} = g^{ij} = \mathbf{g}^i \cdot \mathbf{g}^j \neq \delta_i^j \text{ (contrav. metric coefficient)} \\ g_i^j = \mathbf{g}_i \cdot \mathbf{g}^j = \delta_i^j \text{ (mixed metric coefficient)} \end{cases} \tag{2.54}$$

Using Eqs. (2.42) and (2.53), one obtains the Kronecker delta

$$\begin{aligned} \delta_i^j = \mathbf{g}_i \cdot \mathbf{g}^j &= \frac{\partial x^k}{\partial u^i}\frac{\partial u^j}{\partial x^l}\mathbf{e}_k \cdot \mathbf{e}_l = \frac{\partial x^k}{\partial u^i}\frac{\partial u^j}{\partial x^l}\delta_k^l \\ &= \frac{\partial x^k}{\partial u^i}\frac{\partial u^j}{\partial x^k} = \frac{\partial u^j}{\partial u^i} \end{aligned} \tag{2.55a}$$

The Kronecker delta is defined by

$$\delta_i^j \equiv \begin{cases} 0 \text{ for } i \neq j \\ 1 \text{ for } i = j \end{cases} \tag{2.55b}$$

As an example, the covariant metric tensor **M** in the cylindrical coordinates results from Eq. (2.31).

$$\mathbf{M} = \begin{bmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & r^2 & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{2.56a}$$

The contravariant metric coefficients in the contravariant metric tensor $\mathbf{M}^{-1}$ are calculated from inverting the covariant metric tensor **M**.

$$\mathbf{M}^{-1} = \begin{bmatrix} g^{11} & g^{12} & g^{13} \\ g^{21} & g^{22} & g^{23} \\ g^{31} & g^{32} & g^{33} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & r^{-2} & 0 \\ 0 & 0 & 1 \end{bmatrix} \tag{2.56b}$$

Analogously, the covariant metric tensor **M** in the spherical coordinates results from Eq. (2.40).

$$\mathbf{M} = \begin{bmatrix} g_{11} & g_{12} & g_{13} \\ g_{21} & g_{22} & g_{23} \\ g_{31} & g_{32} & g_{33} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \rho^2 & 0 \\ 0 & 0 & (\rho \sin \varphi)^2 \end{bmatrix} \tag{2.57a}$$

The contravariant metric coefficients in the contravariant metric tensor $\mathbf{M}^{-1}$ are calculated from inverting the covariant metric tensor **M**.

$$\mathbf{M}^{-1} = \begin{bmatrix} g^{11} & g^{12} & g^{13} \\ g^{21} & g^{22} & g^{23} \\ g^{31} & g^{32} & g^{33} \end{bmatrix} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & \rho^{-2} & 0 \\ 0 & 0 & (\rho \sin \varphi)^{-2} \end{bmatrix} \tag{2.57b}$$

2.3.3 Tensors of Second Order and Higher Orders

Mapping an arbitrary vector $\mathbf{x} \in \mathbf{R}^N$ by a linear functional $\mathbf{T}$, one obtains its image vector $\mathbf{y} = \mathbf{T}\mathbf{x}$ [2, 3].

$$\begin{aligned} &\mathbf{T} : \mathbf{R}^N \rightarrow \quad \mathbf{R}^N \\ &\mathbf{T} : \mathbf{x} \rightarrow \mathbf{y} = \mathbf{T}\mathbf{x} \equiv \mathbf{T} \cdot \left(x^j \mathbf{g}_{\mathrm{j}} \right) = x^j \mathbf{T} \cdot \mathbf{g}_j \\ &\qquad\qquad\qquad\quad = x^j T_{ik} \mathbf{g}^i \left(\mathbf{g}^k \cdot \mathbf{g}_j \right) = x^j T_{ik} \delta_j^k \mathbf{g}^i = T_{ij} x^j \mathbf{g}^i \end{aligned} \tag{2.58}$$

where $\mathbf{T}$ is a second-order tensor $\in \mathbf{R}^N \times \mathbf{R}^N$.

It is obvious that the image vector $\mathbf{y} = \mathbf{T}\mathbf{x}$ is a tensor of one lower order compared to the tensor $\mathbf{T}$ that can be considered as a linear operator.

The second-order tensor $\mathbf{T}$ can be generated from the tensor product (dyadic product) of two vectors $\mathbf{u}$ and $\mathbf{v}$, as denoted in Eq. (2.60).

Let $\mathbf{u}$ and $\mathbf{v}$ be two arbitrary vectors. They can be written in the covariant and contravariant bases as

$$\begin{cases} \mathbf{u} = u^i \mathbf{g}_i = u_i \mathbf{g}^i \in \mathbf{R}^N; \\ \mathbf{v} = v^j \mathbf{g}_j = v_j \mathbf{g}^j \in \mathbf{R}^N \end{cases} \tag{2.59}$$

The tensor product of two vectors $\mathbf{u}$ and $\mathbf{v}$ results in the second-order tensor $\mathbf{T}$.

$$\begin{aligned} &\mathbf{T} : \mathbf{u}, \mathbf{v} \in \mathbf{R}^N \rightarrow \mathbf{T} \equiv \mathbf{u} \otimes \mathbf{v} \in \mathbf{R}^N \times \mathbf{R}^N \\ &\mathbf{T} = u^i v^j \mathbf{g}_i \otimes \mathbf{g}_j \equiv u^i v^j \mathbf{g}_i \mathbf{g}_j \equiv T^{ij} \mathbf{g}_i \mathbf{g}_j \\ &\mathbf{T} = u_i v_j \mathbf{g}^i \otimes \mathbf{g}^j \equiv u_i v_j \mathbf{g}^i \mathbf{g}^j \equiv T_{ij} \mathbf{g}^i \mathbf{g}^j \end{aligned} \tag{2.60}$$

Note that the terms $\mathbf{g}_i\mathbf{g}_j$ and $\mathbf{g}^i\mathbf{g}^j$ are called the covariant and contravariant basis tensors. Hence, they are not the same notations as the covariant and contravariant metric coefficients g_{ij} and g^{ij}, respectively.

$$\begin{aligned} &\mathbf{g}_i \mathbf{g}_j \neq \mathbf{g}_i \cdot \mathbf{g}_j \equiv g_{ij} \\ &\mathbf{g}^i \mathbf{g}^j \neq \mathbf{g}^i \cdot \mathbf{g}^j \equiv g^{ij} \end{aligned}$$

Similarly, one obtains the properties of the mixed basis tensors:

6 A ;D /
+,- * *. * $ +A 7 + D B /
// D/ A D " D/ A & /"
(!

1.1 FROM MÖBIUS TO GYROGROUPS

Möbius transformations of the complex open unit disc $\mathbb{D}$,

$$\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\} \tag{1.1}$$

of the complex plane $\mathbb{C}$ are studied in most books on function theory of one complex variable. According to [31, p. 176], these are important for at least two reasons: (i) they play a central role in non-Euclidean geometry [51], and (ii) they are the only automorphisms of the disc.

Ahlfors' book [1], *Conformal Invariants: Topics in Geometric Function Theory*, begins with a presentation of the *polar decomposition* of the most general Möbius self-transformation of the complex open unit disc $\mathbb{D}$,

$$z \mapsto e^{i\theta} \frac{a + z}{1 + \bar{a}z} = e^{i\theta}(a \oplus z) , \tag{1.2}$$

where $a, z \in \mathbb{D}$, $\overline{a}$ being the complex conjugate of a, and where $\theta \in \mathbb{R}$ is a real number [12, p. 211], [17, p. 185], [23, pp. 6 – 7], [31, pp. 177 – 178]. In (1.2) we present the Möbius polar decomposition in a form that suggests the *Möbius addition*, $\oplus$, which we define by the equation

$$a \oplus z = \frac{a+z}{1+\overline{a}z} \, . \tag{1.3}$$

Naturally, Möbius subtraction, $\ominus$, is given by $a \ominus z = a \oplus (-z)$, so that $z \ominus z = 0$ and $\ominus z = 0 \ominus z = 0 \oplus (-z) = -z$.

Interestingly, Möbius addition possesses the *gyroautomorphic inverse property*

$$\ominus(a \oplus b) = \ominus a \ominus b \tag{1.4}$$

and the *left cancellation law*

$$\ominus a \oplus (a \oplus z) = z \tag{1.5}$$

for all $a, b, z \in \mathbb{D}$. Contrasting the left cancellation law (1.5) of Möbius addition, care must be taken with its right counterpart since, in general,

$$(a \oplus z) \ominus z \neq a \, . \tag{1.6}$$

Indeed, in (1.15) below we will introduce a secondary binary operation, $\boxplus$, which is a binary *cooperation* called a Möbius *coaddition*, and which gives rise to the *right cancellation law*, (1.18), of Möbius addition.

Möbius addition is neither commutative nor associative. Fortunately, the failure of associativity is a source of rich theory, the theory of gyrogroups and gyrovector spaces, as we will see in this book.

To measure the extent of which Möbius addition deviates from commutativity we define the *gyrations*

$$\mathrm{gyr}[a, b] = \frac{a \oplus b}{b \oplus a} = \frac{1 + a\overline{b}}{1 + \overline{a}b} \tag{1.7}$$

for $a, b \in \mathbb{D}$. Being unimodular complex numbers, $|\mathrm{gyr}[a, b]| = 1$, gyrations represent rotations of the disc $\mathbb{D}$ about its center. In the special case when $a = 0$ or $b = 0$ or $a = \lambda b$ for some real number λ, the gyration $\mathrm{gyr}[a, b]$ is trivial, that, is, $\mathrm{gyr}[a, b] = 1$. The number -1 cannot be represented by a gyration since the equation $\mathrm{gyr}[a, b] = -1$ has no solution for a and b in the disc $\mathbb{D}$.

Gyrations respect Möbius addition,

$$\mathrm{gyr}[a, b](c \oplus d) = \mathrm{gyr}[a, b]c \oplus \mathrm{gyr}[a, b]d \tag{1.8}$$

for all $a, b, c, d \in \mathbb{D}$, and the inverse $\mathrm{gyr}^{-1}[a, b]$ of a gyration $\mathrm{gyr}[a, b]$ is the gyration $\mathrm{gyr}[b, a]$,

$$\mathrm{gyr}^{-1}[a, b] = \mathrm{gyr}[b, a] \, , \tag{1.9}$$

as we see from (1.7). Hence, gyrations are special automorphisms of the Möbius groupoid $(\mathbb{D}, \oplus)$. We recall that a groupoid $(G, \oplus)$ is a nonempty set, G, with a binary operation, $\oplus$, and that an automorphism of a groupoid $(G, \oplus)$ is a bijective self map f of G that respects its binary operation $\oplus$, that is, $f(a \oplus b) = f(a) \oplus f(b)$. The set of all automorphisms of a groupoid $(G, \oplus)$ forms a group, denoted $Aut(G, \oplus)$. The formal definition of groups will be presented in Def. 1.3, p. 5.

To emphasize that gyrations are automorphisms, they are also called *gyroautomorphisms*. The automorphism $\phi(z) = -z$ of the disc is not a gyroautomorphism of the disc since the equation $(1 + a\bar{b})/(1 + \bar{a}b) = -1$ for $a, b \in \mathbb{D}$ has no solution in the disc. Consequently, the gyroautomorphisms of the disc do not form a group under gyroautomorphism composition.

It follows from the gyration definition in (1.7) that Möbius addition obeys the *gyrocommutative law*:

$$a \oplus b = \text{gyr}[a, b](b \oplus a) \tag{1.10}$$

for all $a, b \in \mathbb{D}$. The Möbius gyrocommutative law (1.10) is not terribly surprising since it is generated by definition. But, we are not finished!

Coincidentally, the gyration gyr$[a, b]$, which "repairs" in (1.10) the breakdown of commutativity in Möbius addition, "repairs" the breakdown of associativity in Möbius addition as well. Indeed, it gives rise to the following gyroassociative laws (left and right),

$$\begin{aligned} a \oplus (b \oplus z) &= (a \oplus b) \oplus \text{gyr}[a, b]z\,, \\ (a \oplus b) \oplus z &= a \oplus (b \oplus \text{gyr}[b, a]z)\,, \end{aligned} \tag{1.11}$$

for all $a, b, z \in \mathbb{D}$. Hence, gyrations measure simultaneously the extent to which Möbius addition deviates from both associativity and commutativity.

Möbius gyrations are expressible in terms of Möbius addition. Indeed, solving the first identity in (1.11) for gyr$[a, b]z$ by means of the Möbius left cancellation law (1.5) we have

$$\text{gyr}[a, b]z = \ominus(a \oplus b) \oplus \{a \oplus (b \oplus z)\}\,. \tag{1.12}$$

Möbius gyrations gyr$[a, b]$, $a, b \in \mathbb{D}$, thus endow the Möbius disc groupoid $(\mathbb{D}, \oplus)$ with a group-like structure, naturally called a *gyrogroup*. In fact, Möbius gyrations do more than that. They contribute their own rich structure to the gyrogroup. Thus, for instance, they possess the *loop properties* (left and right)

$$\begin{aligned} \text{gyr}[a \oplus b, b] &= \text{gyr}[a, b]\,, \\ \text{gyr}[a, b \oplus a] &= \text{gyr}[a, b]\,, \end{aligned} \tag{1.13}$$

and the nested gyration identity

$$\text{gyr}[b, \ominus\text{gyr}[b, a]a] = \text{gyr}[a, b]\,, \tag{1.14}$$

as one can straightforwardly check.

Möbius addition $\oplus$, as a primary addition in the disc, comes with *Möbius coaddition*, $\boxplus$, as a secondary addition in the disc. Möbius coaddition is defined in terms of Möbius addition and Möbius gyrations by the equation

$$a \boxplus b = a \oplus \text{gyr}[a, \ominus b]b \tag{1.15}$$

for all $a, b \in \mathbb{D}$. It turns out that Möbius coaddition is commutative (but not associative), given by the equation

$$a \boxplus b = \frac{(1 - |a|^2)b + (1 - |b|^2)a}{1 - |a|^2|b|^2} \tag{1.16}$$

for all $a, b \in \mathbb{D}$, as we see from (1.15) and (1.7).

Replacing b by $\ominus b$ in (1.15), and noting that $\mathrm{gyr}[a, \ominus b]$ is an automorphism, it follows from (1.15) that

$$a \boxminus b = a \oplus \mathrm{gyr}[a, b](\ominus b) = a \ominus \mathrm{gyr}[a, b]b\,. \tag{1.17}$$

for all $a, b \in \mathbb{D}$, where we use the obvious notation, $a \boxminus b = a \boxplus (\ominus b)$.

In terms of Möbius coaddition, the *right cancellation law* of Möbius addition takes the form

$$(a \oplus b) \boxminus b = a\,. \tag{1.18}$$

The right cancellation law (1.18) is associated with the second right cancellation law

$$(a \boxplus b) \ominus b = a\,, \tag{1.19}$$

as one can straightforwardly check. Identities (1.18) and (1.19) present one of the duality symmetries that Möbius addition and coaddition share.

Guided by the group-like structure of Möbius addition, we define a *gyrogroup* to be a group in which the associative law is replaced by the gyroassociative laws (left and right), and a *gyrocommutative gyrogroup* to be a commutative group in which the commutative and associative laws are replaced by the gyrocommutative and gyroassociative laws. Like Möbius gyrations, the gyrations in the gyrocommutative and gyroassociative laws of an abstract gyrogroup must be automorphisms of the gyrogroup.

Thus, the disc $\mathbb{D}$ with its Möbius addition forms a *gyrocommutative gyrogroup* $(\mathbb{D}, \oplus)$ where, strikingly, the concepts of gyrocommutativity and gyroassociativity of the gyrogroup preserve the flavor of their classical counterparts [50, 51]. Mathematical coincidences are not accidental! Hence, in particular, the gyrations that "coincidentally" repair in (1.10) – (1.11) the breakdown of commutativity and associativity need not be peculiar to Möbius addition, as shown in [13, 14], and as we will see in this book.

Indeed, the generalization of groups into gyrogroups that Möbius addition suggests bears an intriguing resemblance to the generalization of the rational numbers to the real ones. The beginner is initially surprised to discover an irrational number, like $\sqrt{2}$, but soon later he or she is likely to realize that there are more irrational numbers than rational ones. Similarly, the gyrogroup structure of Möbius addition initially comes as a surprise. But, interested explorers may soon realize that there are indications that, in some sense, there are more non-group gyrogroups than groups [13].

3 / $! ($! $

or

$$\begin{Bmatrix}\alpha\\ \mu\ \ \nu\end{Bmatrix} A_c \begin{Bmatrix}c\\ \alpha\ \ \sigma\end{Bmatrix} + A_\alpha \frac{\partial}{\partial x^\sigma}\begin{Bmatrix}\alpha\\ \mu\ \ \nu\end{Bmatrix} - \begin{Bmatrix}\alpha\\ \mu\ \ \sigma\end{Bmatrix} A_c \begin{Bmatrix}c\\ \alpha\ \ \nu\end{Bmatrix} - A_c \frac{\partial}{\partial x^\nu}\begin{Bmatrix}c\\ \mu\ \ \sigma\end{Bmatrix} = 0 \text{ by Eq. (4.49)}$$

or

$$\begin{Bmatrix}\alpha\\ \mu\ \ \nu\end{Bmatrix} A_c \begin{Bmatrix}c\\ \alpha\ \ \sigma\end{Bmatrix} + A_c \frac{\partial}{\partial x^\sigma}\begin{Bmatrix}c\\ \mu\ \ \nu\end{Bmatrix} - \begin{Bmatrix}\alpha\\ \mu\ \ \sigma\end{Bmatrix}\begin{Bmatrix}c\\ \alpha\ \ \nu\end{Bmatrix} A_c - A_c \frac{\partial}{\partial x^\nu}\begin{Bmatrix}c\\ \mu\ \ \sigma\end{Bmatrix} = 0$$

or

$$\left[\begin{Bmatrix}\alpha\\ \mu\ \ \nu\end{Bmatrix}\begin{Bmatrix}c\\ \alpha\ \ \sigma\end{Bmatrix} + \frac{\partial}{\partial x^\sigma}\begin{Bmatrix}c\\ \mu\ \ \nu\end{Bmatrix} - \begin{Bmatrix}\alpha\\ \mu\ \ \sigma\end{Bmatrix}\begin{Bmatrix}c\\ \alpha\ \ \nu\end{Bmatrix} - \frac{\partial}{\partial x^\nu}\begin{Bmatrix}c\\ \mu\ \ \sigma\end{Bmatrix}\right] A_c = 0$$

or

$$\left[-\frac{\partial}{\partial x^\nu}\begin{Bmatrix}c\\ \mu\ \ \sigma\end{Bmatrix} + \frac{\partial}{\partial x^\sigma}\begin{Bmatrix}c\\ \mu\ \ \nu\end{Bmatrix} - \begin{Bmatrix}\alpha\\ \mu\ \ \sigma\end{Bmatrix}\begin{Bmatrix}c\\ \alpha\ \ \nu\end{Bmatrix} + \begin{Bmatrix}\alpha\\ \mu\ \ \nu\end{Bmatrix}\begin{Bmatrix}c\\ \alpha\ \ \sigma\end{Bmatrix}\right] A_c = 0$$

or

$$R^c_{\mu\sigma\nu} A_c = 0, \quad \text{i.e. } R^c_{\mu\sigma\nu} = 0;\ \text{as } A_c \text{ is arbitrary.}$$

Thus, we see that the RHS of Eq. (4.50) is integrable only when the curvature tensor vanishes. Consequently, Eq. (4.49) is integrable only when $R^c_{\mu\sigma\nu} = 0$.

Now, we can carry the vector A_μ to any point by parallel displacement. This gives a unique result independent of the path of transfer. If a vector is displaced in this way we obtain a uniform vector field. Thus, the construction of uniform vector field is only possible when the curvature tensor vanishes.

4.3 Einstein Space

Einstein space is defined as a space which is homogeneous with regard to the Ricci tensor R_{ij}. Thus, a space for which

$$R_{ij} = \lambda g_{ij};\quad \lambda = \text{invariant at all points} \tag{4.54}$$

at every point of the space, then that space is called *Einstein space.* Inner multiplication of g^{ij} shows that

$$g^{ij} R_{ij} = \lambda g^{ij} g_{ij} \Rightarrow R = \lambda N. \tag{4.55}$$

Thus for an Einstein space,

$$R_{ij} = \lambda g_{ij} = \frac{1}{N} R g_{ij}. \tag{4.56}$$

Hence, for an Einstein space Eq. (4.56) holds at every point of the space.

Theorem 4.3.1 *A space of constant curvature is an Einstein space.*

Proof: Let the Riemannian curvature κ at P of V_N for the orientation determined by p^i and q^i, is given in Eq. (4.34) as

$$\kappa = \frac{p^h q^i p^j q^k R_{hijk}}{p^h q^i p^j q^k \left[g_{hj} g_{ik} - g_{ij} g_{kh}\right]}.$$

Since κ is constant and independent of the orientation so,

$$\kappa = \frac{R_{hijk}}{g_{hj} g_{ik} - g_{ij} g_{kh}}$$

or

$$R_{hijk} = \kappa \left[g_{hj} g_{ik} - g_{ij} g_{kh}\right].$$

Multiplying by g^{hk}, we get

$$\kappa g^{hk} \left[g_{hj} g_{ik} - g_{ij} g_{kh}\right] = g^{hk} R_{hijk}$$

or

$$\kappa \left(\delta_i^h g_{hj} - N g_{ij}\right) = R_{ij}; \quad \text{since, } g^{hk} R_{hijk} = R_{ij}$$

or

$$\kappa \left(g_{ij} - N g_{ij}\right) = R_{ij}$$

or

$$\kappa \left(1 - N\right) g_{ij} g^{ij} = R_{ij} g^{ij}; \text{ multiplying by } g^{ij}$$

or

$$\kappa N (1 - N) = R; \quad \text{as } R_{ij} g^{ij} = R.$$

Therefore,

$$R_{ij} = (1 - N) g_{ij} \frac{R}{N(1 - N)} = \frac{R}{N} g_{ij}.$$

This is the necessary and sufficient condition for the space V_N to be Einstein space.

EXAMPLE 4.3.1 *If $g^{ik} R_{kj} = R^i_j$ and $g^{ij} R_{ij} = R$, show that $R^i_{j,i} = \frac{1}{2} \frac{\partial R}{\partial x^j}$. Hence, show that for an Einstein space, the scalar curvature R is constant.*

Solution: Here, we use the Bianchi identity, Eq. (4.20), $R_{pkjt,i} + R_{pkti,j} + R_{pkij,t} = 0$. The covariant differentiation of the relation $g^{ik} R_{kj} = R^i_j$ with respect to x^l is given by

$$R^i_{j,l} = g^{ik}_{,l} R_{kj} + g^{ik} R_{kj,l} = g^{ik} R_{kj,l}; \quad \text{as } g^{ik}_{,l} = 0.$$

Thus, the divergence of R^i_j is given by

$$\begin{aligned}
R^i_{j,i} &= g^{ik}R_{kj,i} = g^{ik}R^t_{kjt,i};\ \text{as } R^t_{kit} = R_{kj} \\
&= g^{ik}\left(g^{pt}R_{pkjt}\right)_{,i};\quad \text{as } g^{pt}R_{pkjt} = R^t_{kjt} \\
&= g^{ik}g^{pt}R_{pkjt,i};\quad \text{as } g^{pt}_{,i} = 0 \\
&= -g^{ik}g^{pt}\left[R_{pkti,j} + R_{pkij,t}\right] = -g^{pt}\left[g^{ik}R_{pkti,j} + g^{ik}R_{pkij,t}\right] \\
&= -g^{pt}\left[g^{ki}R_{kpti,j} + g^{ik}R_{kpji,t}\right] \\
&\quad\ \text{as } R_{kpti} = -R_{pkti} \text{ and } R_{kpji} = R_{pkij} \\
&= -g^{pt}\left[-R^i_{pti,j} + R^i_{pji,t}\right] = -g^{pt}\left[-R_{pt,j} + R_{pj,t}\right] \\
&= \left(g^{pt}R_{pt}\right)_{,j} - g^{pt}R_{pj,t} = R_{,j} - R^t_{j,t} = R_{,j} - R^i_{j,i} \\
&\quad\ \text{replacing the dummy index } t \text{ by } i
\end{aligned}$$

or

$$2R^i_{j,i} = R_{,j} = \frac{\partial R}{\partial x^j} \Rightarrow R^i_{j,i} = \frac{1}{2}\frac{\partial R}{\partial x^j}.$$

For an Einstein space, $R_{ij} = \frac{R}{N}g_{ij}$, therefore,

$$g^{ki}R_{ij} = \frac{R}{N}g_{ij}g^{ki} \Rightarrow R^k_j = \frac{R}{N}\delta^k_j$$

or

$$R^k_{j,k} = \frac{1}{N}R_{,k}\delta^k_j = \frac{1}{N}R_{,j}$$

or

$$\frac{1}{2}R_{,j} = \frac{1}{N}R_{,j} \Rightarrow R_{,j} = 0;\quad \text{for } N > 2.$$

Therefore, for an Einstein space, the scalar curvature R is constant.

EXAMPLE 4.3.2 *For a V_2 referred to an orthogonal system of parametric curves $(g_{12} = 0)$, show that*

$$\begin{aligned}
R_{12} &= 0,\quad R_{11}g_{22} = R_{22}g_{11} = R_{1221} \\
R &= g^{ij}R_{ij} = \frac{2R_{1221}}{g_{11}g_{22}},\quad \textit{consequently, } R_{ij} = \frac{R}{2}g_{ij}.
\end{aligned}$$

Hence, show that V_2 is an Einstein space.

Solution: Given that, in a V_2, $g_{12} = 0$ so that $g^{12} = 0$. Also,

$$g^{ij} = \frac{1}{g_{ij}} \Rightarrow g^{11} = \frac{1}{g_{11}}, \quad g^{22} = \frac{1}{g_{22}}.$$

The metric of V_2 is given by

$$\begin{aligned} ds^2 &= g_{ij}dx^i dx^j; \quad i, j = 1, 2 \\ &= g_{11}(dx^1)^2 + g_{22}(dx^2)^2; \quad \text{as } g_{12} = 0. \end{aligned}$$

Also, we know that $g^{hk}R_{hijk} = R_{ij}$ and

$$g = \begin{vmatrix} g_{11} & g_{12} \\ g_{21} & g_{22} \end{vmatrix} = \begin{vmatrix} g_{11} & 0 \\ 0 & g_{22} \end{vmatrix} = g_{11}g_{22}.$$

(a) Here, we have to show that $R_{12} = 0$. For this,

$$\begin{aligned} R_{12} &= g^{hk}R_{h12k} = g^{h1}R_{h121} + g^{h2}R_{h122} = g^{h1}R_{h121}; \quad \text{as } R_{h122} = 0 \\ &= g^{11}R_{1121} + g^{21}R_{2121} = 0; \quad \text{as } g^{12} = 0 \text{ and } R_{1121} = 0. \end{aligned}$$

(b) Using the relation $g^{hk}R_{hijk} = R_{ij}$ we get

$$\begin{aligned} R_{11} &= g^{hk}R_{h11k} = g^{2k}R_{211k} = g^{22}R_{2112} = \frac{R_{2112}}{g_{22}}. \\ R_{22} &= g^{hk}R_{h22k} = g^{1k}R_{122k} = g^{11}R_{1221} = \frac{R_{1221}}{g_{11}}. \end{aligned}$$

Since $R_{2112} = R_{1221}$, it follows that, $R_{11}g_{22} = R_{1221} = R_{22}g_{11}$. Therefore, in a two-dimensional Riemannian space the components of a Ricci tensor are proportional to the components of a metric tensor.

(c) From the definition of R, we get

$$\begin{aligned} R &= g^{ij}R_{ij} = g^{i1}R_{i1} + g^{i2}R_{i2} \\ &= g^{11}R_{11} + g^{22}R_{22}; \quad \text{as } g^{12} = 0 \\ &= \frac{R_{11}}{g_{11}} + \frac{R_{22}}{g_{22}} = \frac{R_{1221}}{g_{22}g_{11}} + \frac{R_{1221}}{g_{11}g_{22}} \\ &= \frac{2R_{1221}}{g_{11}g_{22}}; \quad \text{as } R_{2112} = R_{1221}. \end{aligned}$$

(d) From (c), we see that

$$R = \frac{2R_{1221}}{g_{11}g_{22}} = \frac{2R_{1221}}{g}; \quad \text{as } g = g_{11}g_{22}$$
$$\Rightarrow R_{1221} = \frac{1}{2}Rg.$$

Therefore, the relation in (b) can be written in the form

$$R_{11}g_{22} = \frac{1}{2}Rg = R_{22}g_{11}$$

from which it follows that

$$\begin{aligned} R_{11} &= \frac{Rg}{2g_{22}} = \frac{Rg_{11}g_{22}}{2g_{22}} = \frac{1}{2}Rg_{11} \\ R_{22} &= \frac{Rg}{2g_{11}} = \frac{Rg_{11}g_{22}}{2g_{11}} = \frac{1}{2}Rg_{22} \\ R_{12} &= \frac{1}{2}Rg_{12} = 0; \quad \text{as } g_{12} = 0. \end{aligned}$$

Consequently, we get $R_{ij} = \frac{R}{2}g_{ij}$. This shows that V_2 is an Einstein space.

4.4 Mean Curvature

Let $\lambda^i_{h|}$ be the components of unit vector in a direction at a point P of a V_N. Let $\lambda^i_{k|}$ be the components of unit vector forming an orthogonal ennuple. One vector out of N vectors $\lambda^i_{k|}$ is $\lambda^i_{h|}$ and hence, we can say that $\lambda^i_{k|}$ are components of $N-1$ vectors where $h \neq k$ and $k = 1, 2, \ldots, N$.

Let the Riemannian curvature at P of V_N for the orientation determined by $\lambda^i_{h|}$ and $\lambda^i_{k|}$ $(k \neq h)$ be denoted by K_{hk} and is given by

$$\begin{aligned} K_{hk} &= \frac{\lambda^p_{h|}\lambda^q_{k|}\lambda^r_{h|}\lambda^s_{k|}R_{pqrs}}{\lambda^p_{h|}\lambda^q_{k|}\lambda^r_{h|}\lambda^s_{k|}\left(g_{pr}g_{qs} - g_{ps}g_{qr}\right)} \\ &= \frac{\lambda^p_{h|}\lambda^q_{k|}\lambda^r_{h|}\lambda^s_{k|}R_{pqrs}}{\left(\lambda^p_{h|}\lambda^r_{h|}g_{pr}\right)\left(\lambda^q_{k|}\lambda^s_{k|}g_{qs}\right) - \left(\lambda^p_{h|}\lambda^s_{k|}g_{ps}\right)\left(\lambda^q_{k|}\lambda^r_{h|}g_{qr}\right)}. \end{aligned} \tag{4.57}$$

Since unit vectors $\lambda^i_{h|}$ and $\lambda^i_{k|}$ are orthogonal, so,

$$\lambda^p_{h|}\lambda^r_{h|}g_{pr} = 1 \text{ and } \lambda^p_{h|}\lambda^s_{k|}g_{ps} = 0.$$

Therefore, from Eq. (4.57), we get

$$K_{hk} = \frac{\lambda^p_{h|}\lambda^q_{k|}\lambda^r_{h|}\lambda^s_{k|}R_{pqrs}}{1.1 - 0.0} = \lambda^p_{h|}\lambda^q_{k|}\lambda^r_{k|}\lambda^s_{k|}R_{pqrs}. \tag{4.58}$$

Since the right-hand side of Eq. (4.58) vanishes for $h = k$, and so we say K_{hh} is equal to zero. Let $M_h = \sum_{k=1}^{N} K_{hk}$. Hence from Eq. (4.58) we have,

$$\begin{aligned}
\sum_{k=1}^{N} K_{hk} = M_h &= \sum_{k=1}^{N} \lambda^p_{h|}\lambda^q_{k|}\lambda^r_{h|}\lambda^s_{k|}R_{pqrs} \\
&= \lambda^p_{h|}\lambda^q_{h|} \sum_{k=1}^{N} \lambda^q_{k|}\lambda^s_{k|}R_{pqrs} \\
&= \lambda^p_{h|}\lambda^r_{h|}g^{qs}R_{pqrs}; \text{ as } \sum_{k=1}^{N} \lambda^q_{k|}\lambda^s_{k|} = g^{qs} \\
&= -\lambda^p_{h|}\lambda^r_{h|}g^{qs}R_{qprs} = -\lambda^p_{h|}\lambda^r_{h|}R^s_{pqs} = -\lambda^p_{h|}\lambda^r_{h|}R_{pr}.
\end{aligned} \tag{4.59}$$

This shows that M_h is independent of $(N-1)$ orthogonal direction choosen to complete an orthogonal ennuple. Here, M_h is defined as mean curvature or Riccian curvature of V_N for the direction $\lambda^p_{h|}$. Summing Eq. (4.58) over the N mutually orthogonal directions, we get

$$\sum_{h=1}^{N} M_h = -\sum_{h=1}^{N} \lambda^p_{h|}\lambda^r_{h|}R_{pr} = -g^{pr}R_{pr} = -R,$$

where R is the scalar curvature. This proves that the sum of mean curvatures for N mutual orthogonal directions is independent of the directions chosen to complete an orthogonal ennuple and has the value $-R$.

4.4.1 Ricci's Principal Directions

Let us suppose that $\lambda^i_{h|}$ is not a unit vector and therefore, the mean curvature M_h in this case is given by

$$M_h = -\frac{R_{ij}\lambda^i_{h|}\lambda^j_{h|}}{g_{ij}\lambda^i_{h|}\lambda^j_{h|}} \Rightarrow \left(R_{ij} + M_h g_{ij}\right)\lambda^i_{h|}\lambda^j_{h|} = 0.$$

Differentiating this equation with respect to $\lambda^i_{h|}$, we get

$$\frac{\partial M_h}{\partial \lambda^i_{h|}} g_{jk}\lambda^j_{h|}\lambda^k_{h|} + 2\left(R_{ij} + M_h g_{ij}\right)\lambda^j_{h|} = 0.$$

For extreme value of M_h, we must have $\frac{\partial M_h}{\partial \lambda^i_{h|}} = 0$, and so

$$(R_{ij} + M_h g_{ij})\,\lambda^j_{h|} = 0,$$

which are called *Ricci's principal direction* of the space and they are principal directions of Ricci tensor R_{ij}.

EXAMPLE 4.4.1 *For a two-dimensional manifold, prove that* $K_{pq} = -\frac{R}{2}$.

Solution: In V_2, we know R_{1212} is the only non-vanishing Riemann–Christoffel tensor given by

$$R_{1212} = \frac{1}{2}Rg; R = \text{ total curvature.}$$

Let the Riemannian curvature at P of V_N for the orientation determined by $\lambda^i_{p|}$ and $\lambda^i_{q|}$ $(q \neq p)$ be denoted by K_{pq} and from Eq. (4.57) we get,

$$\begin{aligned} K_{pq} &= \frac{\lambda^h_{p|}\lambda^i_{q|}\lambda^j_{p|}\lambda^k_{q|}R_{hijk}}{\lambda^h_{p|}\lambda^i_{q|}\lambda^j_{p|}\lambda^k_{q|}\left(g_{hj}g_{ik} - g_{hk}g_{ij}\right)} \\ &= \frac{\lambda^1_{p|}\lambda^2_{q|}\lambda^1_{p|}\lambda^2_{q|}R_{1212}}{\lambda^1_{p|}\lambda^2_{q|}\lambda^1_{p|}\lambda^2_{q|}\left(g_{11}g_{22} - g_{12}g_{21}\right)} = \frac{R_{1212}}{g_{12}^2 - g_{11}g_{22}} = \frac{R_{1212}}{-g} = -\frac{1}{2}R. \end{aligned}$$

4.5 Geodesics in a V_N

Consider a curve $\Gamma : x^i = x^i(t)$ in a V_N, an N-dimensional Riemannian space, on it and let $x^i(t)$ be the co-ordinates of a general point P on it. Let the points A and B of the path correspond, respectively, to the value t_1 and t_2 of the parameter.

Consider two points on the path close to each other with co-ordinates x^i and $x^i + dx^i$. Let the parameter take values t and $t + dt$ corresponding to these two points, respectively. The interval ds between the two points is given by

$$ds^2 = g_{ij}dx^i dx^j = g_{ij}\frac{dx^i}{dt}\frac{dx^j}{dt}dt^2. \tag{4.60}$$

The total interval between A and B along the path therefore,

$$\begin{aligned} S &= \int_{t_1}^{t_2} \sqrt{g_{ij}\frac{dx^i}{dt}\frac{dx^j}{dt}}\,dt \\ &= \int_A^B F(x^i, \dot{x}^i)dt, \text{ say; where } F(x^i, \dot{x}^i) = \sqrt{g_{ij}\dot{x}^i\dot{x}^j}. \end{aligned} \tag{4.61}$$

In order Γ is a geodesic, integral Eq. (4.61) should be stationary. In order that integral Eq. (4.61) is stationary, we have the Euler-Lagrange condition,

$$\frac{\partial F}{\partial \dot{x}^l} - \frac{d}{dt}\left(\frac{\partial F}{\partial \dot{x}^l}\right) = 0$$

or

$$\frac{1}{2\dot{s}}\frac{\partial g_{ij}}{\partial x^l}\dot{x}^i\dot{x}^j - \left[-\frac{\ddot{s}}{\dot{s}}g_{li}\dot{x}^i + \frac{1}{\dot{s}}\frac{\partial g_{li}}{\partial \dot{x}^j}\dot{x}^j\dot{x}^i + \frac{1}{\dot{s}}g_{li}\ddot{x}^i\right] = 0$$

or

$$g_{li}\ddot{x}^i - \frac{\ddot{s}}{\dot{s}}g_{li}\dot{x}^i + [li, j]\dot{x}^i\dot{x}^j = 0. \tag{4.62}$$

Multiplying this relation by g^{lm} and perform summation over l, we get

$$\ddot{x}^m - \frac{\ddot{s}}{\dot{s}}\dot{x}^m + \left\{\begin{matrix} m \\ i \quad j \end{matrix}\right\}\dot{x}^i\dot{x}^j = 0. \tag{4.63}$$

Equation (4.63) of geodesic can be further simplified by taking $s = t$, so that $\dot{s} = 1$, $\ddot{s} = 0$, and therefore, Eq. (4.63) becomes

$$\frac{d^2x^i}{ds^2} + \left\{\begin{matrix} i \\ j \quad k \end{matrix}\right\}\frac{dx^j}{ds}\frac{dx^k}{ds} = 0, \tag{4.64}$$

where s itself is chosen as the parameter. This, of course, represents a set of N coupled differential equations. Equation (4.64) is known as geodesic equation in V_N.

EXAMPLE 4.5.1 *Show that on the surface of a sphere all great circles are geodesics while no other circle is a geodesic.*

Solution: The components of the metric tensor on the surface of a sphere of radius a are $g_{11} = a^2, g_{22} = a^2\sin^2\theta, g_{12} = g_{21} = 0$ and $g = a^4\sin^2\theta$ so that the metric is $ds^2 = a^2(d\theta)^2 + a^2\sin^2\theta(d\phi)^2$. The non-vanishing Christoffel symbols are

$$\left\{\begin{matrix} 2 \\ 1 \quad 2 \end{matrix}\right\} = \cot\theta = \left\{\begin{matrix} 2 \\ 2 \quad 1 \end{matrix}\right\};\ \left\{\begin{matrix} 1 \\ 2 \quad 2 \end{matrix}\right\} = -\sin\theta\cos\theta.$$

Thus, the geodesic equation reduces to (with $\theta = x^1, \phi = x^2$)

$$\frac{d^2\theta}{ds^2} - \sin\theta\cos\theta\left(\frac{d\phi}{ds}\right)^2 = 0 \tag{i}$$

$$\frac{d^2\phi}{ds^2} + 2\cot\theta\frac{d\theta}{ds}\frac{d\phi}{ds} = 0. \tag{ii}$$

(a) Consider a great circle on the surface of the sphere and choose the z axis $(\theta = 0)$ to be normal to the plane of the circle, so that the great circle is the equator. The parametric equation of the great circle is

$$\theta = \frac{\pi}{2}, \quad \phi = cs + d; \quad c \neq 0, \tag{iii}$$

where c and d are independent of s, θ and ϕ. It is evident that Eq. (iii) satisfy Eqs. (i) and (ii), so that the great circle is a geodesic. Since the choice of the polar axis $\theta = 0$ is arbitrary, it follows that any great circle is a geodesic.

(b) Consider a circle on the sphere such that the plane of the circle does not pass through the centre of the sphere. Again, choose the direction $\theta = 0$ to be normal to the plane of the circle so that the parametric equation of the circle is

$$\theta = \theta_0, \ \phi = ps + q; \ \theta_0 \in (0, \pi) - \left\{\frac{\pi}{2}\right\}; \ p \neq 0, \tag{iv}$$

where p and q are independent of s, θ and ϕ. On substitution, it is seen that Eq. (ii) is satisfied but Eq. (i) is reduces to

$$p^2 \sin\theta_0 \cos\theta_0 = 0.$$

The conditions on θ_0 and p of Eq. (iv) show that this equation cannot be satisfied, proving that the circle is not a geodesic.

Now, we find the lines of shortest distance of the sphere. From Eq. (4.61), we have,

$$S = a \int_A^B F(x^i, \dot{x}^i) dt,$$

where

$$F(x^i, \dot{x}^i) = \sqrt{g_{ij}\dot{x}^i\dot{x}^j} = \sqrt{1 + \dot{\phi}^2 \sin^2\theta}.$$

In order Γ is a geodesic, then Euler–Lagrange equation reduces to,

$$F\dot{\phi} = \text{constant} \ \Rightarrow \frac{\dot{\phi}\sin^2\theta}{\sqrt{1 + \dot{\phi}^2 \sin^2\theta}} = c$$

$$\Rightarrow \dot{\phi}^2 = \frac{c^2}{\sin^4\theta - c^2\sin^2\theta} = \frac{c^2 \operatorname{cosec}^4\theta}{(1 - c^2) - c^2\cot^2\theta}$$

$$\Rightarrow \dot{\phi} = \frac{k \ \operatorname{cosec}^2\theta}{\sqrt{1 - k^2\cot^2\theta}}; k^2 = \frac{c^2}{1 - c^2}$$

$$\Rightarrow \phi = \alpha - \sin^{-1}(k\cot\theta); \ \text{ i.e. } \sin(\alpha - \phi) = k\cot\theta.$$

Let us verify these curves are great circles. Multiplied last equation by $\alpha \sin\theta$, we get

$$(\alpha \sin\theta \cos\phi)\sin\alpha - (\alpha \sin\theta \sin\phi)\cos\alpha = k\alpha\cos\theta$$

or

$$x \sin\alpha - y\cos\alpha = kz.$$

This represents a plane through the centre of the sphere, and the section of the sphere by this plane is a great circle.

4.5.1 Parallel Vector Fields

In an Euclidean space, a vector field $A_i(x^j)$ is said to be a field of parallel vectors if the components A_i are constants, i.e. $A_{i,j} = 0$, i.e. or, suppose that a vector A_i defined at a point x^j undergoes a displacement dx^j to the point $x^j + dx^j$, where, the vector becomes $A_i + \partial A_i$. We shall say that A_i undergoes a parallel displacement if $\frac{\partial A_i}{\partial x^j} = 0$. For example, a uniform electric field is a field of parallel vectors; the gravitational field of the earth in a sufficiently small region of space is a field of parallel vectors.

Here, our object is to generalise the concept of parallel displacement of surface vectors and tensors in Riemannian space, due to Levi Civita. Let us consider a space curve Γ, total of points, whose co-ordinates satisfy equation of the form

$$\Gamma: \; x^i = x^i(t), \tag{4.65}$$

where x^i (belongs to the class C^1) are functions of a single parameter t. Let a vector A be localised at some point P of Γ whose components A^i are functions of t. If we construct at every point of Γ, a vector equal to A in magnitude and parallel to it in direction, we obtain what is known as a parallel field of vectors along the curve Γ. We have shown in Chapter 3 that if A_i is a vector, its co-ordinate derivative $\frac{\partial A_i}{\partial x^j}$ is not a tensor, but the intrinsic derivative $\frac{\delta A_i}{\delta t}$ along the curve Eq. (4.65) is a tensor. To retain the tensor character, therefore, we must define the parallel displacement of a tensor in a Riemannian space differently. If A^i is a solution of the system of differential equation

$$\frac{\delta A^i}{\delta t} = \frac{dA^i}{dt} + \begin{Bmatrix} i \\ j \;\; k \end{Bmatrix} A^j \frac{dx^k}{ds} \tag{4.66}$$

then the vectors A^i are said to form a parallel vector field along the curve Γ given by Eq. (4.65). We say that if the vector A is a parallel field along Γ, then the vectors A do not change along the curve. Thus, the vector A suffers a parallel displacement along Γ if the intrinsic derivative of the tensor along the curve vanishes, (Figure 4.1), i.e.

$$A^i_{,j}\frac{dx^i}{dt} = \frac{\delta A^i}{\delta t} = 0. \tag{4.67}$$

% / 3 " CCC

Conversely, we can show that every solution of system Eq. (4.67) yields a parallel vector field along Γ. Indeed, from the theory of differential equations it is known that this system of first order differential equations has a unique solution when the values of the components A^i are specified at a point of Γ. But the vector field formed by constructing a family of vectors of fixed lengths, parallel to a given vector, satisfies the system. Hence, every solution of Eq. (4.67) satisfies the initial conditions must form a parallel field along Γ.

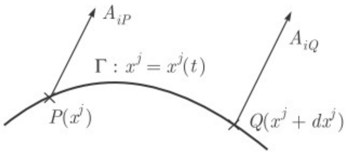

Figure 4.1: Parallel vectors A_{iP} and A_{iQ}.

In other words, we say that A^i is parallely displaced with respect to Riemannian space along the curve Γ, if Eq. (4.67) holds at all points of Γ. Thus, we have a field of parallel vectors, if,

$$A^i_{,j}\frac{dx^i}{dt} = 0 \Rightarrow g_{ik}\left(A^i_{,j}\frac{dx^j}{dt}\right) = 0 \Rightarrow \left(g_{ik}A^i\right)_{,j}\frac{dx^j}{dt} = 0$$

$$\Rightarrow A_{k,j}\frac{dx^j}{dt} = 0; \text{i.e.}\quad A_{i,j}\frac{dx^j}{dt} = 0$$

or

$$\left[\frac{dA^i}{dx^j} + \left\{\begin{matrix} i \\ \alpha \ \ j \end{matrix}\right\} A^\alpha\right]\frac{dx^j}{dt} = 0$$

or

$$\frac{dA^i}{dt} + \left\{\begin{matrix} i \\ \alpha \ \ j \end{matrix}\right\} A^\alpha \frac{dx^j}{dt} = 0$$

or

$$dA^i = -\left\{\begin{matrix} i \\ j \ \ k \end{matrix}\right\} A^j dx^k \tag{4.68}$$

along the curve. The converse follows, as previously, for the existence and uniqueness of solution of such systems of differential equations. Similarly, the condition for a parallel displacement of a covariant vector A_i is

$$dA_i = \left\{\begin{matrix} j \\ i \ \ k \end{matrix}\right\} A_j dx^k. \tag{4.69}$$

Also, it follows from the observation that $A_{i,k} = g_{i\alpha} A^{\alpha}_{,k}$ whenever $A_i = g_{ij} A^j$. Thus, the increments in A^i and A_i due to a displacement dx^j along the curve are given by Eqs. (4.68) and (4.69), respectively.

Result 4.5.1 Now, consider a point $P(x^i)$ and two displacements dx^i and δx^i from P giving rise to the points $Q(x^i + dx^i)$ and $R(x^i + \delta x^i)$, respectively, as seen in Figure 4.2.

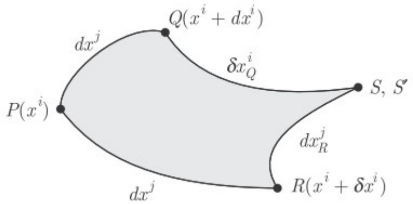

Figure 4.2: Generalised infinitesimal parallelogram.

Imagine the segment $PR = \delta x^i$ being parallely displaced such that as the end point P goes to Q, the other end R goes to S. The displacement QS will be

$$QS \equiv \delta x^i_Q = \delta x^i + d(\delta x^i), \tag{4.70}$$

which makes the co-ordinates of the points S,

$$S \equiv \left[x^i + dx^i + \delta x^i_Q\right] = \left[x^i + dx^i + \delta x^i + d(\delta x^i)\right], \tag{4.71}$$

where by Eq. (4.68), we have

$$d(\delta x^i) = -\left\{ \begin{matrix} i \\ j \quad k \end{matrix} \right\}_P \delta x_j dx^k. \tag{4.72}$$

The subscript P on the Christoffel symbol means is to be evaluated at P. Similarly, imagine the segment $PQ = dx^i$ being parallely displaced such that as the point P goes to R, the other end Q goes to S'. The displacement RS' will be given by

$$RS = dx^i_R = \delta x^i + d(\delta x^i), \tag{4.73}$$

which makes the co-ordinates of the point S'

$$S' \equiv \left[x^i + dx^i + \delta x^i_R\right] = \left[x^i + \delta x^i + dx^i + \delta(dx^i)\right], \tag{4.74}$$

$$\text{where,}\quad \delta(dx^i) = -\left\{ \begin{matrix} i \\ j \quad k \end{matrix} \right\}_P dx_j \delta x^k = -\left\{ \begin{matrix} i \\ j \quad k \end{matrix} \right\}_P dx_k \delta x^j, \tag{4.75}$$

which follows by interchanging j and k and using the symmetric property of the Christoffel symbol. Equations (4.72) and (4.75) show that $d(\delta x^i) = \delta(dx^i)$ indicating that the point S' coincides with S. The closed figure $PQRS$ can be regarded as the generalised infinitesimal parallelogram with opposite sides parallel to each other in the Riemannian space.

Result 4.5.2 (**Curvature of Riemannian space**). Here we have introduced the curvature tensor by considering the parallel displacement of a vector along two different paths. Consider an infinitesimal parallelogram PQRS (Figure 4.3) as described with adjacent sides $PQ = dx^i$ and $PR = \delta x^i$. Imagine a constravariant vector A^i_p defined at the point P being parally displaced is the following two ways:

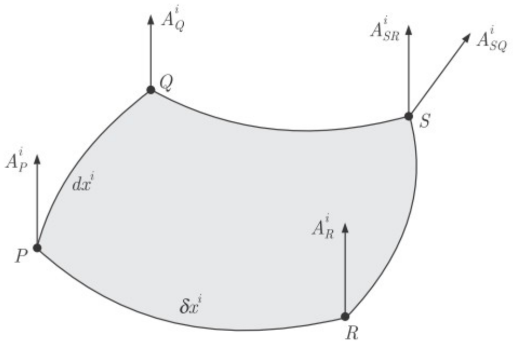

Figure 4.3: Curvature of Riemannian space.

(i) Displace A^i_p parallely from P to Q resulting A^i_Q and then displace A^i_Q parallely from Q to S giving the vector A^i_{SQ}.

(ii) Displace A^i_p parallely from P to R giving A^i_R parallely from R to S resulting the vector A^i_{SR}.

The vector A^i_Q obtained by a parallel displacement of A^i_P is given by

$$A^i_Q = A^i_P + dA^i_P; \quad \text{where } dA^i_P = -\left\{ \begin{matrix} i \\ j \ \ k \end{matrix} \right\}_P A^i_P dx^k. \tag{i}$$

This vector is parallely displaced from Q to S resulting the vector A^i_{SQ} which will be given by

$$A^i_{SQ} = A^i_Q + \delta A^i_Q = A^i_Q - \left\{ \begin{matrix} i \\ l \ \ h \end{matrix} \right\}_Q A^l_Q \, \delta x^h. \tag{ii}$$

The Christoffel symbol depends on the metric tensor which in turn is a function of co-ordinates. For a small displacement, we can therefore write

$$\left\{ \begin{matrix} i \\ l \ \ h \end{matrix} \right\}_Q = \left\{ \begin{matrix} i \\ l \ \ h \end{matrix} \right\}_P + \left\{ \begin{matrix} i \\ l \ \ h \end{matrix} \right\}_{P,m} dx^m \tag{iii}$$

where $\begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{P,m} = \left[\frac{\partial}{\partial x^m} \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}\right]_{at\ P}$. Substituting Eqs. (iii) and (i) in Eq. (ii), we have

$$A^i_{SQ} = A^i_P - \begin{Bmatrix} i \\ j \quad k \end{Bmatrix}_P A^j_P \, dx^k - \left[\begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_P + \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{P,m} dx^m\right]$$

$$\left[A^l_P - \begin{Bmatrix} l \\ j \quad k \end{Bmatrix}_P A^j_P \, dx^k\right] \delta x^h$$

$$= A^i - \begin{Bmatrix} i \\ j \quad k \end{Bmatrix} A^j \, dx^k - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} A^l \delta x^h - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{,m} A^l \, dx^m \, \delta x^h$$

$$+ \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} \begin{Bmatrix} l \\ j \quad k \end{Bmatrix} A^j \, dx^k \, dx^h + O\left[(dx^k)^3\right], \qquad (iv)$$

where we have dropped the subscript P from the right hand side of (iv) because all the quantities are to be evaluated at P. The vector A^i_{SR} obtained by a parallel displacement along the path PRS will be simply given by an interchange of dx^i and dx^i in the expression for A^i_{SQ}:

$$A^i_{SR} = A^i - \begin{Bmatrix} i \\ j \quad k \end{Bmatrix} A^j \, \delta x^k - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} A^l dx^h - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{,m} A^l \, \delta x^m \, dx^h$$

$$+ \begin{Bmatrix} l \\ l \quad h \end{Bmatrix} \begin{Bmatrix} l \\ j \quad k \end{Bmatrix} A^j \delta x^k \, dx^h + O\left[(dx^k)^3\right]. \qquad (v)$$

Subtracting (iv) from (v) we get

$$A^i_{SR} - A^i_{SR} = \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{,m} A^l \, dx^m \, \delta x^h - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix}_{,m} A^l \, \delta x^m \, dx^h$$

$$+ \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} \begin{Bmatrix} l \\ j \quad k \end{Bmatrix} A^j \, \delta x^k \, dx^h - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} \begin{Bmatrix} l \\ j \quad k \end{Bmatrix} A^j \, dx^k \, \delta x^h. \qquad (vi)$$

Replacing l by j and m by k in the first two terms on the right hand side of (vi) and interchanging k and h in the second and third terms, the Eq. (vi) can be written as

$$A^i_{SR} - A^i_{SQ} = R^i_{jhk} \, A^j \, dx^k \, \delta x^h, \qquad \text{(vii)}$$

where

$$R^i_{jkh} = \begin{Bmatrix} i \\ j \quad h \end{Bmatrix}_{,k} - \begin{Bmatrix} i \\ j \quad k \end{Bmatrix}_{,h} + \begin{Bmatrix} i \\ l \quad k \end{Bmatrix} \begin{Bmatrix} i \\ j \quad h \end{Bmatrix} - \begin{Bmatrix} i \\ l \quad h \end{Bmatrix} \begin{Bmatrix} l \\ j \quad k \end{Bmatrix} \qquad (viii)$$

Since A^j, dx^k and δx^h are arbitrary vectors, if follows from quotient law that R^i_{jkh} is a tensor of rank four, known as the Riemann-Christoffel curvature tensor. It is independent of the vector A^i and depends only on the metric tensor and its first and second derivatives.

It follows that if a tensor is parallely displaced along a closed curve until we come back to the starting point, the resulting vector will not necessarily be the same as the original vector in a non-Euclidean space.

EXAMPLE 4.5.2 *If A^i and B^i are two vectors of constant magnitudes and undergo parallel displacements along a curve then show that they are inclined at a constant angle.*

Solution: Let the two vectors A^i and B^i be of constant magnitudes, so that their lengths do not change as we move along the curve Γ. Let these vectors suffer parallel displacement along a curve Γ, so by hypothesis

$$\frac{\delta A^i}{\delta t} = 0 = \frac{\delta B^i}{\delta t},$$

at each point of Γ. The angle θ between the vectors A^i and B^i, is given by

$$\cos\theta = g_{ij}A^iB^j.$$

The angle θ between the vectors A^i and B^i remains fixed as the parameter t is allowed to change. Here, $g_{ij}A^iB^j$ is an invariant. Differentiating intrinsically with respect to t, we get

$$\begin{aligned}\frac{\delta}{\delta t}(\cos\theta) &= \frac{\delta}{\delta t}\left(g_{ij}A^iB^j\right) = \frac{d}{dt}\left(g_{ij}A^iB^j\right)\\ &= g_{ij}\frac{\delta A^i}{\delta t}B^j + g_{ij}A^i\frac{\delta B^j}{\delta t} = g_{ij}\cdot 0\cdot B^j + g_{ij}A^i\cdot 0 = 0\end{aligned}$$

or

$$\frac{d}{dt}(\cos\theta) = 0 \Rightarrow \cos\theta = \text{constant, i.e. } \theta = \text{constant.}$$

Thus, we conclude that $g_{ij}A^iB^j$ is constant along Γ. It follows directly from the result that, if $A^i = B^i$, then $g_{ij}A^iA^j = A^2$ is constant along Γ and this implies $\theta = $ constant.

EXAMPLE 4.5.3 *Prove that geodesics are autoparallel curves.*

Solution: To prove the result, it is enough to prove that the unit tangent vector, say λ^i, suffers a parallel displacement along a geodesic curve Γ. Let $\Gamma : x^i = x^i(t)$ be a geodesic in a Riemannian space. Then the co-ordinates of the points on the geodesic satisfy the geodesic equation,

$$\frac{d^2x^i}{dt^2} + \left\{ \begin{matrix} i \\ j \ \ k \end{matrix} \right\} \frac{dx^j}{dt}\frac{dx^k}{dt} = 0$$

or

$$\frac{d\lambda^i}{dt} + \left\{ \begin{matrix} i \\ j \ \ k \end{matrix} \right\} \lambda^j \frac{dx^k}{dt} = 0$$

or

$$\left[\frac{\partial\lambda^i}{\partial x^k} + \left\{ \begin{matrix} i \\ j \ \ k \end{matrix} \right\} \lambda^j\right] \frac{dx^k}{dt} = 0$$

or

$$\lambda^i_{,k}\frac{dx^k}{dt} = 0; \text{ i.e. } \lambda^i_{,j}\frac{dx^j}{dt} = 0,$$

at each point on Γ. This result shows that the unit vectors form a system of parallel vectors along a geodesic. Hence, it follows from the definition of parallel displacement that the field of tangent vectors to a geodesic is a field of parallel vectors.

EXAMPLE 4.5.4 *Any vector of constant magnitude which undergoes a parallel displacement along a geodesic is inclined at a constant angle to the curve.*

Solution: Let a vector A^i of constant magnitude undergo a parallel displacement along a geodesic Γ, so that,

$$\frac{\delta A^i}{\delta t} = A^i_{,j}\frac{dx^j}{dt} = 0$$

at each point of Γ. Let λ^i be a unit tangent vector to the curve Γ, so that,

$$\frac{\delta\lambda^i}{\delta t} = \lambda^i_{,j}\frac{dx^j}{dt} = 0$$

at each point of Γ, since geodesics are autoparallel curves. Let θ be the angle between the vector λ^i and a curve Γ at any point of Γ, i.e. θ is the angle between A^i and λ^i, then,

$$A^i\lambda_i = A \cdot 1 \cdot \cos\theta$$

or

$$\frac{d}{dt}(A\cos\theta) = \frac{d}{dt}(A^i\lambda_i) = (A^i\lambda_i)_{,j}\frac{dx^i}{dt}$$

or

$$\begin{aligned} -A\sin\theta\frac{d\theta}{dt} &= A^i_{,j}\frac{dx^j}{dt}\lambda_i + A^i\lambda_{i,j}\frac{dx^j}{dt} \\ &= 0t_1 + A^i 0 = 0. \end{aligned}$$

or

$$\sin\theta\frac{d\theta}{dt} = 0; \quad \text{as } A \neq 0,$$

or

$$\sin\theta = 0 \quad \text{or } \frac{d\theta}{dt} = 0 \Rightarrow \theta = 0 \quad \text{or } \theta = \text{ constant.}$$

EXAMPLE 4.5.5 *If the intrinsic derivative of a vector vanishes, then show that the magnitude of the vector is constant.*

Solution: Let the intrinsic derivative of a vector A^i be zero so that

$$\frac{\delta A^i}{\delta t} = A^i_{,j}\frac{dx^j}{dt} = 0.$$

We have to show that $A^2 = A^i A_i$ is constant. Differentiating both sides with respect to a parameter t and noting that the intrinsic derivative of a scalar is ordinary derivative, we have

$$\begin{aligned}\frac{dA^2}{dt} &= \frac{d}{dt}\left(A^i A_i\right) = \left(A^i A_i\right)_{,j}\frac{dx^j}{ds}\\ &= A^i_{,j}\frac{dx^j}{dt}A_i + A^i A_{i,j}\frac{dx^j}{ds} = 0A_i + A^i 0 = 0\end{aligned}$$

or

$$A^2 = \text{constant } \Rightarrow A = \text{constant.}$$

Thus, if the derived vector of a given vector A in the direction of a given curve Γ vanishes at all points of a curve, then the magnitude of the vector is constant. If A^i forms a field of parallel vectors along the curve $x^i = x(t)$, then we have

$$\frac{\delta A^i}{\delta t} = A^i_{,j}\frac{dx^j}{dt} = 0.$$

Then similarly, as above we can show that $A =$ constant. Thus, the magnitude of a vector remain invariant under parallel displacement.

EXAMPLE 4.5.6 *Show that the parallel displacement of a vector taken all around a circle on the surface of a sphere does not lead back to the same vector except when the circle is a great circle, that is, a geodesic.*

Solution: Choose spherical polar co-ordinates $x^1 = \theta$ and $x^2 = \phi$ on the surface of the sphere. The non-vanishing Christoffel symbols are,

$$\left\{\begin{matrix} 2 \\ 1\ 2 \end{matrix}\right\} = \cot\theta = \left\{\begin{matrix} 2 \\ 2\ 1 \end{matrix}\right\}; \quad \left\{\begin{matrix} 1 \\ 2\ 2 \end{matrix}\right\} = -\sin\theta\cos\theta.$$

Choose a small circle normal to the polar axis so that its parametric equation is

$$\theta = \alpha, \phi = ps + q; \quad p \neq 0 \text{ with } \frac{d\theta}{dt} = 0.$$

Consider a vector $A^i = (a^1, A^2)$ at a point on the circle which may be taken to be $\phi = 0$. When the vector is displaced parallely along the circle, the change in its components is given, from Eq. (4.69), by

$$\frac{dA^1}{dt} = -\left\{ \begin{matrix} 1 \\ j \quad k \end{matrix} \right\} A^j \frac{dx^k}{dt} = A^2 \sin\alpha \cos\alpha \frac{d\phi}{dt} \tag{i}$$

$$\frac{dA^2}{dt} = -\left\{ \begin{matrix} 2 \\ j \quad k \end{matrix} \right\} A^j \frac{dx^k}{dt} = -A \cot\alpha \frac{d\phi}{dt}. \tag{ii}$$

Now, for any function f of θ and ϕ through t, we have

$$\frac{df}{dt} = \frac{\partial f}{\partial \theta}\frac{d\theta}{dt} + \frac{\partial f}{\partial \phi}\frac{d\phi}{dt} = \frac{\partial f}{\partial \phi}\frac{d\phi}{dt},$$

which reduces Eqs. (i) and (ii) to

$$\frac{\partial A^1}{\partial \phi} = A^2 \sin\alpha\cos\alpha; \quad \frac{\partial A^2}{\partial \phi} = -A^1 \cot\alpha. \tag{iii}$$

Differentiating once again with respect to ϕ and substituting one in the other, Eq. (iii) give rise to the decoupled equations

$$\frac{\partial^2 A^1}{\partial \phi^2} = -A^1 \cos^2\alpha; \quad \frac{\partial^2 A^2}{\partial \phi^2} = -A^2 \cos^2\alpha, \tag{iv}$$

whose solution, consistent with Eq. (iii), is

$$\begin{aligned} A^1 &= \sin\alpha\,[c\cos(\phi\cos\alpha) + d\sin(\phi\cos\alpha)] \\ A^2 &= d\cos(\phi\cos\alpha) - c\sin(\phi\cos\alpha). \end{aligned}$$

At $\phi = 0$, the components of the vector are given by

$$A^1(\phi = 0) = c\sin\alpha, \quad A^2(\phi = 0) = d, \tag{v}$$

whereas, after parallel displacement once around the circle, the components become,

$$\begin{aligned} A^1(\phi = 2\pi) &= \sin\alpha\,[c\cos(2\pi\cos\alpha) + d\sin(2\pi\cos\alpha)] \\ A^2(\phi = 2\pi) &= d\cos(2\pi\cos\alpha) - c\sin(2\pi\cos\alpha), \end{aligned}$$

which are not the same as those given by Eq. (v) except when $\alpha = \frac{\pi}{2}$, i.e. when the displacement is along the geodesic.

CHAPTER 1

Gyrogroups

Gyrogroups are generalized groups, which are best motivated by the algebra of Möbius transformations of the complex open unit disc. Groups are classified into commutative and noncommutative groups and, in full analogy, gyrogroups are classified into gyrocommutative and nongyrocommutative gyrogroups. Some commutative groups admit scalar multiplication, giving rise to vector spaces. In full analogy, some gyrocommutative gyrogroups admit scalar multiplication, giving rise to gyrovector spaces. Furthermore, vector spaces form the algebraic setting for the standard model of Euclidean geometry and, in full analogy, gyrovector spaces form the algebraic setting for various models of the hyperbolic geometry of Bolyai and Lobachevsky.

The evolution from Möbius to gyrogroups began soon after the discovery in 1988 [48] that Einstein velocity addition law of relativistically admissible velocities, which is seemingly structureless, is in fact rich of structure. Later, the rich structure that Einstein velocity addition law encodes turned out to be a gyrocommutative gyrogroup and a gyrovector space. The resulting notions of gyrogroups and gyrovector spaces preserve the flavor of their classical counterparts, groups and vector spaces. They are useful and fascinating enough to be made part of the lore learned by all undergraduate and graduate mathematics and physics students. Being a natural generalization of groups and vector spaces, gyrogroups and gyrovector spaces lay a fruitful bridge between nonassociative algebra and hyperbolic geometry, just as groups and vector spaces lay a fruitful bridge between associative algebra and Euclidean geometry. More than 150 years have passed since the German mathematician August Ferdinand Möbius (1790 – 1868) first studied the transformations that now bear his name [30, p. 71]. Yet, the rich structure he thereby exposed is still far from being exhausted, as the evolution from Möbius to gyrogroups demonstrates in Sections 1.1 – 1.3 of this chapter.

1.1 FROM MÖBIUS TO GYROGROUPS

Möbius transformations of the complex open unit disc $\mathbb{D}$,

$$\mathbb{D} = \{z \in \mathbb{C} : |z| < 1\} \tag{1.1}$$

of the complex plane $\mathbb{C}$ are studied in most books on function theory of one complex variable. According to [31, p. 176], these are important for at least two reasons: (i) they play a central role in non-Euclidean geometry [51], and (ii) they are the only automorphisms of the disc.

Ahlfors' book [1], *Conformal Invariants: Topics in Geometric Function Theory*, begins with a presentation of the *polar decomposition* of the most general Möbius self-transformation of the complex open unit disc $\mathbb{D}$,

$$z \mapsto e^{i\theta} \frac{a+z}{1+\bar{a}z} = e^{i\theta}(a \oplus z) , \tag{1.2}$$

where $a, z \in \mathbb{D}$, $\overline{a}$ being the complex conjugate of a, and where $\theta \in \mathbb{R}$ is a real number [12, p. 211], [17, p. 185], [23, pp. 6 – 7], [31, pp. 177 – 178]. In (1.2) we present the Möbius polar decomposition in a form that suggests the *Möbius addition*, $\oplus$, which we define by the equation

$$a \oplus z = \frac{a + z}{1 + \overline{a}z} \,. \tag{1.3}$$

Naturally, Möbius subtraction, $\ominus$, is given by $a \ominus z = a \oplus (-z)$, so that $z \ominus z = 0$ and $\ominus z = 0 \ominus z = 0 \oplus (-z) = -z$.

Interestingly, Möbius addition possesses the *gyroautomorphic inverse property*

$$\ominus(a \oplus b) = \ominus a \ominus b \tag{1.4}$$

and the *left cancellation law*

$$\ominus a \oplus (a \oplus z) = z \tag{1.5}$$

for all $a, b, z \in \mathbb{D}$. Contrasting the left cancellation law (1.5) of Möbius addition, care must be taken with its right counterpart since, in general,

$$(a \oplus z) \ominus z \neq a \,. \tag{1.6}$$

Indeed, in (1.15) below we will introduce a secondary binary operation, $\boxplus$, which is a binary *cooperation* called a Möbius *coaddition*, and which gives rise to the *right cancellation law*, (1.18), of Möbius addition.

Möbius addition is neither commutative nor associative. Fortunately, the failure of associativity is a source of rich theory, the theory of gyrogroups and gyrovector spaces, as we will see in this book.

To measure the extent of which Möbius addition deviates from commutativity we define the *gyrations*

$$\mathrm{gyr}[a, b] = \frac{a \oplus b}{b \oplus a} = \frac{1 + a\overline{b}}{1 + \overline{a}b} \tag{1.7}$$

for $a, b \in \mathbb{D}$. Being unimodular complex numbers, $|\mathrm{gyr}[a, b]| = 1$, gyrations represent rotations of the disc $\mathbb{D}$ about its center. In the special case when $a = 0$ or $b = 0$ or $a = \lambda b$ for some real number λ, the gyration $\mathrm{gyr}[a, b]$ is trivial, that, is, $\mathrm{gyr}[a, b] = 1$. The number -1 cannot be represented by a gyration since the equation $\mathrm{gyr}[a, b] = -1$ has no solution for a and b in the disc $\mathbb{D}$.

Gyrations respect Möbius addition,

$$\mathrm{gyr}[a, b](c \oplus d) = \mathrm{gyr}[a, b]c \oplus \mathrm{gyr}[a, b]d \tag{1.8}$$

for all $a, b, c, d \in \mathbb{D}$, and the inverse $\mathrm{gyr}^{-1}[a, b]$ of a gyration $\mathrm{gyr}[a, b]$ is the gyration $\mathrm{gyr}[b, a]$,

$$\mathrm{gyr}^{-1}[a, b] = \mathrm{gyr}[b, a] \,, \tag{1.9}$$

as we see from (1.7). Hence, gyrations are special automorphisms of the Möbius groupoid $(\mathbb{D}, \oplus)$. We recall that a groupoid $(G, \oplus)$ is a nonempty set, G, with a binary operation, $\oplus$, and that an automorphism of a groupoid $(G, \oplus)$ is a bijective self map f of G that respects its binary operation $\oplus$, that is, $f(a\oplus b) = f(a)\oplus f(b)$. The set of all automorphisms of a groupoid $(G, \oplus)$ forms a group, denoted $Aut(G, \oplus)$. The formal definition of groups will be presented in Def. 1.3, p. 5.

To emphasize that gyrations are automorphisms, they are also called *gyroautomorphisms*. The automorphism $\phi(z) = -z$ of the disc is not a gyroautomorphism of the disc since the equation $(1 + a\bar{b})/(1 + \bar{a}b) = -1$ for $a, b \in \mathbb{D}$ has no solution in the disc. Consequently, the gyroautomorphisms of the disc do not form a group under gyroautomorphism composition.

It follows from the gyration definition in (1.7) that Möbius addition obeys the *gyrocommutative law*:

$$a\oplus b = \text{gyr}[a, b](b\oplus a) \tag{1.10}$$

for all $a, b \in \mathbb{D}$. The Möbius gyrocommutative law (1.10) is not terribly surprising since it is generated by definition. But, we are not finished!

Coincidentally, the gyration gyr$[a, b]$, which "repairs" in (1.10) the breakdown of commutativity in Möbius addition, "repairs" the breakdown of associativity in Möbius addition as well. Indeed, it gives rise to the following gyroassociative laws (left and right),

$$\begin{aligned} a\oplus(b\oplus z) &= (a\oplus b)\oplus\text{gyr}[a, b]z\,, \\ (a\oplus b)\oplus z &= a\oplus(b\oplus\text{gyr}[b, a]z)\,, \end{aligned} \tag{1.11}$$

for all $a, b, z \in \mathbb{D}$. Hence, gyrations measure simultaneously the extent to which Möbius addition deviates from both associativity and commutativity.

Möbius gyrations are expressible in terms of Möbius addition. Indeed, solving the first identity in (1.11) for gyr$[a, b]z$ by means of the Möbius left cancellation law (1.5) we have

$$\text{gyr}[a, b]z = \ominus(a\oplus b)\oplus\{a\oplus(b\oplus z)\}\,. \tag{1.12}$$

Möbius gyrations gyr$[a, b]$, $a, b \in \mathbb{D}$, thus endow the Möbius disc groupoid $(\mathbb{D}, \oplus)$ with a group-like structure, naturally called a *gyrogroup*. In fact, Möbius gyrations do more than that. They contribute their own rich structure to the gyrogroup. Thus, for instance, they possess the *loop properties* (left and right)

$$\begin{aligned} \text{gyr}[a\oplus b, b] &= \text{gyr}[a, b]\,, \\ \text{gyr}[a, b\oplus a] &= \text{gyr}[a, b]\,, \end{aligned} \tag{1.13}$$

and the nested gyration identity

$$\text{gyr}[b, \ominus\text{gyr}[b, a]a] = \text{gyr}[a, b]\,, \tag{1.14}$$

as one can straightforwardly check.

Möbius addition $\oplus$, as a primary addition in the disc, comes with *Möbius coaddition*, $\boxplus$, as a secondary addition in the disc. Möbius coaddition is defined in terms of Möbius addition and Möbius gyrations by the equation

$$a \boxplus b = a\oplus\text{gyr}[a, \ominus b]b \tag{1.15}$$

for all $a, b \in \mathbb{D}$. It turns out that Möbius coaddition is commutative (but not associative), given by the equation

$$a \boxplus b = \frac{(1-|a|^2)b + (1-|b|^2)a}{1-|a|^2|b|^2} \tag{1.16}$$

for all $a, b \in \mathbb{D}$, as we see from (1.15) and (1.7).

Replacing b by $\ominus b$ in (1.15), and noting that $\mathrm{gyr}[a, \ominus b]$ is an automorphism, it follows from (1.15) that

$$a \boxminus b = a \oplus \mathrm{gyr}[a, b](\ominus b) = a \ominus \mathrm{gyr}[a, b]b\,. \tag{1.17}$$

for all $a, b \in \mathbb{D}$, where we use the obvious notation, $a \boxminus b = a \boxplus (\ominus b)$.

In terms of Möbius coaddition, the *right cancellation law* of Möbius addition takes the form

$$(a \oplus b) \boxminus b = a\,. \tag{1.18}$$

The right cancellation law (1.18) is associated with the second right cancellation law

$$(a \boxplus b) \ominus b = a\,, \tag{1.19}$$

as one can straightforwardly check. Identities (1.18) and (1.19) present one of the duality symmetries that Möbius addition and coaddition share.

Guided by the group-like structure of Möbius addition, we define a *gyrogroup* to be a group in which the associative law is replaced by the gyroassociative laws (left and right), and a *gyrocommutative gyrogroup* to be a commutative group in which the commutative and associative laws are replaced by the gyrocommutative and gyroassociative laws. Like Möbius gyrations, the gyrations in the gyrocommutative and gyroassociative laws of an abstract gyrogroup must be automorphisms of the gyrogroup.

Thus, the disc $\mathbb{D}$ with its Möbius addition forms a *gyrocommutative gyrogroup* $(\mathbb{D}, \oplus)$ where, strikingly, the concepts of gyrocommutativity and gyroassociativity of the gyrogroup preserve the flavor of their classical counterparts [50, 51]. Mathematical coincidences are not accidental! Hence, in particular, the gyrations that "coincidentally" repair in (1.10) – (1.11) the breakdown of commutativity and associativity need not be peculiar to Möbius addition, as shown in [13, 14], and as we will see in this book.

Indeed, the generalization of groups into gyrogroups that Möbius addition suggests bears an intriguing resemblance to the generalization of the rational numbers to the real ones. The beginner is initially surprised to discover an irrational number, like $\sqrt{2}$, but soon later he or she is likely to realize that there are more irrational numbers than rational ones. Similarly, the gyrogroup structure of Möbius addition initially comes as a surprise. But, interested explorers may soon realize that there are indications that, in some sense, there are more non-group gyrogroups than groups [13].

$\mathbf{p}_{\mathbf{vw}}^m = \frac{\gamma_{\mathbf{v}}\mathbf{v}+\gamma_{\mathbf{w}}\mathbf{w}}{\gamma_{\mathbf{v}}+\gamma_{\mathbf{w}}}$
$\mathbb{C}_{\mathbf{uvw}} = \frac{\gamma_{\mathbf{u}}\mathbf{u}+\gamma_{\mathbf{v}}\mathbf{v}+\gamma_{\mathbf{w}}\mathbf{w}}{\gamma_{\mathbf{u}}+\gamma_{\mathbf{v}}+\gamma_{\mathbf{w}}}$

Fig. 6.16 The gyromidpoints of the three sides of a gyrotriangle **uvw** in the Einstein gyrovector plane $(\mathbb{R}_s^2, \oplus_{\text{E}}, \otimes_{\text{E}})$ are shown along with its gyromedians and gyrocentroid. Interestingly, Einsteinian gyromidpoints and gyrocentroids have interpretation in relativistic mechanics, fully analogous to the interpretation of Euclidean midpoints and centroids in classical mechanics that one discovers in the vector space approach to Euclidean geometry [Hausner (1998)]; see Fig. 10.3.

We will now study the gyrotriangle gyromedians and gyrocentroid in Einstein, Fig. 6.16, Möbius,Fig. 6.20, and PV gyrovector spaces, Fig. 6.21, [Ungar (2004a)].

6.22.1 *In Einstein Gyrovector Spaces*

Einstein gyrovector spaces $(\mathbb{V}_s, \oplus_{\text{E}}, \otimes_{\text{E}})$ are particularly suitable for the study of gyromedians and gyrocentroids since gyrolines are Euclidean straight lines so that the calculation of points of intersection of gyrolines can be performed by methods of linear algebra. The resulting determination of gyrocentroids in Einstein gyrovector spaces, Fig. 6.16, can readily be translated into other isomorphic gyrovector spaces.

It follows from (6.330), by (3.195), p. 92, and the scalar associative law of gyrovector spaces, that the gyromidpoint $\mathbf{p}_{\mathbf{uv}}^{m}$ in Einstein gyrovector spaces is given by the equation

$$\begin{aligned}\mathbf{p}_{\mathbf{uv}}^{m} &= \tfrac{1}{2}\otimes_{\rm E}(\mathbf{u}\boxplus_{\rm E}\mathbf{v})\\ &= \tfrac{1}{2}\otimes_{\rm E}\{2\otimes_{\rm E}\tfrac{\gamma_{\mathbf{u}}\mathbf{u}+\gamma_{\mathbf{v}}\mathbf{v}}{\gamma_{\mathbf{u}}+\gamma_{\mathbf{v}}}\}\\ &= \frac{\gamma_{\mathbf{u}}\mathbf{u}+\gamma_{\mathbf{v}}\mathbf{v}}{\gamma_{\mathbf{u}}+\gamma_{\mathbf{v}}}\end{aligned} \tag{6.331}$$

We have thus obtained the following

Theorem 6.92 (The Einstein Gyromidpoint). *Let* $\mathbf{u},\mathbf{v}\in\mathbb{V}_s$ *be any two points of an Einstein gyrovector space* $(\mathbb{V}_s,\oplus_{\rm E},\otimes_{\rm E})$. *The gyromidpoint* $\mathbf{p}_{\mathbf{uv}}^{m}$ *of the gyrosegment* $\mathbf{uv}$ *is given by the equation*

$$\mathbf{p}_{\mathbf{uv}}^{m} = \frac{\gamma_{\mathbf{u}}\mathbf{u}+\gamma_{\mathbf{v}}\mathbf{v}}{\gamma_{\mathbf{u}}+\gamma_{\mathbf{v}}} \tag{6.332}$$

The gyromidpoints of the three sides of a gyrotriangle $\mathbf{uvw}$ in the Einstein gyrovector plane $(\mathbb{R}_s^2,\oplus_{\rm E},\otimes_{\rm E})$, and its gyrocentroid are shown in Fig. 6.16. Gyromidpoints are gyrocovariant under left gyrotranslations, Theorem 6.37. Therefore a left gyrotranslation by $\mathbf{x}\in\mathbb{R}_s^2$ of the gyrosegment $\mathbf{uv}$ in Fig. 6.16 into the gyrosegment $(\ominus\mathbf{x}\oplus\mathbf{u})(\ominus\mathbf{x}\oplus\mathbf{v})$ in Fig. 6.17 does not distort the gyrosegment gyromidpoint. Hence, the gyromidpoint of the gyrotranslated gyrosegment $(\ominus\mathbf{x}\oplus\mathbf{u})(\ominus\mathbf{x}\oplus\mathbf{v})$, Fig. 6.17, is given by the equation

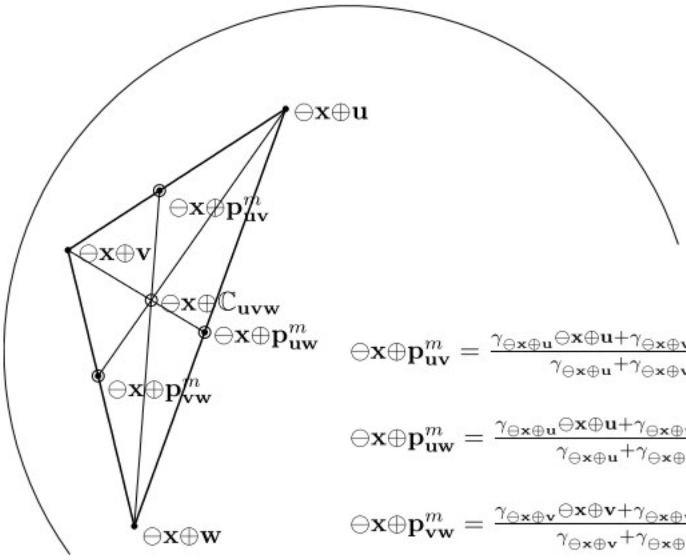
$$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{uv}}^{m} = \mathbf{p}_{(\ominus\mathbf{x}\oplus\mathbf{u})(\ominus\mathbf{x}\oplus\mathbf{v})}^{m} \tag{6.333}$$

thus uncovering the interesting identity

$$\ominus\mathbf{x}\oplus\frac{\gamma_{\mathbf{u}}\mathbf{u}+\gamma_{\mathbf{v}}\mathbf{v}}{\gamma_{\mathbf{u}}+\gamma_{\mathbf{v}}} = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}} \tag{6.334}$$

in any Einstein gyrovector space.

Gyrolines in the Beltrami-Klein ball model of hyperbolic geometry, that is, in Einstein gyrovector spaces, are Euclidean straight lines. Hence, by elementary techniques of linear algebra, one can verify that the three gyromedians in Fig. 6.16 are concurrent, and that the point of concurrency, that is, the gyrocentroid $C_{\mathbf{uvw}}$ of gyrotriangle $\mathbf{uvw}$, is given by the elegant equation (6.335) that we place in the following theorem.



$\ominus\mathbf{x}\oplus\mathbf{u}$
$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{uv}}^{m}$
$\ominus\mathbf{x}\oplus\mathbf{v}$
$\ominus\mathbf{x}\oplus\mathbb{C}_{\mathbf{uvw}}$
$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{uw}}^{m}$
$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{vw}}^{m}$
$\ominus\mathbf{x}\oplus\mathbf{w}$

$$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{uv}}^{m} = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}}$$

$$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{uw}}^{m} = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}\ominus\mathbf{x}\oplus\mathbf{w}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}}$$

$$\ominus\mathbf{x}\oplus\mathbf{p}_{\mathbf{vw}}^{m} = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}\ominus\mathbf{x}\oplus\mathbf{w}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}}$$

$$\ominus\mathbf{x}\oplus\mathbb{C}_{\mathbf{uvw}} = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}\ominus\mathbf{x}\oplus\mathbf{w}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}+\gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}}$$

Fig. 6.17 A left gyrotranslation by $\mathbf{x}\in(\mathbb{R}_s^2, \oplus, \otimes)$ of the gyrotriangle **uvw** of Fig. 6.16 in an Einstein plane is shown. Gyromidpoints are gyrocovariant under left gyrotranslations, Theorem 6.37. Hence, a left gyrotranslation of a gyrotriangle does not distort its side-gyromidpoints and gyrocentroid. Accordingly, related formulas are left gyrotranslated gyrocovariantly.

Theorem 6.93 (The Einstein Gyrotriangle Gyrocentroid). *Let* $\mathbf{u}, \mathbf{v}, \mathbf{w} \in \mathbb{V}_s$ *be any three nongyrocollinear points of an Einstein gyrovector space* $(\mathbb{V}_s, \oplus_E, \otimes_E)$. *The gyrocentroid* $\mathbb{C}_{\mathbf{uvw}}^{m}$ *of the gyrotriangle* **uvw**, *Fig. 6.16, is given by the equation*

$$\mathbb{C}_{\mathbf{uvw}} = \frac{\gamma_{\mathbf{u}}\mathbf{u} + \gamma_{\mathbf{v}}\mathbf{v} + \gamma_{\mathbf{w}}\mathbf{w}}{\gamma_{\mathbf{u}} + \gamma_{\mathbf{v}} + \gamma_{\mathbf{w}}} \tag{6.335}$$

Gyromidpoints are gyrocovariant, Theorem 6.37. Therefore a left gyrotranslation by $\mathbf{x}\in\mathbb{R}_s^2$ of the gyrotriangle **uvw** in Fig. 6.16 into the gyrotriangle $(\ominus\mathbf{x}\oplus\mathbf{u})(\ominus\mathbf{x}\oplus\mathbf{v})(\ominus\mathbf{x}\oplus\mathbf{w})$ in Fig. 6.17 does not distort the gyrotriangle side gyromidpoints and gyrocentroid. Hence, the gyrocentroid of the gyrotranslated gyrotriangle $(\ominus\mathbf{x}\oplus\mathbf{u})(\ominus\mathbf{x}\oplus\mathbf{v})(\ominus\mathbf{x}\oplus\mathbf{w})$, Fig. 6.17, is given by the

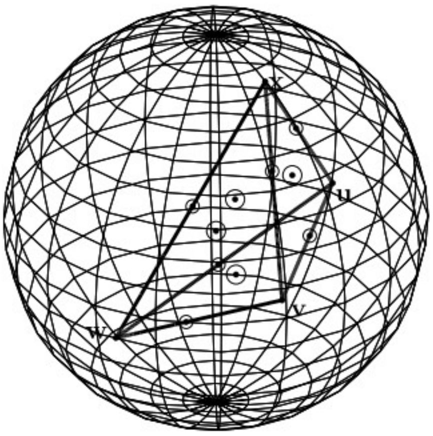


Fig. 6.18 The hyperbolic tetrahedron $\mathbf{uvwx}$, that is, a gyrotetrahedron, is shown in the Einstein gyrovector space
$$\mathbb{R}^3_s = (\mathbb{R}^3_s, \oplus_E, \otimes_E)$$
underlying the Beltrami ball model of hyperbolic geometry. The gyrotetrahedron $\mathbf{uvwx}$ is shown inside the s-ball $\mathbb{R}^3_s$ of the Euclidean 3-space $\mathbb{R}^3$ where it lives. The faces of the gyrotetrahedron are gyrotriangles.

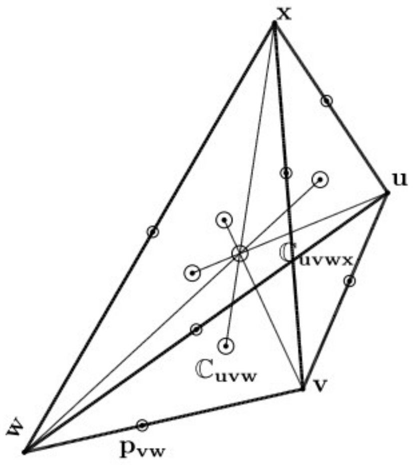

Fig. 6.19 Shown are also the gyromidpoints of the 6 sides and the gyrocentroids of the 4 faces. The gyroline joining a vertex of a gyrotetrahedron and the hyperbolic centroid, gyrocentroid, of the opposite face is called a gyrotetrahedron gyromedian. The four gyromedians of the gyrotetrahedron $\mathbf{uvwx}$ are concurrent. The point of concurrency is the gyrotetrahedron gyrocentroid $\mathbb{C}_{\mathbf{uvwx}}$.

equation

$$\begin{aligned} \ominus\mathbf{x}\oplus\mathbb{C}_{\mathbf{uvw}} &= \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}\ominus\mathbf{x}\oplus\mathbf{w}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{v}} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}} \\ &= \mathbb{C}_{\ominus\mathbf{x}\oplus\mathbf{u}\ominus\mathbf{x}\oplus\mathbf{v}\ominus\mathbf{x}\oplus\mathbf{w}} \end{aligned} \tag{6.336}$$

thus uncovering the interesting identity

$$\begin{aligned} &\ominus\mathbf{x}\oplus\frac{\gamma_{\mathbf{u}}\mathbf{u} + \gamma_{\mathbf{v}}\mathbf{v} + \gamma_{\mathbf{w}}\mathbf{w}}{\gamma_{\mathbf{u}} + \gamma_{\mathbf{v}} + \gamma_{\mathbf{w}}} \\ &\quad = \frac{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}}\ominus\mathbf{x}\oplus\mathbf{u} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{v}}\ominus\mathbf{x}\oplus\mathbf{v} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}\ominus\mathbf{x}\oplus\mathbf{w}}{\gamma_{\ominus\mathbf{x}\oplus\mathbf{u}} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{v}} + \gamma_{\ominus\mathbf{x}\oplus\mathbf{w}}} \end{aligned} \tag{6.337}$$

in any Einstein gyrovector space.

Euclidean triangle centroids have classical mechanical interpretation [Hausner (1998)]. Interestingly, we will see in Chaps. 10-11 on Einstein's special theory of relativity that gyrocentroids in Einstein two and three-dimensional gyrovector spaces have analogous relativistic mechanical interpretation in which the gamma factor plays the role of the relativistic mass correction.

Further extension to n-dimensional gyrotetrahedrons in n-dimensional Einstein gyrovector spaces, $n \geq 3$, shown in Figs. 6.18 and 6.19 for $n = 3$, is obvious. Thus, for instance, the gyrocentroid $\mathbb{C}_{\mathbf{uvwx}}$ of the gyrotetrahedron **uvwx** in Fig. 6.19 is given by the equation

$$\mathbb{C}_{\mathbf{uvwx}} = \frac{\gamma_{\mathbf{u}}\mathbf{u} + \gamma_{\mathbf{v}}\mathbf{v} + \gamma_{\mathbf{w}}\mathbf{w} + \gamma_{\mathbf{x}}\mathbf{x}}{\gamma_{\mathbf{u}} + \gamma_{\mathbf{v}} + \gamma_{\mathbf{w}} + \gamma_{\mathbf{x}}} \tag{6.338}$$

6.22.2 *In Möbius Gyrovector Spaces*

Let

$$\begin{aligned} G_e &= (\mathbb{V}_s, \oplus_{\mathrm{E}}, \otimes_{\mathrm{E}}) \\ G_m &= (\mathbb{V}_s, \oplus_{\mathrm{M}}, \otimes_{\mathrm{M}}) \end{aligned} \tag{6.339}$$

be, respectively, the Einstein and the Möbius gyrovector spaces of the ball $\mathbb{V}_s$ of a real inner product space $\mathbb{V}$. They are gyrovector space isomorphic, with the isomorphism ϕ_{EM} and its inverse isomorphism ϕ_{ME} from G_m into G_e shown in Table 6.1, p. 226. Accordingly, the correspondence between elements of G_m and G_e is given by the equations

$$\begin{aligned} \mathbf{v}_e &= 2\otimes_{\mathrm{M}}\mathbf{v}_m \\ \mathbf{v}_m &= \tfrac{1}{2}\otimes_{\mathrm{E}}\mathbf{v}_e \end{aligned} \tag{6.340}$$

$\mathbf{v}_e \in G_e$, $\mathbf{v}_m \in G_m$.

Hence, by (6.340) and the first identity in (6.304) we have

$$\gamma_{\mathbf{v}_e} = \gamma_{2\otimes_{\mathrm{M}}\mathbf{v}_m} = 2\gamma_{\mathbf{v}_m}^2 - 1 \tag{6.341}$$

Similarly, following (6.340) and (6.301) we have

$$\gamma_{\mathbf{v}_e}\mathbf{v}_e = \gamma_{2\otimes_{\mathrm{M}}\mathbf{v}_m} 2\otimes_{\mathrm{M}}\mathbf{v}_m = 2\gamma_{\mathbf{v}_m}^2\mathbf{v}_m \tag{6.342}$$

Vector Algebra

$a \in \mathbb{R}^3$ be a three-dimensional (in particular, two-dimensional) vector.

Graphically, a is a directed line segment. Its magnitude is denoted by $|a|$.

The scalar product $a.b$ of vector a and b is a scalar quantity (i.e., a real number) defined by

$a.b = |a||b| \cos\theta$, where $\theta \, (0 \leq \theta \leq \pi)$.

7.3 The Gyroline Element of Möbius Gyrovector Spaces

In this section we uncover the Riemannian line element to which the gyrometric of the Möbius gyrovector space $(\mathbb{R}^n_c, \oplus_{\rm M}, \otimes_{\rm M})$ gives rise.

Let us consider the gyrodifferential (7.12),

$$\begin{aligned}\Delta\mathbf{s}_{\rm M} &= (\mathbf{v} + \Delta\mathbf{v})\ominus_{\rm M}\mathbf{v}\\ &= \begin{pmatrix} x_1 + \Delta x_1 \\ x_2 + \Delta x_2 \end{pmatrix} \ominus_{\rm M} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}\end{aligned} \tag{7.22}$$

in the Möbius gyrovector plane $(\mathbb{R}^2_c, \oplus_{\rm M}, \otimes_{\rm M})$, where ambiguously, $+$ is the Euclidean addition in $\mathbb{R}^2$ and in $\mathbb{R}$. To calculate $\mathbf{X}_1$ and $\mathbf{X}_2$ we have

$$\begin{aligned} d\mathbf{s}_{\rm M} &= \left[\frac{\partial\Delta\mathbf{s}_{\rm M}}{\partial\Delta x_1}\right]_{\left\{\begin{array}{l}\Delta x_1 = 0\\ \Delta x_2 = 0\end{array}\right\}} dx_1 \quad + \quad \left[\frac{\partial\Delta\mathbf{s}_{\rm M}}{\partial\Delta x_2}\right]_{\left\{\begin{array}{l}\Delta x_1 = 0\\ \Delta x_2 = 0\end{array}\right\}} dx_2 \\ &= \mathbf{X}_1(x_1, x_2)dx_1 + \mathbf{X}_2(x_1, x_2)dx_2 \end{aligned} \tag{7.23}$$

where $\mathbf{X}_1, \mathbf{X}_2 : \mathbb{R}^2_c \to \mathbb{R}^2$, obtaining

$$\begin{aligned}\mathbf{X}_1(x_1, x_2) &= \frac{c^2}{c^2 - r^2}(1,\, 0) \in \mathbb{R}^2\\ \mathbf{X}_2(x_1, x_2) &= \frac{c^2}{c^2 - r^2}(0,\, 1) \in \mathbb{R}^2\end{aligned} \tag{7.24}$$

where $r^2 = x_1^2 + x_2^2$.

The gyrometric coefficients of the gyrometric of the Möbius gyrovector plane in the Cartesian x_1x_2-coordinates are therefore

$$\begin{aligned} E &= \mathbf{X}_1\cdot\mathbf{X}_1 = \frac{c^4}{(c^2 - r^2)^2}\\ F &= \mathbf{X}_1\cdot\mathbf{X}_2 = 0\\ G &= \mathbf{X}_2\cdot\mathbf{X}_2 = \frac{c^4}{(c^2 - r^2)^2}\end{aligned} \tag{7.25}$$

Hence, the gyroline element of the Möbius gyrovector plane $(\mathbb{R}^2_c, \oplus_{\rm M}, \otimes_{\rm M})$

is the Riemannian line element

$$\begin{aligned} ds_{\mathrm{M}}^2 &= \|d\mathbf{s}_{\mathrm{M}}\|^2 \\ &= Edx_1^2 + 2Fdx_1dx_2 + Gdx_2^2 \\ &= \frac{c^4}{(c^2-r^2)^2}(dx_1^2+dx_2^2) \end{aligned} \tag{7.26}$$

known as the Poincaré metric. Thus, for instance, the Riemannian line element of the Poincaré disc or, equivalently, the Möbius gyrovector plane $(\mathbb{R}^2_{c=2}, \oplus_{\mathrm{M}}, \otimes_{\mathrm{M}})$, is [McCleary (1994), p. 226]

$$ds_{\mathrm{M}}^2 = \frac{dx_1^2 + dx_2^2}{(1-\frac{r^2}{c^2})^2} \tag{7.27}$$

An interesting elementary study of the Riemannian structure (7.26) in the context of the hyperbolic plane is presented in the introductory chapter of [Helgason (1984)]. The Riemannian line element ds_{M}^2 is identified in [Farkas and Kra (1992), p. 216] as a Riemannian metric on the Riemann surface $\mathbb{D}_{c=1}$, where $\mathbb{D}_{c=1}$ is the Poincaré complex open unit disc.

Following Riemann [Stahl (1993), p. 73] we note that E, G and $EG - F^2 = EG$ are all positive in the open disc $\mathbb{R}^2_c$, so that the quadratic form (7.26) is *positive definite* [Kreyszig (1991), p. 84].

The gyrocurvature of the Möbius gyrovector plane is the Gaussian curvature K of the surface with the line element (7.26). It is a negative constant,

$$K = -\frac{4}{c^2} \tag{7.28}$$

as one can calculate from (7.21).

Extending (7.26) from $n = 2$ to $n \geq 2$ we have

$$\begin{aligned} ds_{\mathrm{M}}^2 &= \frac{c^4}{(c^2-\mathbf{r}^2)^2}d\mathbf{r}^2 \\ &= \frac{d\mathbf{r}^2}{(1+\frac{1}{4}K\mathbf{r}^2)^2} \end{aligned} \tag{7.29}$$

The Riemannian line element ds_{M}^2 reduces to its Euclidean counterpart in the limit of large c,

$$\lim_{c\to\infty} ds_{\mathrm{M}}^2 = d\mathbf{r}^2 \tag{7.30}$$

as expected.

The study of the line element (7.29) by Riemann is described in [Coxeter (1998), p. 12]. In two dimensions it is known as the Poincaré metric of the Poincaré disc [McCleary (1994)]. We have thus established the following theorem.

Theorem 7.4 *The gyroline element of a Möbius gyrovector space* $(\mathbb{R}^n_c, \oplus_M, \otimes_M)$ *is given by the equation*

$$ds^2_{\rm M} = \frac{c^4}{(c^2 - \mathbf{r}^2)^2} d\mathbf{r}^2 \tag{7.31}$$

and its gyrocurvature is given by the equation

$$K = -\frac{4}{c^2} \tag{7.32}$$

In particular, for $n = 2$ *and* $c = 1$ *the gyroline element* (7.31) *coincides with the Riemannian line element of the Poincaré disc model of hyperbolic geometry.*

A Riemannian metric g in $\mathbb{R}^n$ has the form

$$g = \sum_{i,j=1}^{n} g_{ij} dx_i dx_j \tag{7.33}$$

Two Riemannian metrics g_1 and g_2 are said to be *conformal* to each other if there is a positive smooth (that is, infinitely differentiable) function $f : \mathbb{R}^n \to \mathbb{R}^{>0}$ such that $g_1 = f g_2$ [Lee (1997)], $\mathbb{R}^{>0} = \{r \in \mathbb{R} : r > 0\}$ being the positive ray of the real line $\mathbb{R}$.

The Riemannian metric of Möbius gyrovector spaces $(\mathbb{R}^n_c, \oplus_{\rm M}, \otimes_{\rm M})$, given by (7.29), is conformal to the Riemannian metric

$$d\mathbf{r}^2 = \sum_{i=1}^{n} dx_i^2 \tag{7.34}$$

of the Euclidean n-space $\mathbb{R}^n$. Hence, hyperbolic spheres in Möbius gyrovector spaces are also Euclidean spheres. However, Euclidean and hyperbolic sphere centers need not coincide, as shown in Fig. 7.1. The reason in terms of analogies that Euclidean and hyperbolic geometry share is clear. For any two tangent Euclidean circles with centers $\mathbf{a}, \mathbf{c}$ and concurrent point $\mathbf{b}$, the points $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are collinear. In full analogy, for any two tangent Möbius circles with centers $\mathbf{a}, \mathbf{c}$ and concurrent point $\mathbf{b}$, the points $\mathbf{a}, \mathbf{b}, \mathbf{c}$ are gyrocollinear, as shown in Fig. 7.1.

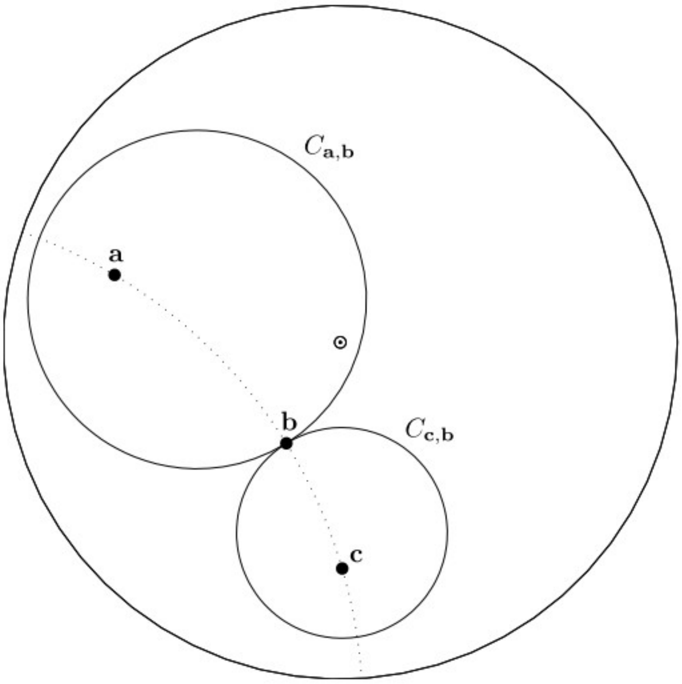

Fig. 7.1 The Möbius gyrocircle $C_{\mathbf{a},\mathbf{b}}$, given by the equation

$$\mathbf{a}\oplus_{\text{M}} \begin{pmatrix} \cos\theta & -\sin\theta \\ \sin\theta & \cos\theta \end{pmatrix} (\ominus_{\text{M}}\mathbf{a}\oplus_{\text{M}}\mathbf{b}), \qquad 0 \le \theta < 2\pi,$$

is the hyperbolic circle in the Möbius gyrovector plane $(\mathbb{R}^2_c, \oplus_{\text{M}}, \otimes_{\text{M}})$. It is a Euclidean circle with hyperbolic radius $\|\ominus_{\text{M}}\mathbf{a}\oplus_{\text{M}}\mathbf{b}\|$, hyperbolically centered at **a**.
A second gyrocircle, $C_{\mathbf{c},\mathbf{b}}$, that intersects $C_{\mathbf{a},\mathbf{b}}$ at a single point, **b**, is shown. In full analogy with Euclidean geometry, the two gyrocenters **a** and **c** and the concurrent point **b** are gyrocollinear.

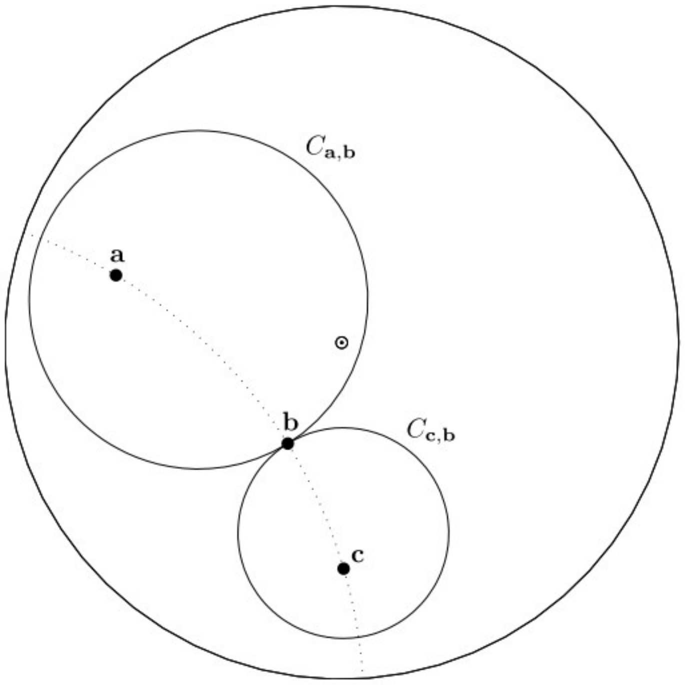
7.4 The Cogyroline Element of Möbius Gyrovector Spaces

In this section we uncover the Riemannian line element to which the cogyrometric of the Möbius gyrovector space $(\mathbb{R}^n_c, \oplus_{\text{M}}, \otimes_{\text{M}})$ gives rise.

Let us consider the cogyrodifferential (7.12),

$$\begin{aligned} \Delta\mathbf{s}_{\text{CM}} &= (\mathbf{v} + \Delta\mathbf{v}) \boxminus_{\text{M}} \mathbf{v} \\ &= \begin{pmatrix} x_1 + \Delta x_1 \\ x_2 + \Delta x_2 \end{pmatrix} \boxminus_{\text{M}} \begin{pmatrix} x_1 \\ x_2 \end{pmatrix} \end{aligned} \tag{7.35}$$

in the Möbius gyrovector plane $(\mathbb{R}^2_c, \oplus_{\text{M}}, \otimes_{\text{M}})$, where $+$ is the Euclidean



$C_{\mathbf{a},\mathbf{b}}$

that trivial. In general, the nature of the issues considered involves frame fields adapted to the surface, not constant frame fields. As for the standard concept of (Levi-Civita) connection on a surface, it is here a matter of neglecting the normal component in the differentiation of tangent vectors to the surface.

As has been the case through the text, we shall continue to use the moving frame method. One has not yet taken full advantage of it. We do better than appears to be the case in the literature by the use of surface-adapted 3-D frame fields that are canonically determined by the diagonalization of the second fundamental form of surfaces.

We shall see that the Frenet frame field is canonically determined by curves and that the "geodesic frame field" is canonically determined by the pair of curve and surface. There is the coordinate frame field on surfaces, canonically determined by the pair of surface and coordinate system on it. There are also the canonical frame fields of 3-D Euclidean space, i.e. the constant orthonormal frame fields denoted as $(\mathbf{i}, \mathbf{j}, \mathbf{k})$. Missing is the canonical frame field of an embedded surface.

For comparison purposes, there will be some paragraphs which are not proper part of the theory of curves and surfaces with the theory of moving frames. They illustrate the cumbersomeness of the by now almost abandoned traditional approach. If we removed those comparisons, our treatment would be more than two pages shorter.

A.2 Surfaces in 3-D Euclidean space

A.2.1 Representations of surfaces; metrics

One way of giving a surface is in the form

$$\mathbf{x} = x^i(u, v)\mathbf{a}_i, \tag{2.1a}$$

where $\mathbf{a}_i$ is a fixed basis, $\mathbf{i}, \mathbf{j}, \mathbf{k}$. Equivalently, we have

$$x = x(u, v), \quad y = x(u, v), \quad z = z(u, v), \tag{2.1b}$$

for a given domain of the parameters. These actually are coordinates on the surface. We may also give it as

$$f(x, y, z) = 0. \tag{2.2}$$

The connection between (2.1) and (2.2) can be established as follows. We solve for u and v in two of the equations (2.1b) and substitute in the third of those equations, then taking all terms to the left hand side. On the other hand, we go back from (2.2) to (2.1) by writing, for instance,

$$x = u, \qquad y = v. \tag{2.3}$$

Substitution of (2.3) in (2.2) allows us to view z as an implicit function of x and y. Of course, one may then use other parametrizations through an invertible system of equations

$$u' = u'(u, v), \qquad v' = v'(u, v). \tag{2.4}$$

The metric of 3-D Euclidean space in terms of Cartesian systems is

$$ds^2 = \sum_i (dx^i)^2, \qquad i = 1, 2, 3. \tag{2.5}$$

where

$$dx^i = x^i{}_{,\alpha}\, du^\alpha, \qquad \alpha = 1, 2 \tag{2.6}$$

and where $x^i = (x, y, z)$ and $u^1 = u,\ u^2 = v$. A subscript after a comma means partial differentiation. The variable with respect to which the differentiation takes place is apparent in any such expressions. Once these operations have been performed, any trace of x, y, z, dx, dy and dz has disappeared and we are left with

$$ds^2 = g_{\alpha\beta}(u^\gamma) du^\alpha du^\beta, \tag{2.7}$$

which is also written as

$$ds^2 = Edu^2 + 2Fdudv + Gdv^2. \tag{2.8}$$

It is the called the first fundamental form. Clearly

$$E = g_{11}, \quad F = g_{12}, \quad G = g_{22}. \tag{2.9}$$

The positive definiteness of the metric implies

$$EG - F^2 > 0, \tag{2.10}$$

as we are about to show.

(2.8) is the way in which one expresses distance on curves, which is actually computed as

$$\sqrt{E\left(\frac{du}{d\lambda}\right)^2 + 2F\left(\frac{du}{d\lambda}\right)\left(\frac{dv}{d\lambda}\right) + G\left(\frac{dv}{d\lambda}\right)^2} d\lambda, \tag{2.11}$$

where λ is a parameter on the curve. In general, we can take the parameter to be v itself. (2.11) then becomes

$$\int \sqrt{E\mu^2 + 2F\mu + G}\ dv, \tag{2.12}$$

where μ is du/dv. The equation

$$y = Ex^2 + 2Fx + G \tag{2.13}$$

is a parabola. If the metric is positive definite, this is an upright parabola with vertex above the x axis. It does not cut the line $y = 0$. Thus the roots of $Ex^2 + 2Fx + G = 0$ must be imaginary, which implies

$$EG - F^2 > 0. \tag{2.14}$$

A.2.2 Normal to a surface, orthonormal frames, area

Vectors normal to a surface are not tangent vectors. Hence, they cannot be given as a linear combination of tangent vectors, but rather in terms of, for example, the basis $\mathbf{a}_i = \mathbf{i}, \mathbf{j}, \mathbf{k}$. Given the surface $f(x, y, z) = 0$, its tangent plane at (x_0, y_0, z_0) is obtained by substituting $x^i - x_0^i$ for dx^i in $f_{,i}\, dx^i = 0$, i.e.

$$f_{,i} \cdot (x^i - x_0^i) = 0, \tag{2.15}$$

where the dot is used for product, thus preempting taking $x^i - x_0^i$ as argument of $f_{,i}$. Let $g(x, y, z)$ be defined as $-f(x, y, z)$. The equation $g(x, y, z) = 0$ represents the same surface as $f(x, y, z) = 0$. But the unit vectors

$$\frac{\sum f_{,i}\, \mathbf{a}_i}{\sqrt{\sum (f_{,i})^2}}, \qquad \frac{\sum g_{,i}\, \mathbf{a}_i}{\sqrt{\sum (g_{,i})^2}}$$

are opposite of each other. Whether we take one or the other as the unit normal to the plane is not significant at this point.

Differentiating (2.1), we get

$$d\mathbf{x} = dx^i(u, v)\mathbf{a}_i = \mathbf{x}_{,u} du + \mathbf{x}_{,v} dv. \tag{2.16}$$

$\mathbf{x}_{,u}$ and $\mathbf{x}_{,v}$ are defined by these relations. They constitute a tangent coordinate vector basis field. It is not, therefore, orthonormal in general. The equation of the plane at the point of coordinates (u_0, v_0) is given by

$$\mathbf{x} = \mathbf{x}_0 \ + \ \mathbf{x}_{,u} \cdot (u - u_0) \ + \ \mathbf{x}_{,v} \cdot (v - v_0), \tag{2.17}$$

where $\mathbf{x}_0$, $\mathbf{x}_{,u}$ and $\mathbf{x}_{,v}$ are evaluated at (u_0, v_0). The dots at mid height have been put for the same reason as in (2.15). In moving frame notation, they are the equivalent of

$$d\mathbf{P} = \omega^i \mathbf{e}_i, \qquad \mathbf{P} = \mathbf{P}_0 \ + \ X^i \mathbf{e}_i. \tag{2.18}$$

The following is a necessary step to launch the moving frame method once the equation of a surface has been given. Let $(\hat{\omega}^1, \hat{\omega}^2)$ be any pair of differential 1-forms that satisfies

$$ds^2 = g_{\alpha\beta}(u, v) du^\alpha du^\beta = (\hat{\omega}^1)^2 + (\hat{\omega}^2)^2. \tag{2.19}$$

A first (retrospectively very important) consequence of the normalized form of the metric is that $\hat{\omega}^3$ is zero on the surface. Hence, the pull-back to the surface of the torsion of Euclidean space (torsion which, of course, is zero) reads

$$0 = d\hat{\omega}^3 = \hat{\omega}^\alpha \wedge \hat{\omega}^3_\alpha = \Gamma^3_{\alpha\beta} \hat{\omega}^\alpha \wedge \hat{\omega}^\beta, \tag{2.20}$$

where, for the last step, we have used that the pull-back of $\hat{\omega}^3_\alpha$ is a linear function of only $\hat{\omega}^1$ and $\hat{\omega}^2$. We immediately get $\Gamma^3_{12} = \Gamma^3_{21}$, which we prefer to write as

$$\Gamma^1_{32} = \Gamma^2_{31} \tag{2.21}$$

(on the surface).

We now proceed to diagonalize the expression

$$g_{\alpha\beta}du^{\alpha}du^{\beta} \equiv g_{11}du^2 + 2g_{12}dudv + g_{22}dv^2, \tag{2.22}$$

by first obtaining

$$g_{\alpha\beta}du^{\alpha}du^{\beta} - \frac{1}{g_{11}}(g_{11}du + g_{12}dv)^2 = dv^2\frac{g_{22}g_{11} - g_{12}^2}{g_{11}}, \tag{2.23}$$

as per Eq. (4.51) of chapter 3. We thus have

$$g_{\alpha\beta}du^{\alpha}du^{\beta} = \left(\frac{g_{11}du + g_{12}dv}{\sqrt{g_{11}}}\right)^2 + dv^2\frac{g_{22}g_{11} - g_{12}^2}{g_{11}}, \tag{2.24}$$

and

$$\hat{\omega}^1 = \frac{g_{11}du + g_{12}dv}{\sqrt{g_{11}}}, \qquad \hat{\omega}^2 = dv\frac{(g_{22}g_{11} - g_{12}^2)^{1/2}}{\sqrt{g_{11}}} \tag{2.25}$$

and, further,

$$\hat{\omega}^1 \wedge \hat{\omega}^2 = (g_{22}g_{11} - g_{12}^2)^{1/2}du \wedge dv = \sqrt{EG - F^2}\, du \wedge dv. \tag{2.26}$$

Clearly, there is an infinite number of pairs $(\hat{\omega}^1, \hat{\omega}^2)$ that orthogonalize the metric of the surface. (2.25) is just one of them. We shall use this freedom to determine *frame fields adapted to surfaces*.

A.2.3 The equations of Gauss and Weingarten

The connection equations of Euclidean space are simply $d\mathbf{a}_i = 0$ in terms of a Cartesian frame field. The equations of Gauss and Weingarten are the connection equations of 3-D Euclidean space when the frame field is constituted by $\mathbf{x}_{,u}$, $\mathbf{x}_{,v}$ and the unit vector $\mathbf{N}$ perpendicular to the plane that they determine.

At a time when the concept of connection equations did not exist, Gauss wrote the differentiation of the tangent frame field $(\mathbf{x}_{,u}, \mathbf{x}_{,v})$ as

$$\mathbf{x}_{,u,u} = \Gamma^1_{11}\mathbf{x}_{,u} + \Gamma^2_{11}\mathbf{x}_{,v} + e\mathbf{N}, \tag{2.27a}$$

$$\mathbf{x}_{,u,v} = \Gamma^1_{12}\mathbf{x}_{,u} + \Gamma^2_{12}\mathbf{x}_{,v} + f\mathbf{N}, \tag{2.27b}$$

$$\mathbf{x}_{,v,v} = \Gamma^1_{22}\mathbf{x}_{,u} + \Gamma^2_{22}\mathbf{x}_{,v} + g\mathbf{N}, \tag{2.27c}$$

which reflects the state of the art of the time. $d(\mathbf{x}_{,u})$ is a differential 2-form on the surface, valued in 3-D Euclidean vector space. It can be written as the following bilinear combination

$$d(\mathbf{x}_{,u}) = \Gamma^1_{1\alpha}du^{\alpha}\mathbf{x}_{,u} + \Gamma^2_{1\alpha}du^{\alpha}\mathbf{x}_{,v} + \Gamma^3_{1\alpha}du^{\alpha}\mathbf{N} \tag{2.28}$$

(and similarly for $d\mathbf{x}_{,v}$). Here we can read that

$$\mathbf{x}_{,u,u} = \Gamma^1_{11}\mathbf{x}_{,u} + \Gamma^2_{11}\mathbf{x}_{,v} + \Gamma^3_{11}\mathbf{N}, \tag{2.29}$$

(and similarly for $\mathbf{x}_{,u,v}$ and $\mathbf{x}_{,v,v}$).

The two Weingarten equations are

$$\mathbf{N}_{,u} = \frac{fF - eG}{EG - F^2}\mathbf{x}_{,u} + \frac{eF - fE}{EG - F^2}\mathbf{x}_{,v}, \tag{2.30a}$$

$$\mathbf{N}_{,v} = \frac{gF - fG}{EG - F^2}\mathbf{x}_{,u} + \frac{fF - gE}{EG - F^2}\mathbf{x}_{,v}. \tag{2.30b}$$

In terms of orthonormal frames, we would replace

(a) $\mathbf{x}_{,u}$ and $\mathbf{x}_{,v}$ with $\hat{\mathbf{e}}_\alpha$,

(b) (e, f, g) with Γ's as stated above. We shall later see how they were introduced originally.

(c) (E, G, F) with $(1, 1, 0)$.

Notice the great simplification that then results. Further simplification follows in section 4 when we adopt the canonical frame field of surfaces.

A.3 Curves in 3-D Euclidean space

A.3.1 Frenet's frame field and formulas

Curves in E^3 are 1-dimensional manifolds, if we eliminate the points where the curve intersects itself. They can be given as the intersection of two surfaces

$$f(x, y, z) = 0, \qquad g(x, y, z) = 0, \tag{3.1}$$

or as

$$x = x(u), \quad y = y(u), \quad z = z(u), \tag{3.2}$$

which is the developed form of

$$\mathbf{x} = x^i(u)\mathbf{a}_i. \tag{3.3}$$

The relation between (3.1) and (3.2) is obtained by solving for two of the Cartesian coordinates in (3.1), and then changing parameter if one so wishes. In the opposite direction, we eliminate u in (3.2)

The distance on the curve between two points on the same is obtained by integration of

$$ds = \sqrt{\left(\frac{dx}{du}\right)^2 + \left(\frac{dy}{du}\right)^2 + \left(\frac{dz}{du}\right)^2}\, du. \tag{3.4}$$

Frenet's frame is the 3-D frame field adapted to a curve that, if we require it to be orthonormal, is canonically determined by the curve.

The first element of the frame is the unit tangent vector $\mathbf{t}$,

$$\mathbf{t} \equiv \frac{d\mathbf{x}}{ds} = \frac{d\mathbf{x}}{du}\frac{1}{ds/du}, \tag{3.5}$$

with ds/du obtained from (3.4). $\mathbf{t}$ is obviously a unit vector

$$\mathbf{t} \cdot \mathbf{t} = 1, \tag{3.6}$$

since $d\mathbf{x} \cdot d\mathbf{x}$ is ds^2. The tangent line to a curve at its point $\mathbf{x}_0$ is

$$\mathbf{x} = \mathbf{x}_0 + \mathbf{t}s, \tag{3.7}$$

s being assigned the value zero at $\mathbf{x}_0$.

From (3.6), we define a curvature vector $\boldsymbol{\kappa} \equiv \frac{d\mathbf{t}}{ds}$. We then have:

$$\mathbf{t} \cdot \boldsymbol{\kappa} = \frac{\mathbf{dt}}{\mathbf{ds}} \cdot \boldsymbol{\kappa} = \mathbf{0} \tag{3.8}$$

which means that the equations

$$\boldsymbol{\kappa} = \kappa \mathbf{n} = \frac{1}{\rho} \mathbf{n} \tag{3.9}$$

define $\mathbf{n}$, κ and ρ if we demand that $\mathbf{n}$ be a unit vector. This vector is the second element of a right handed orthonormal frame. One refers to κ and ρ respectively as curvature and radius of curvature. Because of the sought orthonormality of the frame, the coefficient of $\mathbf{n}'$ relative to $\mathbf{b}$ will be the negative of the coefficient of $\mathbf{b}'$ relative to $\mathbf{n}$. Thus:

$$\mathbf{n}' = -\kappa \mathbf{t} + \tau \mathbf{b}, \qquad \mathbf{b}' = -\tau \mathbf{n}. \tag{3.10}$$

τ is called torsion of the curve.

Equations (3.9) and (3.10) are called the Frenet equations. $\mathbf{b}$ is perpendicular to the plane of plane curves. It is then of constant direction and actually a constant vector, since it is of unit size. τ is, therefore, zero. Plane curves are torsionless. On the other hand, a helix has torsion since the plane of $\mathbf{t}$ and $\mathbf{n}$ keeps changing. This plane is called the osculating plane.

A.3.2 Geodesic frame fields and formulas

We are going to study surfaces through curves on them. It is then useful to consider 3-D right handed orthonormal frames ($\hat{\mathbf{u}}_i = \mathbf{t}, \mathbf{u}, \mathbf{N}$). $\mathbf{u}$ is a vector in the tangent plane and $\mathbf{N}$ is usually taken on the opposite side (of the tangent plane) to $\boldsymbol{\kappa}$ (see example in next paragraph). We shall refer to this frame field as the geodesic frame field of the curve on the given surface.

One defines the *normal and geodesic curvatures* $\boldsymbol{\kappa}_n$ and $\boldsymbol{\kappa}_g$ of the curve at a point by means of the decomposition

$$\mathbf{t}' \equiv \frac{d\mathbf{t}}{ds} = \boldsymbol{\kappa} \equiv \boldsymbol{\kappa}_n + \boldsymbol{\kappa}_g = -\kappa_n \mathbf{N} + \kappa_g \mathbf{u}. \tag{3.11}$$

We follow Struik and use the subscript "$_n$" even though the projection is on $\mathbf{N}$, not on $\mathbf{n}$ (see (3.9)). We have introduced the minus sign in front of $\kappa_n \mathbf{N}$ so that

κ_n be positive under the most usual convention when choosing the direction of the normal to the sphere. Thus the normal $\mathbf{n}$ to a parallel is inwards, whereas the normal at the same point to the sphere itself is usually taken to be outwards. This example is also useful in connection with how the radii of curvature of the parallel and of the sphere are related. Recall that the magnitudes of the curvatures and their associated radii are the inverses of each other.

Orthonormality determines the $\mathbf{t}$ component of $\mathbf{N}'$. We thus have,

$$\mathbf{N}' \equiv \frac{d\mathbf{N}}{ds} = \kappa_n \mathbf{t} + \tau_g \mathbf{u}, \tag{3.12}$$

which defines the coefficient τ_g, called geodesic torsion of the curve. Using again orthonormality, we obtain

$$\mathbf{u}' \equiv \frac{d\mathbf{u}}{ds} = -\kappa_g \mathbf{t} - \tau_g \mathbf{N}. \tag{3.13}$$

A.4 Curves on surfaces in 3-D Euclidean space

A.4.1 Canonical frame field of a surface

We clearly have

$$\kappa_n = -\boldsymbol{\kappa} \cdot \mathbf{N} = -\frac{d\mathbf{t}}{ds} \cdot \mathbf{N} = \mathbf{t} \cdot \frac{d\mathbf{N}}{ds} = \frac{d\mathbf{x}}{ds} \cdot \frac{d\mathbf{N}}{ds}. \tag{4.1}$$

$d\mathbf{x} \cdot d\mathbf{N}$ is a quadratic symmetric differential form on du and dv:

$$d\mathbf{x} \cdot d\mathbf{N} = e du^2 + 2f du dv + g dv^2. \tag{4.2}$$

It is called the *second fundamental form.* We do not have any use for this form, as there is a much better way to study normal curvature through the introduction of the concept of canonical frame field of a surface.

Let $\hat{\mathbf{u}}_\alpha$ denote any orthonormal, counterclockwise 2-D frame tangent to the surface and let $\hat{\mathbf{u}}_3$ be $\mathbf{N}$. Since only zero forms and 1-forms live on a curve, the last ones are multiples of each other. Formal division by a differential 1-form is justified and we get

$$\kappa_n = \frac{\hat{\omega}'^{\alpha} \hat{\mathbf{u}}_\alpha}{ds} \cdot \frac{\hat{\omega}_3'^{i} \hat{\mathbf{u}}_i}{ds} = \frac{\hat{\Gamma}'^{1}_{31} (\hat{\omega}'^{1})^2 + (\hat{\Gamma}'^{1}_{32} + \hat{\Gamma}'^{2}_{31}) \hat{\omega}'^{1} \hat{\omega}'^{2} + \hat{\Gamma}'^{2}_{32} (\hat{\omega}'^{2})^2}{ds^2}. \tag{4.3}$$

Equation (4.3) applies to a one-dimensional manifold of frames related at each point by rotations around the normal to the surface. We reserve the use of unprimed quantities for the orthonormal frame $(\hat{\mathbf{e}}_1, \hat{\mathbf{e}}_2, \hat{\mathbf{e}}_3)$ that satisfies

$$\hat{\Gamma}^{1}_{32} = -\hat{\Gamma}^{2}_{31}, \tag{4.4}$$

and, because of (4.4), also

$$\hat{\Gamma}^{1}_{32} = \hat{\Gamma}^{2}_{31} = 0. \tag{4.5}$$

Vector Algebra

$a \in \mathbb{R}^3$ be a three-dimensional (in particular, two-dimensional) vector.

Graphically, a is a directed line segment. Its magnitude is denoted by $|a|$.

The scalar product $a.b$ of vectors a and b is a scalar quantity (i.e., a real number) defined by

$a.b = |a||b| \cos\theta$, where θ $(0 \leq \theta \leq \pi)$.

05.10.2019

is the angle between the vector a and b.
The scalar product is denoted in the literature by (a, b).

The vectors $a, b \in \mathbb{R}^3$ can be represented in the rectangular Cartesian coordinates in the form

$a=(a^1, a^2, a^3)$, $b=(b^1, b^2, b^3)$,

which means that

$a = a^1 i + a^2 j + a^3 k.$

$(a^1 i)$

$b = b^1 i + b^2 j + b^3 k.$

where i, j, and k are the unit vectors along the first, second and third coordinate axes in $\mathbb{R}^3$, respectively.

Then the scalar product is given by

$$a \cdot b = \sum_{i=1}^{3} a^i b^i.$$

1(175) j) Brans-Dicke theory

Source: https://en.wikipedia.org/wiki/Brans-Dicke_theory

05 10 2019

In theoretical physics the Brans-Dicke theory of gravitation (Jordan-Brans-Dicke theory) is a theoretical framework to explain gravitation.

It is a competitor of Einstein's theory of general relativity.

It is an example of a scalar-tensor theory, a gravitational theory in which the gravitational interaction is mediated by a scalar field as well as the tensor field of general relativity.

Chapter 1

Preliminaries

1.1 Vectors in linear spaces

This section contains basic notion and useful formulae from vector analysis in n-dimensional linear spaces $\mathbb{R}^n$. Following the convenient traditional notation, vectors of dimensions two ($n = 2$) and three ($n = 3$) are denoted by letters in bold faced type.

1.1.1 Three-dimensional vectors

1.1.1.1 Vector algebra

Let $\boldsymbol{a} \in \mathbb{R}^3$ be a three-dimensional (in particular, two-dimensional) vector. Graphically, $\boldsymbol{a}$ is a directed line segment. Its magnitude is denoted by $|\boldsymbol{a}|$.

The *scalar product* $\boldsymbol{a} \cdot \boldsymbol{b}$ of vectors $\boldsymbol{a}$ and $\boldsymbol{b}$ is a scalar quantity (i.e. a real number) defined by

$$\boldsymbol{a} \cdot \boldsymbol{b} = |\boldsymbol{a}||\boldsymbol{b}| \cos \theta, \tag{1.1.1}$$

where θ ($0 \leq \theta \leq \pi$) is the angle between the vectors $\boldsymbol{a}$ and $\boldsymbol{b}$. The scalar product is denoted in the literature by $(\boldsymbol{a}, \boldsymbol{b})$.

The vectors $\boldsymbol{a}, \boldsymbol{b} \in \mathbb{R}^3$ can be represented in the rectangular Cartesian coordinates in the form

$$\boldsymbol{a} = (a^1, a^2, a^3), \quad \boldsymbol{b} = (b^1, b^2, b^3), \tag{1.1.2}$$

which means that

$$\begin{aligned} \boldsymbol{a} &= a^1 \boldsymbol{i} + a^2 \boldsymbol{j} + a^3 \boldsymbol{k}, \\ \boldsymbol{b} &= b^1 \boldsymbol{i} + b^2 \boldsymbol{j} + b^3 \boldsymbol{k}, \end{aligned} \tag{1.1.3}$$

where $\boldsymbol{i}$, $\boldsymbol{j}$ and $\boldsymbol{k}$ are the unit vectors along the first, second and third coordinate axes in $\mathbb{R}^3$, respectively. Then the scalar product (1.1.1) is given by

$$\boldsymbol{a} \cdot \boldsymbol{b} = \sum_{i=1}^{3} a^i b^i. \tag{1.1.4}$$

The *vector product* of the vectors (1.1.3) is a vector given by

$$\boldsymbol{a}\times\boldsymbol{b}=\begin{vmatrix}\boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k}\\ a^1 & a^2 & a^3\\ b^1 & b^2 & b^3\end{vmatrix} \tag{1.1.5}$$

or (see also Eq. (8.2.22))

$$\boldsymbol{a}\times\boldsymbol{b}=(a^2b^3-a^3b^2)\boldsymbol{i}+(a^3b^1-a^1b^3)\boldsymbol{j}+(a^1b^2-a^2b^1)\boldsymbol{k}. \tag{1.1.6}$$

The vector product is also denoted by $[\boldsymbol{a},\boldsymbol{b}]$ or $[\boldsymbol{a}\,\boldsymbol{b}]$.

Proposition 1.1.1. The vector product defined by Eq. (1.1.5) has the following properties:
(i) the vector product is anticommutative,

$$\boldsymbol{a}\times\boldsymbol{b}=-\boldsymbol{b}\times\boldsymbol{a};$$

(ii) the magnitude of the vector $\boldsymbol{a}\times\boldsymbol{b}$ is equal to the area of the parallelogram with the sides $\boldsymbol{a}$ and $\boldsymbol{b}$, i.e.

$$|\boldsymbol{a}\times\boldsymbol{b}|=|\boldsymbol{a}||\boldsymbol{b}|\sin\theta,$$

where $\theta(0\le\theta\le\pi)$ is the angle between the vectors $\boldsymbol{a}$ and $\boldsymbol{b}$;
(iii) the vector $\boldsymbol{a}\times\boldsymbol{b}$ is orthogonal to the plane spanned by $\boldsymbol{a}$ and $\boldsymbol{b}$ and is such that the triplet $\boldsymbol{a}$, $\boldsymbol{b}$ and $\boldsymbol{a}\times\boldsymbol{b}$ forms a right-handed system.

Given three vectors $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c}\in\mathbb{R}^3$, one can produce the *mixed product*

$$\boldsymbol{a}\cdot(\boldsymbol{b}\times\boldsymbol{c})$$

called also the *scalar triple product*. Geometrically, the mixed product is equal to the volume of the parallelepiped having $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c}$ as its edges, provided that the triplet $\boldsymbol{a},\boldsymbol{b},\boldsymbol{c}$ forms a right-handed system. For the vectors written in the rectangular Cartesian coordinates in the form (1.1.2), the mixed product is given by

$$\boldsymbol{a}\cdot(\boldsymbol{b}\times\boldsymbol{c})=\begin{vmatrix}a^1 & a^2 & a^3\\ b^1 & b^2 & b^3\\ c^1 & c^2 & c^3\end{vmatrix}. \tag{1.1.7}$$

One can consider also the *vector triple product* $\boldsymbol{a}\times(\boldsymbol{b}\times\boldsymbol{c})$. It can be computed by the equation

$$\boldsymbol{a}\times(\boldsymbol{b}\times\boldsymbol{c})=(\boldsymbol{a}\cdot\boldsymbol{c})\boldsymbol{b}-(\boldsymbol{a}\cdot\boldsymbol{b})\boldsymbol{c}. \tag{1.1.8}$$

1.1.1.2 Differential calculus of vectors

Here we consider vector fields. The calculations are given in the rectangular Cartesian reference frame. In particular, the independent variables are the coordinates x, y, z of the position vector $\boldsymbol{x} = (x, y, z)$.

A *vector field* $\boldsymbol{a} = (a^1, a^2, a^3)$ is a vector function

$$\boldsymbol{a} = \boldsymbol{a}(x, y, z)$$

depending upon the position vector $\boldsymbol{x} = (x, y, z)$.

Hamilton's operator ∇ is a vector given in the rectangular Cartesian coordinates (x, y, z) by

$$\nabla = \boldsymbol{i}\,\frac{\partial}{\partial x} + \boldsymbol{j}\,\frac{\partial}{\partial y} + \boldsymbol{k}\,\frac{\partial}{\partial z}, \tag{1.1.9}$$

where $\boldsymbol{i}$, $\boldsymbol{j}$ and $\boldsymbol{k}$ are unit vectors along the x, y and z axes, respectively. In other words, Hamilton's operator is the vector $\nabla = (\nabla_x, \nabla_y, \nabla_z)$ with the components

$$\nabla_x = \frac{\partial}{\partial x}, \quad \nabla_y = \frac{\partial}{\partial y}, \quad \nabla_z = \frac{\partial}{\partial z}.$$

The familiar operations of gradient, divergence and curl are written via Hamilton's operator as follows.

The *gradient* of a scalar field $\phi = \phi(x, y, z)$ is the vector field

$$\operatorname{grad}\phi = \nabla\phi \equiv \frac{\partial\phi}{\partial x}\,\boldsymbol{i} + \frac{\partial\phi}{\partial y}\,\boldsymbol{j} + \frac{\partial\phi}{\partial z}\,\boldsymbol{k}. \tag{1.1.10}$$

The *divergence* of a vector field $\boldsymbol{a}$ is the scalar product of the vectors ∇ and $\boldsymbol{a} = (a^1, a^2, a^3)$:

$$\operatorname{div}\boldsymbol{a} \overset{\text{def}}{=} \nabla\cdot\boldsymbol{a} = \nabla_x a^1 + \nabla_y a^2 + \nabla_z a^3 \equiv \frac{\partial a^1}{\partial x} + \frac{\partial a^2}{\partial y} + \frac{\partial a^3}{\partial z}. \tag{1.1.11}$$

The *curl* or *rotation* of a vector field $\boldsymbol{a} = \boldsymbol{a}(x, y, z)$ is the vector product of the vectors ∇ and $\boldsymbol{a}$:

$$\operatorname{curl}\boldsymbol{a} \equiv \operatorname{rot}\boldsymbol{a} \overset{\text{def}}{=} \nabla\times\boldsymbol{a} = \begin{vmatrix} \boldsymbol{i} & \boldsymbol{j} & \boldsymbol{k} \\ \dfrac{\partial}{\partial x} & \dfrac{\partial}{\partial y} & \dfrac{\partial}{\partial z} \\ a^1 & a^2 & a^3 \end{vmatrix} \tag{1.1.12}$$

or (see also Eq. (8.2.23))

$$\nabla\times\boldsymbol{a} = \left(\frac{\partial a^3}{\partial y} - \frac{\partial a^2}{\partial z}\right)\boldsymbol{i} + \left(\frac{\partial a^1}{\partial z} - \frac{\partial a^3}{\partial x}\right)\boldsymbol{j} + \left(\frac{\partial a^2}{\partial x} - \frac{\partial a^1}{\partial y}\right)\boldsymbol{k}. \tag{1.1.13}$$

Let $\boldsymbol{a}$, $\boldsymbol{b}$ and ϕ, ψ be vector and scalar fields, respectively, and let α, β be arbitrary constants. The operator ∇ together with formulae of *vector algebra* enables one to relate scalar and vector fields through differentiation and to obtain the following equations:

$$\begin{aligned}
&1.\quad \nabla(\alpha\phi + \beta\psi) = \alpha\nabla\phi + \beta\nabla\psi,\\
&2.\quad \nabla\cdot(\alpha\boldsymbol{a} + \beta\boldsymbol{b}) = \alpha\nabla\cdot\boldsymbol{a} + \beta\nabla\cdot\boldsymbol{b},\\
&3.\quad \nabla\times(\alpha\boldsymbol{a} + \beta\boldsymbol{b}) = \alpha\nabla\times\boldsymbol{a} + \beta\nabla\times\boldsymbol{b},\\
&4.\quad \nabla(\phi\psi) = \psi\nabla\phi + \phi\nabla\psi,\\
&5.\quad \nabla\cdot(\phi\boldsymbol{a}) = (\nabla\phi)\cdot\boldsymbol{a} + \phi(\nabla\cdot\boldsymbol{a}),\\
&6.\quad \nabla\times(\phi\boldsymbol{a}) = (\nabla\phi)\times\boldsymbol{a} + \phi\nabla\times\boldsymbol{a},\\
&7.\quad \nabla\cdot(\boldsymbol{a}\times\boldsymbol{b}) = \boldsymbol{b}\cdot(\nabla\times\boldsymbol{a}) - \boldsymbol{a}\cdot(\nabla\times\boldsymbol{b}),\\
&8.\quad \nabla\cdot(\nabla\phi) \equiv \nabla^2\phi \equiv \Delta\phi = \frac{\partial^2\phi}{\partial x^2} + \frac{\partial^2\phi}{\partial y^2} + \frac{\partial^2\phi}{\partial z^2},\\
&9.\quad \nabla\cdot(\nabla\times\boldsymbol{a}) = 0,\\
&10.\ \nabla\times(\nabla\phi) = 0,\\
&11.\ \nabla\times(\nabla\times\boldsymbol{a}) = \nabla(\nabla\cdot\boldsymbol{a}) - \nabla^2\boldsymbol{a}.
\end{aligned} \tag{1.1.14}$$

Note that the 11th equation of (1.1.14) follows from Eq. (1.1.8).

Equations (1.1.14) are often written in the notation (1.1.10)–(1.1.11). For example, the equations 5, 9, 10 and 11 are written:

$$\begin{aligned}
&5'.\quad \operatorname{div}(\phi\,\boldsymbol{a}) = \phi\operatorname{div}\boldsymbol{a} + \boldsymbol{a}\cdot\operatorname{grad}\phi,\\
&9'.\quad \operatorname{div}\operatorname{rot}\boldsymbol{a} = 0,\\
&10'.\ \operatorname{rot}\operatorname{grad}\phi = 0,\\
&11'.\ \operatorname{rot}\operatorname{rot}\boldsymbol{a} = \operatorname{grad}(\operatorname{div}\boldsymbol{a}) - \Delta\,\boldsymbol{a},
\end{aligned}$$

where

$$\Delta \equiv \nabla^2 = \frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} + \frac{\partial^2}{\partial z^2}$$

is the *Laplacian.*

1.1.1.3 Integral calculus of vectors

Green's theorem: Let V be an arbitrary region in the (x, y) plane with the boundary ∂V. Then

$$\int_{\partial V} Pdx + Qdy = \int_V \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right) dxdy \tag{1.1.15}$$

Brought to you by | Stockholms Universitet
Authenticated
Download Date | 10/31/15 1:40 AM

for any (differentiable) functions $P(x,y)$ and $Q(x,y)$.

Stokes' theorem: Let V be an (orientable) surface in the space (x,y,z) with the boundary ∂V, and let $P(x,y,z), Q(x,y,z)$ and $R(x,y,z)$ be any (differentiable) functions. Then

$$\begin{aligned}\int_{\partial V} Pdx + Qdy + Rdz = \int_V \left(\frac{\partial Q}{\partial x} - \frac{\partial P}{\partial y}\right) dx\,dy + \left(\frac{\partial R}{\partial y} - \frac{\partial Q}{\partial z}\right) dy\,dz \\ + \left(\frac{\partial P}{\partial z} - \frac{\partial R}{\partial x}\right) dz\,dx.\end{aligned} \tag{1.1.16}$$

Equation (1.1.16) is written in the vector notation as follows:

$$\int_{\partial V} \boldsymbol{A} \cdot d\boldsymbol{x} = \int_V \operatorname{curl} \boldsymbol{A} \cdot \boldsymbol{dS}.$$

Here $\boldsymbol{A} = (P,Q,R)$, $d\boldsymbol{x} = (dx,dy,dz)$ and $\boldsymbol{dS} = \boldsymbol{\nu} dS$, where $\boldsymbol{\nu}$ is the unit outward normal to the surface V.

The divergence theorem (the Gauss-Ostrogradsky theorem): Let V be a volume in the space (x,y,z) with the closed boundary ∂V and $\boldsymbol{A}$ be any vector field. Then

$$\int_{\partial V} (\boldsymbol{A} \cdot \boldsymbol{\nu})\,dS = \int_V (\nabla \cdot \boldsymbol{A})\,dx\,dy\,dz \equiv \int_V \operatorname{div} \boldsymbol{A}\,dx\,dy\,dz, \tag{1.1.17}$$

where $\boldsymbol{\nu}$ is the unit outward normal to the boundary ∂V of V.

1.1.2 General case

In what follows, we denote by $\mathbb{R}^n$ a real n-dimensional vector (linear) space. Its elements are n-dimensional vectors $x = (x^1, \ldots, x^n)$, where x^i denote the Cartesian coordinates of a point $x = (x^1, \ldots, x^n) \in \mathbb{R}^n$ referred to rectangular axes. Thus, the *scalar product* of vectors $x = (x^1, \ldots, x^n)$ and $y = (y^1, \ldots, y^n) \in \mathbb{R}^n$ are defined by the formula similar to (1.1.4):

$$x \cdot y = \sum_{i=1}^{n} x^i y^i. \tag{1.1.18}$$

The length of a vector $x = (x^1, \ldots, x^n)$ is

$$|x| = \sqrt{x \cdot x} \equiv \sqrt{\sum_{i=1}^{n} (x^i)^2}\,. \tag{1.1.19}$$

05.10.2019

is the angle between the vector a and b. The scalar product is denoted in the literature by (a, b).

The vectors $a, b \in \mathbb{R}^3$ can be represented in the rectangular Cartesian coordinates in the form

$a=(a^1, a^2, a^3), \quad b=(b^1, b^2, b^3),$

which means that

$a = a^1 i + a^2 j + a^3 k.$

$(a^1 i)$

$b = b^1 i + b^2 j + b^3 k.$

where i, j and k are the unit vectors along the first, second and third coordinate axes in $\mathbb{R}^3$, respectively.

Then the scalar product is given by

$$a.b = \sum_{i=1}^{3} a^i b^i.$$

~~1(95)~~ j) Brans-Dicke theory

Source: https://en.wikipedia.org/wiki/Brans-Dicke_theory

05.10.2019 X

In theoretical physics the Brans-Dicke theory of gravitation (Jordan-Brans-Dicke theory) is a theoretical framework to explain gravitation.

It is a competitor of Einstein's theory of general relativity.

It is an example of a scalar-tensor theory, a gravitational theory in which the gravitational interaction is mediated by a scalar field as well as the tensor field of general relativity.

\end{aligned}
$$

Chapter 1

Trigonometric Identity

1.1. Trigonometric Ratios for Any Angle

Any angle and its measures

1. Positive angle, negative angle and zero angle

If a ray rotating around the endpoint counterclockwise formed as the positive angle, its measurement is positive, and if a ray rotating around the endpoint clockwise formed as the positive angle, its measurement is negative (see Fig. 1.1):

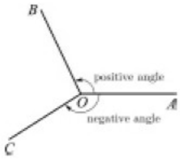

Fig. 1.1.

2. Coterminal angle

In the process of angle forming, we can find there are numerous angles whose initial and terminal sides coincide with a certain angle α. Their range is 360° integer times that of α in size. We put the set of the angles (including α itself) with the same edge as α:

$$\{\beta | \beta = k \cdot 360^\circ + \alpha,\ k \in Z\}.$$

Namely, any angle with the same terminal side as angle α can be expressed as a total of angle α and integer number of perigons.

3. Quadrant angle

If the terminal ray of an angle in standard position lies in the first quadrant, then the angle is said to be a first-quadrant angle. Similarly, second-, third-, and fourth-quadrant angles are defined as follows:

First-quadrant angles: $\{\alpha | k \cdot 360^\circ < \alpha < k \cdot 360^\circ + 90^\circ,\ \mathrm{k} \in Z\}$;

Second-quadrant angles:
$\{\alpha | k \cdot 360° + 90° < \alpha < k \cdot 360° + 180°, k \in Z\}$;
Third-quadrant angles:
$\{\alpha | k \cdot 360° + 180° < \alpha < k \cdot 360° + 270°, k \in Z\}$;
Fourth-quadrant angles:
$\{\alpha | k \cdot 360° + 270° < \alpha < k \cdot 360° + 360°, k \in Z\}$.

4. Quadrantal angle

If the terminal ray of an angle in standard position lies along an axis, the angle is called a quadrantal angle.

- If the terminal ray of the angle lies along positive y-axis, then $\theta = 360°k + 90°$, $k \in Z$.
- If the terminal ray of the angle lies along negative y-axis, then $\theta = 360°k - 90°$, $k \in Z$.
- If the terminal ray of the angle lies along y-axis, then $\{\theta | \theta = 180°k + 90°,\ k \in Z\}$.
- If the terminal ray of the angle lies along positive x-axis, then $\theta = 2 \times 180°k + 0°$, $k \in Z$.
- If the terminal ray of the angle lies along negative x-axis, then $\theta = 2 \times 180°\, k + 180°$, $k \in Z$.
- If the terminal ray of the angle lies along x-axis, then $\{\theta | \theta = 180°k,\ k \in Z\}$.

Exercise

1. Find angles between 0° with 360°, that are coterminal with each given angle, and judging in which quadrantal angle.

(1) $-120°$; (2) $640°$;(3) $-950°12'$.

Solution: (1) Since $-120° = -360° + 240°$, it follows that 240° is coterminal with $-120°$, which is the third-quadrant angle.

(2) Since $640° = 360° + 280°$, it follows that 280° is coterminal with 640°, which is the fourth-quadrant angle.

(3) Since $-950°\ 12' = -3 \times 360° + 129°48'$, it follows that $129°48'$ is coterminal with $-950°\ 12'$, which is the third-quadrant angle.

2. Give a set S for the measure of all angles that are coterminal with each given angle, find angles between $-360°$ and $720°$ in S.

(1) $60°$;(2) $-21°$; (3) $363°14'$.

Solution: (1) $S = \{\beta | \beta = 60° + k \cdot 360°, k \in Z\}$.

The angles between $-360°$ and $720°$ in S are as follows:

$$-1 \times 360^\circ + 60^\circ = -300^\circ;$$
$$0 \times 360^\circ + 60^\circ = 60^\circ;$$
$$1 \times 360^\circ + 60^\circ = 420^\circ.$$

(2) $S = \{\beta | \beta = -21^\circ + k \cdot 360^\circ, k \in Z\}$.

The angles between -360° and 720° in S are as follows:

$$0 \times 360^\circ - 21^\circ = -21^\circ;$$
$$1 \times 360^\circ - 21^\circ = 339^\circ;$$
$$2 \times 360^\circ - 21^\circ = 699^\circ.$$

(3) $S = \{\beta | \beta = 363^\circ\, 14' + k \cdot 360^\circ, k \in Z\}$.

The angles between -360° and 720° in S are as follows:

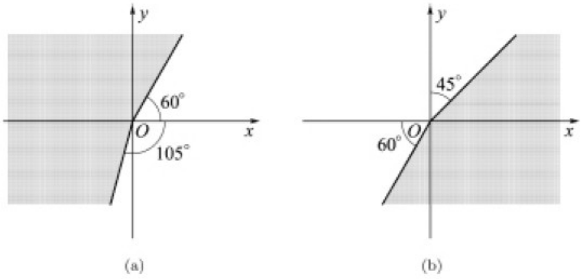
$$-2 \times 360^\circ + 363^\circ 14' = -356^\circ 46';$$
$$-1 \times 360^\circ + 363^\circ 14' = 3^\circ 14';$$
$$0 \times 360^\circ + 363^\circ 14' = 363^\circ 14'.$$

3. Find the set for the angle, which displays the terminal side of the angle in the set of angles in the shadow area (exclusive of boundaries). (See Fig. 1.2.)

Solution:.

(A) $\{\alpha | 60^\circ + k \cdot 360^\circ < a < 255^\circ + k \cdot 360^\circ, k \in Z\}$.

(B) $\{\alpha | - 120^\circ + k \cdot 360^\circ < \alpha < 45^\circ + k \bullet 360^\circ, k \in Z\}$.



(a) (b)

Fig. 1.2.

4. If α is a second-quadrant angle, how about $\frac{\alpha}{2}$? How about 2α?

Solution: If α is a second-quadrant angle, then
$k \cdot 360^\circ + 90^\circ < \alpha < k \cdot 360^\circ + 180^\circ, k \in Z.$

Hence $k \cdot 180^\circ + 45^\circ < \frac{\alpha}{2} < k \cdot 180^\circ + 90^\circ$, because $k \in Z$. Therefore $k = 2n$ or $k = 2n + 1$.

When $k = 2n$, $n \cdot 360^\circ + 45^\circ < \frac{\alpha}{2} < n \cdot 360^\circ + 90^\circ$, therefore $\frac{\alpha}{2}$ is a first-quadrant angle.

When $k = 2n+1$, $n \cdot 360^\circ + 225^\circ < \frac{\alpha}{2} < n \cdot 360^\circ + 270^\circ$, therefore $\frac{\alpha}{2}$ is a third-quadrant angle.

Hence when α is a second-quadrant angle, therefore $\frac{\alpha}{2}$ is a first-quadrant angle or third-quadrant angle. Similarly, $180°+k\cdot720° < 2a < 360°+k \cdot 720°$, $k \in Z$. Hence, when a is the second-quadrant angle, $2a$ is a third-quadrant angle or the fourth-quadrant angle.

Radian

(1) Radian: When an arc of a circle has the same length as the radius of the circle, as shown in Fig. 1.3, the measure of the central angle $\angle AOB$ is by definition 1 radian.

(2) Radian measure: The radian to measure angle.

(3) Equation for the radian measure of the central angle *α*: $|\alpha| = \frac{l}{r}$, where α is the subtended angle in radians, l the arc length, and r the radius.

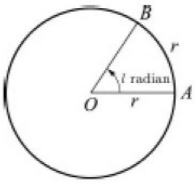


Fig. 1.3.

(4) Conversion formulas between degree measure and radian measure: One revolution measured in radians is 2π and measured in degrees is 360°. We therefore have the conversion formulas:

$$\begin{aligned} 360^{\circ} &= 2\pi \text{ radians} \\ 180^{\circ} &= \pi \text{ radians} \\ 1^{\circ} &= \frac{\pi}{180} \text{ radians} \approx 0.017 \text{ radians} \\ 1 \text{ radian} &= \left(\frac{180}{\pi}\right)^{\circ} \approx 57^{\circ}17'44.8'' \approx 57.3^{\circ}. \end{aligned}$$

Because the radian number is the ratio of the arc length to radius, so it is a real number. Therefore, in expressing the range of angle in radian measure, usually omit the word "radian". Due to different needs, the angle is not only measured in degree, but also in radian. For example, if we want to learn the trigonometric function, we need to draw its image, using the degree measure, which will cause inconvenience. Since the introduction of radian, the set of angles corresponds with the set of real numbers as shown in Fig. 1.4:

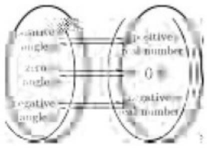

Fig. 1.4.

Degree	0°	15°	30°	45°	60°	75°	90°	105°	120°	135°	150°	180°	210°
Radian	0	$\frac{\pi}{12}$	$\frac{\pi}{6}$	$\frac{\pi}{4}$	$\frac{\pi}{3}$	$\frac{5\pi}{12}$	$\frac{\pi}{2}$	$\frac{7\pi}{12}$	$\frac{2\pi}{3}$	$\frac{3\pi}{4}$	$\frac{5\pi}{6}$	π	$\frac{7\pi}{6}$
Degree	225°	240°	270°	300°	315°	330°	360°						
Radian	$\frac{5\pi}{4}$	$\frac{4\pi}{3}$	$\frac{3\pi}{2}$	$\frac{5\pi}{3}$	$\frac{7\pi}{4}$	$\frac{11\pi}{6}$	2π						

(5) **Formulas for the arc length and area of a sector of a circle**: The following formulas are arc length and area of a sector of a circle, where α $(0 < \alpha < 2\pi)$ is the central angle of a sector, r the radius, l is the length, and S the area (see Fig. 1.5):

$$(1)\ l = \alpha r;$$

$$(2)\ S = \frac{1}{2}\alpha r^2;$$

$$(3)\ S = \frac{1}{2}lr.$$

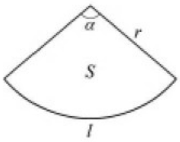

Fig. 1.5.

Exercise

5. The rope is twisted around the rim of 40-cm radius. The lower end B of the rope is hanging an object W (Fig. 1.6). If the wheel rotates counterclockwise by six laps every min, how many seconds does it take to lift objects upward 100 cm from position W?

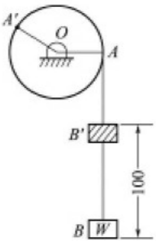

Fig. 1.6.

Solution: When the wheel is rotated in a clockwise direction, the arc length AA $'$ from A to A' is equal to the distance from B to B'. When $BB' = 100$ cm, then $AA' = 100$ cm time arc, and the center angle $\angle AOA'$ corresponding to arc AA' is given by $\frac{100}{40}$ radians.

Since the wheel rotates six times per minute at a uniform speed, the radian $\frac{6\times 2\pi}{60}$ per second is given by $\frac{\pi}{5}$ When T seconds have passed, the radian that passed is

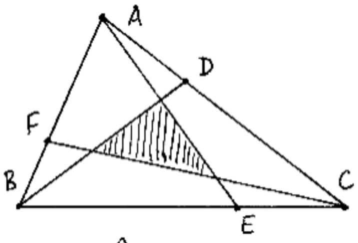
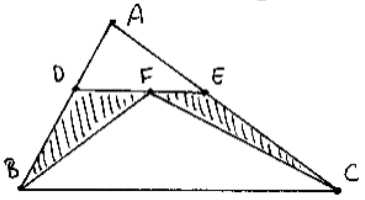
23.3 Let ABC be any triangle. Let D, E, F divide the sides in thirds. Draw AE, BD, CF. Show that the small triangle formed in the inside has area equal to $\frac{1}{7}$ the area of the whole triangle. *Hint*: Review the proof of Proposition 5.4 and use similar triangles.



23.4 Let ABC be any triangle, let DE be a line parallel to the base, and let F be any point on DE. Show that the area of the union of the two triangles DBF and ECF is less than or equal to one-fourth the area of the whole triangle, with equality if and only if D and E are the midpoints of AB and AC.



23.5 To get a feeling for ordered abelian groups, try this one. Let $\mathbb{Q}(\sqrt{2}) = \{a + b\sqrt{2} \mid a, b \in \mathbb{Q}\}$, and similarly $\mathbb{Q}(\sqrt{3})$.

(a) Show that $\mathbb{Q}(\sqrt{2})$ and $\mathbb{Q}(\sqrt{3})$ are isomorphic as abelian groups (under addition).

(b) Show that $\mathbb{Q}(\sqrt{2})$ and $\mathbb{Q}(\sqrt{3})$ are not isomorphic as fields.

(c) Show that $\mathbb{Q}(\sqrt{2})$ and $\mathbb{Q}(\sqrt{3})$ are isomorphic as ordered sets, with the orderings induced by the natural ordering on $\mathbb{R}$. (Here an *ordered set* is a set S, together with a relation $a < b$, having the two properties (i) $a < b$ and $b < c$ implies $a < c$; (ii) if $a, b \in S$, then one and only one of the following holds: $a < b$, $a = b$, $b < a$.)

(d) $\mathbb{Q}(\sqrt{2})$ and $\mathbb{Q}(\sqrt{3})$ are not isomorphic as ordered abelian groups (again taking addition as the group operation).

23.6 Prove Ptolemy's theorem: The rectangle formed of the two diagonals of a cyclic quadrilateral is equal in content to the sum of the two rectangles made by opposite sides of the quadrilateral.

23.7 In a Euclidean plane, show that the results (VI.1) and (VI.14)–(VI.31) hold using equal content for equality of figures.

24 Dissection

As we have seen in the previous sections, Euclid bases his theory of area on adding and subtracting congruent figures. This notion is formalized by Hilbert's definition of equal content (Section 22), which can also be interpreted using a measure of area function (Section 23). While the notion of content gives a good general theory, one could complain that it is not practical, in the sense that if two figures have equal content, one does not know how much must be added in order to make them equidecomposable. In Example 22.1.3, the two figures being compared both have area 1, but to make them equidecomposable, one must add a triangle whose area is infinite in the non-Archimedean field *F*.

In this section we will investigate the stricter notion of when two figures are equidecomposable (Section 22). This leads to the practical problem of *dissection*: given two figures, to find, if possible, an efficient decomposition of the first as a nonoverlapping union of smaller figures, not necessarily triangles, that can be reassembled into the second. A dissection exists if and only if the two figures are equidecomposable. In this case we will also say that one figure can be dissected into the other, or that they are *equivalent by dissection*.

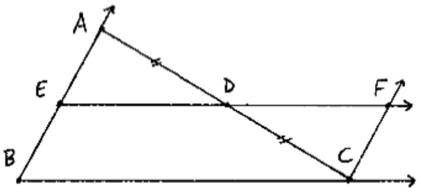
We work in a Hilbert plane with (P), and in some cases use also (A) or (E). We will see that certain of the results, such as the Pythagorean theorem (I.47), which Euclid proved for content, are also true in the stronger sense of dissection. We will prove the theorem, due to Bolyai and Gerwien, that in an Archimedean plane, any two figures of equal area (Section 23) are equivalent by dissection.

The practical problem of finding dissections of one figure into another has received a certain amount of attention among recreational mathematicians, but at this point it seems to be more of an art than a science. Amateurs have discovered a number of clever dissections, but proofs that certain dissections are minimal, or effective bounds on the number of pieces required, seem to be lacking.

We begin this section with some general results on existence of dissections.

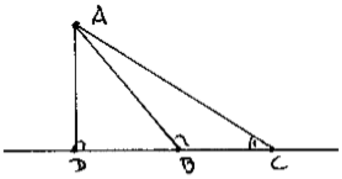
Proposition 24.1
In a Hilbert plane with (P), *any triangle can be dissected into a parallelogram.*

Proof (cf. 22.6) Let *ABC* be the triangle. Let *D* be the midpoint of *AC*. Draw lines through *D* parallel to *BC* and through *C* parallel to *AB*, meeting at *F*. Then $\Delta ADE \cong \Delta CDF$ by (ASA). So ΔABC can be dissected into the parallelogram *BCEF*.



Lemma 24.2
Let ABC be a triangle, and suppose that the foot D of the altitude from A to side BC lands outside the interval BC. Then one of the angles of the triangle, at B or C, is obtuse.

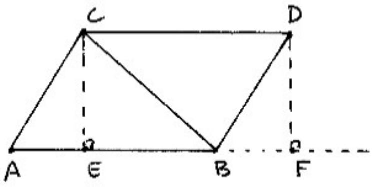
Proof Suppose *B* is between *D* and *C*. Then the angle $\angle ABC$ is an exterior angle of the right triangle *ADB*, so $\angle ABC$ is greater than a right angle, by (I.16).



Proposition 24.3

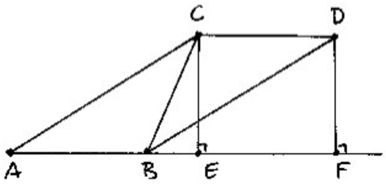
Any parallelogram can be dissected into a rectangle.

Proof Let $ABCD$ be the given parallelogram. Drop the altitudes from C and D to the side AB, with feet E, F. Suppose, for example, that E is inside the interval AB. Then the triangle ΔACE is congruent to the triangle BDF. So the parallelogram is dissected into the rectangle $CDEF$.



Now let us see that we can always apply this construction. In any parallelogram, the opposite angles are equal (I.34) and the sum of the angles is four right angles, so two of the opposite angles are acute. (If not, all four are right angles and there is noting to prove.) So we may assume that the angle at A is acute.

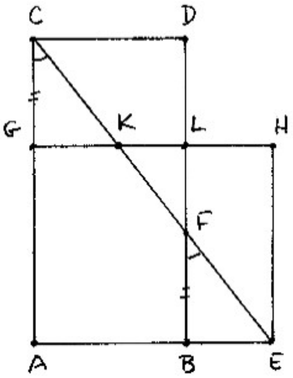
Now, if the altitude from C lands outside AB, then by (24.2) the angle ABC must be obtuse. This forces the angle ACB to be acute (I.32), and in that case, exchanging the roles of B and C, the altitude from B to AC will land inside the segment AC (24.2), so we can apply the construction above.



Proposition 24.4

Given a rectangle $ABCD$, and given a segment AE such that $AB < AE < 2AB$, the rectangle $ABCD$ can be dissected into a rectangle having one side equal to AE.

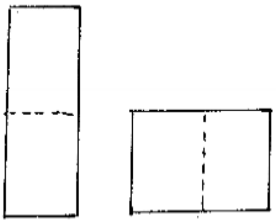
Proof Suppose we are given the rectangle $ABCD$ and the point E. Let C and E be joined, meeting BD at F. Let G be chosen on AC such that $CG \cong BF$. Construct the rectangle $AEGH$, and let K, L be as shown. Because of parallel lines, the angles at C and F are equal. And CG was equal to BF by construction, so by (ASA), $\Delta CGK \cong \Delta FBE$. It follows that $GK \cong BE$, and so by subtraction, $CD \cong AB \cong KH$. Now by (ASA) again, $\Delta CDF \cong \Delta KHE$. This gives a dissection of the rectangle $ABCD$ into the rectangle $AEGH$, as required.



Note that in order for this dissection to work, we need to know that F is below the midpoint of BD, so that G is above the midpoint of AC, and so F is below L. This follows from the hypothesis $AB < AE < 2AB$, because the line from C to the midpoint of BD would meet the line AB at a point M with $AM = 2AB$.

Proposition 24.5
Assume Archimedes' axiom (A). *Given any rectangle ABCD and given any segment EF, there is a rectangle EFGH equivalent by dissection to ABCD.*

Proof Given any rectangle, by cutting it in half and reassembling the two halves along the other sides, we can dissect the original rectangle into a new rectangle with one-half the height and twice the base of the original one. Now by Archimedes' axiom, after doubling or halving AB a finite number of times, we may assume $AB \leq EF < 2AB$. Then we apply (24.4) to get a rectangle $EFGH$ as required.



Corollary 24.6
Assuming (A) *and given a segment EF, any rectilineal figure* (*Section* 22) *can be dissected into a rectangle with one side EF.*

Proof Divide the figure P into a finite number of triangles $T_1, T_2, \ldots, T_n$. For each i first dissect the triangle T_i into a parallelogram (24.1), then to a rectangle (24.3), then to a rectangle R_i with base equal to EF (24.5). Now stacking the rectangles $R_1, R_2, \ldots, R_n$, all of which have base equal to EF, on top of each other, we obtain one big rectangle with base EF, as required.

Theorem 24.7 (Bolyai, Gerwien)
In a Hilbert plane with (P) *and* (A), *let* α *be the area function of* (23.2). *Then two figures P and Q are equivalent by dissection if and only if they have the same area.*

Proof One direction follows from (23.1). The new part, which requires the use of Archimedes' axiom, is that figures of equal area are equivalent by dissection. The proof parallels (23.7), where the analogous result was proved for content.

So suppose figures P and Q have equal area: $\alpha(P) = \alpha(Q)$. By (24.6), they can each be dissected into rectangles with sides $1, a$ and $1, b$. Then $\alpha(P) = a$, $\alpha(Q) = b$, so $a = b$, and the rectangles are equal. Thus by transitivity of equidecomposability (22.2), P can be dissected into Q.

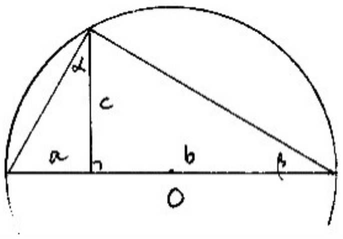
Remark 24.7.1
This result is false without (A), as is shown by Example 22.1.3.

Remark 24.7.2
This proof is effective, since given figures P and Q of equal area, and given a decomposition of each into triangles, the method of proof of the results of this section will lead to a dissection of one to the other. Of course, the dissection found in this way may not be efficient in terms of the number of pieces required.

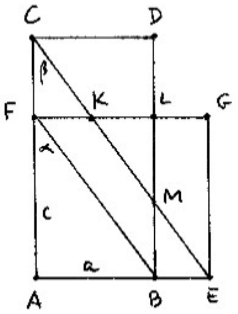
Remark 24.7.3
Combining this result with (23.7) we see that in a Hilbert plane with (P) and (A), two figures have equal content if and only if they are equidecomposable (cf. 22.1.4).

Proposition 24.8
Assume (E). *Let* $ABCD$ *be a rectangle with sides* $a = AB$ *and* $b = AC$ *satisfying* $a \leq b \leq 4a$. *Then there is a segment* $c = AE$ *such that the rectangle* $ABCD$ *can be dissected into a square with side* AE.

Proof Form a segment of length $a + b$, let O be its midpoint, draw a circle with center O passing through the segment's endpoints, and let c be the segment cut off on a perpendicular dividing the segment into $a + b$, from the segment to where it meets the circle. (Here we use (E) for the existence of the intersection point.)



Now let $ABCD$ be the given rectangle, let AE be congruent to the segment c, and let $AEFG$ be the square on side AE. Since the angle in a semicircle is a right angle (III.31), the angles α, β in the circle diagram are equal. These are the same as the angles α, β of the second diagram, by congruent triangles (SAS). Hence the two diagonal lines FB and CE are parallel (I.28). It follows that $CF \cong MB$ and $FK \cong BE$ (I.33). From here the same argument as in the proof of (24.4) shows that $ABCD$ can be dissected into the square $AEFG$.



In order for this construction to work, we need to know that $AB \leq AE < 2AB$. We assumed that $a \leq b$, so the angle $\alpha = \beta$ is less than one-half a right angle, and so $a \leq c \leq b$. On the other hand, if $c \geq 2a$, then by similar triangles it follows that $b \geq 2c$. This implies $b \geq 4a$, contrary to our hypothesis.

Corollary 24.9
In a Euclidean plane with (A), *any rectilineal figure can be dissected into a square.*

Proof Choose a segment AB. By (24.6) the original figure can be dissected into a rectangle $ABCD$ with side AB. Cutting the rectangle in half and reassembling a finite number of times (again using (A)), as in the proof of (24.5), we may assume that the sides $a = AB$ and $b = AC$ satisfy $a \leq b \leq 4a$. Then by (24.8) this rectangle can be dissected into a square.

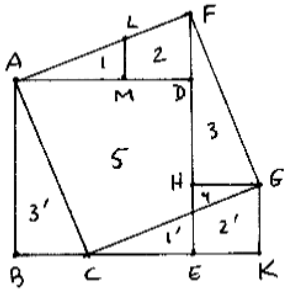
Next, let us look at the Pythagorean theorem (I.47). Euclid's proof shows that the union of the squares on the legs of the right triangle has equal *content* to the square on the hypotenuse. Using Archimedes' axiom (A) one can improve Euclid's results about parallelograms (I.35) and triangles (I.37) to hold also for dissection. Then Euclid's proof will show that (I.47) holds for dissection assuming (A). However, even better than this are several direct proofs of (I.47) by dissection that do not need Archimedes' axiom.

Let us first consider the proof attributed to Thabit b. Qurra (826–901 A.D.).

Proposition 24.10 (I.47)
In a Hilbert plane with (P), *the union of the squares on the legs of a right triangle can be dissected into the square on the hypotenuse.*

Proof Let ABC be the original triangle; let $ABDE$ be the square on AB; let $ACFG$ be the square on AC; fill in the square $GHEK$ and the line LM so that $DM \cong BC$. Then the three triangles ADF, FHG, CKG are congruent to the original triangle ABC, and $GHEK$ is congruent to the square on BC.

Now the square on the hypotenuse is dissected into the five pieces $1, 2, 3, 4, 5$. The first three are congruent to $1', 2', 3'$ by construction. The square on AB is dissected into $1', 3', 5$, while the square on BC is dissected into $2', 4$. So the result is proved.

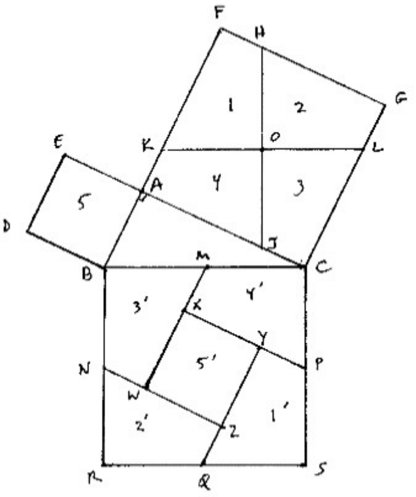


Remark 24.10.1
Here is another proof of (I.47) by dissection. Let ABC be the original right triangle. Draw the squares on the three sides as shown. Let O be the center of the square $ACFG$, and draw lines through O parallel to the sides of the square $BCRS$.

Now let M, N, P, Q be the midpoints of the sides of the square $BCRS$, and draw lines through them parallel to AB and AC, to form the figure shown.

We claim that $1', 2', 3', 4', 5'$ are respectively congruent to $1, 2, 3, 4, 5$, which will complete the proof by dissection.

Since O is the center of the square $ACFG$, it follows that O is also the midpoint of the segments KL and HJ. These two segments are also equal to each other, and from the parallelogram $BCKL$, they are equal to BC. Thus OK, OL, OH, OJ are all equal to one-half of BC; hence are congruent to the segments BM, MC, DP, PS, etc. Since the lines drawn in the big square are parallel to the sides of the square $ACFG$, it follows that $1, 2, 3, 4$ are congruent to $1', 2', 3', 4'$.



It remains to show that $5 \cong 5'$. Note that $MW \cong LC$, since they are corresponding sides of 3 and $3'$. From the parallelogram $BCKL$ we see that $LC \cong BK$. But also $BK \cong MX$. So by subtraction $XW \cong AB$. The figure is symmetrical, so one can also show that $AJ \cong LC$ and $JC \cong KA$; then a similar argument shows that $XY \cong AB$. Thus $5'$ is a square congruent to 5.

Note that a proof by dissection requires

(1) a diagram to show the pieces and how they correspond,
(2) a careful construction stating how and in what order the diagram was drawn, and
(3) a proof, based on the construction (2), showing that corresponding pieces are congruent.

There may be many ways of making the construction, and it is worth contemplating which will make the proof easier.

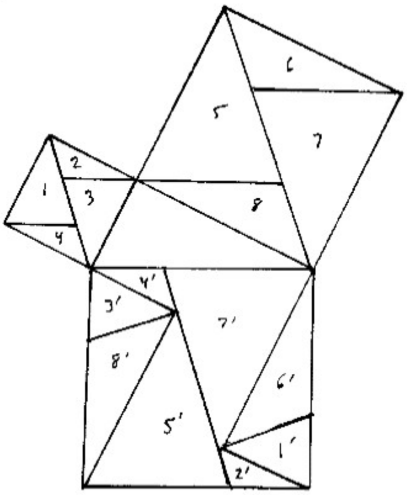
Exercises

The following exercises take place in a Hilbert plane with (P). Assume that it is a Euclidean plane, or the Cartesian plane over a field, as needed.

24.1 Using Archimedes' axiom (A) give a direct proof of (I.37) by dissection.

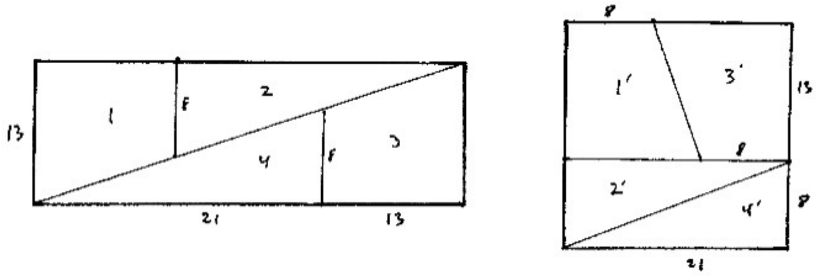
24.2 Dissect a square into three equal smaller squares.

24.3 Use the accompanying diagram to provide another proof of the Pythagorean theorem (I.47) by dissection. You must supply a construction of the diagram, and then a proof based on your construction, that corresponding pieces are congruent.

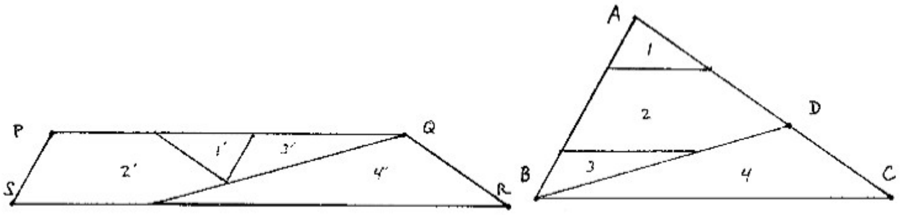


24.4 Find a dissection of an equilateral triangle into a square. After writing your construction and proof, make a model with construction paper and numbered pieces to illustrate your dissection.

24.5 Prove or disprove the existence of a dissection of a square of side 21 into a rectangle of sides 13, 34 according to the diagram below.

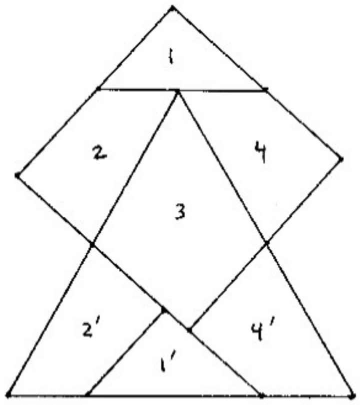


24.6 Let ABC be any triangle. Let D be a point on AC. Prove that there is a dissection of ABC into a trapezoid $PQRS$ as shown. What condition is necessary on the point D for this to work?



24.7 Use the previous exercise to find a dissection of two equilateral triangles of side 1 into a single equilateral triangle of side $\sqrt{2}$.

24.8 Prove the existence of Dudeney's (1929) dissection of an equilateral triangle into a square using four pieces, as suggested in the accompanying diagram.



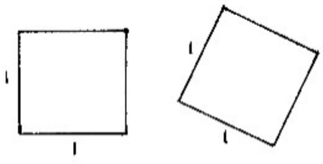
24.9 Dissect a regular pentagon into a square.

24.10 Prove or disprove: For any integer $n \geq 1$, the minimum number of triangles required to dissect a square of side 1 into a rectangle of sides n and $1/n$ is $2n$.

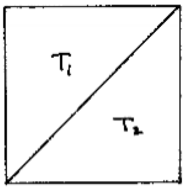
24.11 Dissect a square into eight strictly acute triangles (all angles less than 90°).

24.12 If a square is dissected into n triangles of equal area, then n must be an even number.

24.13 Consider a restricted form of dissection problem, where you can cut the figure in pieces and move the pieces around in the plane, *using translations only* (i.e., no rotations, and no turning pieces over). Show that you can dissect the unit square, with translations only, into the unit square with any other given orientation.



24.14 Divide the unit square by its diagonal into two (congruent) triangles T_1, T_2. Show that it is impossible to dissect T_1 into T_2 using translations only.



24.15 If P and P' are any two figures with the same area, then assuming Archimedes' axiom, show that it is possible to dissect P into P' using translations and 180° rotations only.

24.16 Let T be a triangle whose smallest angle is greater than or equal to 45°. Then T can be dissected into a square using 5 or fewer pieces.

24.17 Let T be a triangle having an angle α with $\tan\alpha < 1/a$ for some $a \in F$, $a > 1$. Then any dissection of T into a square requires $\geq \frac{1}{2}\sqrt{a}$ pieces. In particular, there exist triangles requiring arbitrarily many pieces to dissect into a square.

24.18 Let T be a triangle whose smallest angle α satisfies $\tan\alpha > 1/a$, for some $a \in F$, $a \geq 1$. Then T can be dissected into a square using no more than $3\sqrt{a} + 4$ pieces.

25 Quadratura Circuli

No discussion of area would be complete without mention of the classical problem of squaring the circle. Through the ages this problem has had an influence way beyond the confines of mathematics as an archetype of the insoluble problem. In one of his religious meditations, John Donne (early seventeenth century) mentions squaring the circle as something only God can achieve. Perhaps the expression "to put a round peg in a square hole" is a modern vestige of this old problem. And yet what a natural problem it is! The circle is the perfect round form, while the square is complete with its four equal sides and equal angles. What could be more natural than to transform the one into the other? But the solution has been as elusive as the alchemist's search for a way to transform lead into gold.

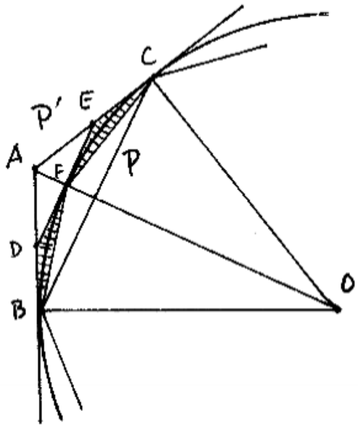
The problem is to construct a square with area equal to a given circle. What does this mean, exactly? By "construction," of course, is meant a geometrical construction with ruler and compass. But what is the area of a circle? In the theory of area presented so far, which corresponds to Euclid's usage in Books I–VI of the *Elements*, we have discussed the area of rectilineal figures only. So there is another problem implicit in the problem of squaring the circle, namely to give a good definition of the area of a circle. In the language of Section 23, we might ask for a measure of area function defined on all plane regions that can be bounded by straight line segments and arcs of circles. A modern approach to this (in the real Cartesian plane) is to use a definite integral to define the area.

Euclid never defines the area of a circle, and wisely avoids the problem of squaring the circle, but in Book XII, he does have a proposition saying that the ratio of the area of one circle to another is equal to the ratio of the squares of their radii. His proof makes use of the "method of exhaustion," which we would call a limiting process. The key result, which is remarkably similar to the treatment of the Riemann integral in modern calculus classes, is this.

Proposition 25.1
In a Euclidean plane with (A), *given a circle* Γ, *one can find an inscribed polygon* P *and a circumscribed polygon* P' *such that the difference in area* $\alpha(P') - \alpha(P)$ *is less than any preassigned quantity* (*as an element of the field* F *of segment arithmetic*).

Proof Start with any inscribed polygon P and any circumscribed polygon P', where the vertices of P are the points of tangency of P'. If we double the number of sides of P and P' by bisecting all the central angles of P, then we get new polygons P_1 and P_1'. We compare the difference of P_1 and P_1' to the difference of P and P'. Let us look at the triangle ABC, which is one piece of $P' - P$. The new difference $P_1' - P_1$ intersected with ABC is represented by the shaded area.

Euclid shows that the shaded area is less than one-half of the area of the triangle ABC. In fact, its area is less than or equal to $\frac{1}{4}$ of the area of that triangle (Exercise 23.4). So every time we double the number of sides, the new difference in areas of outside and inside polygons is less than half of the previous difference. Hence, using Archimedes' axiom (A), it can be made less than any preassigned quantity.



Approximating the circle by its inscribed and circumscribed polygons, Euclid could show that the ratio of the area of a circle to the square of its radius was a constant independent of the size of the circle. This constant, of course, is what we now call π. Archimedes, who lived shortly after Euclid, used the method of approximating by polygons to obtain the estimate $3\frac{10}{71} < \pi < 3\frac{1}{7}$, or in fractions, $\frac{223}{71} < \pi < \frac{22}{7}$. Thus began one facet of the work inspired by the problem of squaring the circle, namely to find increasingly accurate numerical approximations for π. Energetic human calculators worked hard on this problem, so that by

1600, the value of π was known to 15 decimal places, by 1700 to 71 places, and by 1873 to more than 500 places. Even today, the urge to compute is still strong, and with the help of electronic calculators, the value of π has been found to more than one billion decimal places.

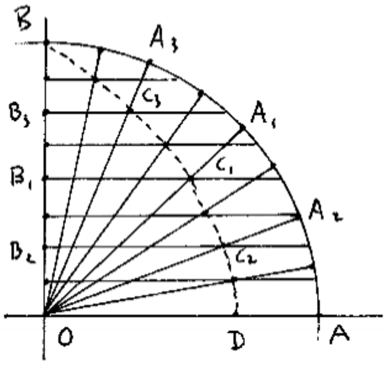
Coming back to the original problem of squaring the circle, it has always been regarded as very difficult, if not impossible. Since Lindemann proved in the 1880s that π is transcendental we have known that the problem as originally stated is mathematically impossible (cf. 13.2). Nevertheless, the problem has exerted a great fascination on the inquiring mind, and over the years, many people have come forward with solutions. The study of these solutions forms a colorful chapter in the history of mathematics.

The solutions can be divided into three general categories.

I. Honest ruler and compass constructions that, however, give only an approximate solution to the problem. One of the best of these depends on the coincidental proximity of the number $\frac{1}{5}(3\sqrt{5}+9) = 3.14164\ldots$ to π.

II. Constructions using additional tools that give an exact solution to the problem. One such known from antiquity uses an auxiliary curve, the *quadratrix*.

Take a quadrant AOB of the unit circle. Let OA_1 bisect the right angle, and let B_1 bisect the interval OB. Let the radius OA_1 meet the horizontal line through B_1 at C_1. Bisect the two 45° angles at O with OA_2 and OA_3, and bisect the intervals OB_1 and B_1B with B_2, B_3. Let the radii meet the corresponding horizontal lines in C_2 and C_3. Continuing in this manner, bisecting angles and segments, one can construct as many points as one likes $C_1, C_2, C_3, \ldots$. The curve passing through these points is called the quadratrix.



With a little help from modern trigonometry we can express the curve parametrically as

$$\begin{cases} x = \dfrac{2\theta}{\pi \tan \theta}, \\ y = \dfrac{2\theta}{\pi}, \end{cases}$$

where θ is the angle of the radius to the x-axis. As θ tends to 0 we obtain the point D where the curve meets the x-axis. Its x-coordinate is $2/\pi$ (Exercise 25.1). So clearly, if we are given a copy of the quadratrix curve, we can obtain the quantity π, and hence can construct a square with area equal to a given circle. Note, however, that this is not an honest ruler and compass construction:

Though we can obtain as many of the C_i as we like by ruler and compass, the point D is obtained only as a limit of the C_i as they approach the x-axis.

III. Solutions by people I would like to call fringe mathematicians, though they have been called by worse names, who have little mathematical training but are attracted to famous problems like the moth to the flame. The hint that a problem may be insoluble inspires them to work even harder, as they have a conviction that they will succeed where others have failed. Their solutions are a jumble of facts and fallacies lacking in logical coherence. Pointing out their errors and quoting the results of established mathematicians only confirms their belief that they have discovered the real truth that all the scholars were too blind to see. Sometimes their solutions come from divine inspiration, which leaves little room for discussion, since one cannot argue with God.

A case in point is Joseph Ignati Carl von Leistner, a knight in the service of Francis I (1708–1765), duke of Lorraine, and later Holy Roman emperor. Herr Leistner discovered that the exact value of π was 3844/1225. When his discovery did not occasion the acclaim he expected, he used his influence with the duke to appoint a imperial commission to report on his work. This commission naturally pointed out his errors, upon which he published a lengthy rebuttal attacking his critics and defending his work. Apparently, Herr Leistner believed that the true value of π would be a ratio of integers, but that no one had yet been clever enough to find the right ones, as he did. One of his arguments goes like this: "Archimedes proposed the values 22/7 and 223/71, but even he acknowledged that they were not correct, while mine is the correct value." Herr Leistner failed to notice that his value fell outside of the bounds proved by Archimedes. On the occasion of his lord's marriage to Maria Theresa of Austria in 1736, Herr Leistner published a treatise on the wonderful coincidence of the numbers 3844 and 1225 with various dates and other numbers from the life of the duke and his bride.

Exercises

25.1 (a) Derive the parametric equations for the quadratrix given in the text.

(b) Use a little first-year calculus to show that the point D has x-coordinate $2/\pi$.

25.2 (a) Let Γ be the circle of radius 1. Find the area of the inscribed polygons of 6, 12, 24, 48, 96, 192 sides, and express them in standard form (Exercise 13.2) as a rational number times an expression involving integers and square roots. Then verify that the area of the inscribed 192-gon is greater than 223/71, thus confirming Archimedes' estimate $223/71 < \pi$. (Check: To four decimals, area of inscribed 48-gon is 3.1326, 96-gon is 3.1394, 192-gon is 3.1410.)

(b) Show that the area of the circumscribed 96-gon is less than 22/7, confirming the inequality $\pi < 22/7$.

3. Let the incircle (with center I) of $\triangle ABC$ touch the side BC at X, and let A' be the midpoint of this side. Then the line $A'I$ (extended) bisects AX.

2.9 Morley's theorem

One of the most surprising theorems in elementary geometry was discovered about 1904 by Frank Morley (the father of Christopher Morley, whose novel, *Thunder on the Left*, has a kink in its time sequence that appeals particularly to geometers). He mentioned it to friends in Cambridge, England, and published it twenty years later in Japan. Meanwhile it was rediscovered and presented as a problem in the Educational Times. Two solutions were sent in, one of which, by M. T. Naraniengar,† is as neat as any of the dozens that have been devised since then. The theorem states:

THEOREM 2.91. *The points of intersection of the adjacent trisectors of the angles of any triangle are the vertices of an equilateral triangle.*

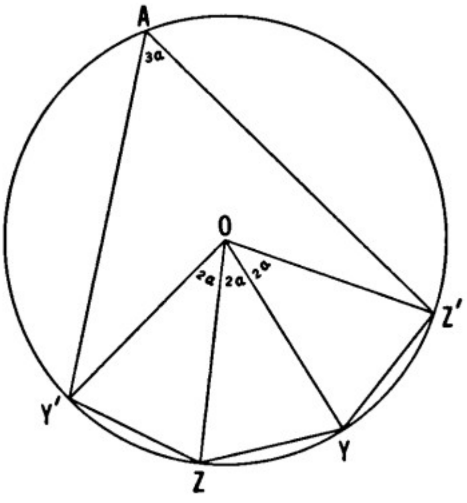

Figure 2.9A

Naraniengar's proof requires a preparatory theorem or lemma (illustrated in Figure 2.9A):

LEMMA. *If four points Y', Z, Y, Z' satisfy the conditions*

---

† Mathematical Questions and Their Solutions from the Educational Times (New Series), **15** (1909), p. 47.

$$Y'Z = ZY = YZ'$$

and

$$\angle YZY' = \angle Z'YZ = 180° - 2\alpha > 60°$$

then they lie on a circle. Moreover, if a point A, *on the side of the line* $Y'Z'$ *away from* Y, *is so situated that* $\angle Y'AZ' = 3\alpha$, *then this fifth point* A *also lies on the same circle.*

To prove the lemma, let the internal bisectors of the equal angles YZY' and $Z'YZ$ meet at O. Then $OY'Z$, OZY, OYZ' are three congruent isosceles triangles having base angles $90° - \alpha$. Their equal sides OY', OZ, OY, OZ' are radii of a circle with center O, and their angles at this common vertex are 2α. In other words, each of the equal chords $Y'Z$, ZY, YZ' subtends an angle 2α at the center O and consequently subtends an angle α at any point on the arc $Y'Z'$ not containing Y. This arc may be described as the locus of points (on the side of the line $Y'Z'$ away from Y) from which the chord $Y'Z'$ subtends an angle 3α. One such point is A; therefore A lies on the circle.

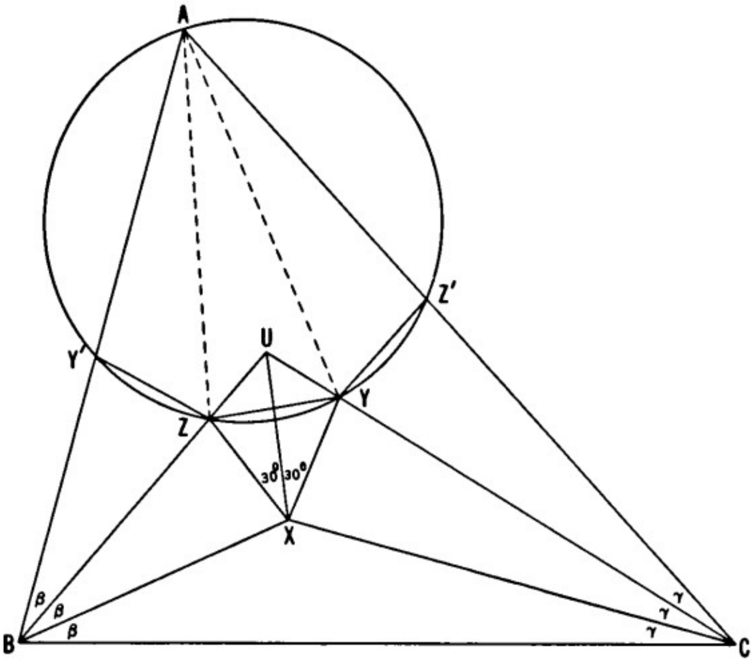

Figure 2.9B

Now we are ready to attack Theorem 2.91 itself. In Figure 2.9B, the trisectors of the angles $B = 3\beta$ and $C = 3\gamma$ meet as shown at the points U and X. In $\triangle BCU$, the angles at B and C are bisected by BX and CX; hence X is the incenter, and the angle at U is bisected by UX. If we construct points Y and Z on the lines CU and BU so that XY and XZ make equal angles 30° with XU on opposite sides, then $\triangle UXY \cong \triangle UXZ$, $XY = XZ$, and since the angle at X is 60° it follows that $\triangle XYZ$ is equilateral.

Also $\triangle UZY$ is isosceles. Its angle at U is the same as that of $\triangle UBC$, whose other angles are 2β and 2γ; therefore the equal angles of $\triangle UYZ$ at Y and Z are each $\beta + \gamma$.

Writing $\alpha = A/3$, we deduce from $A + B + C = 180°$ that

$$\alpha + \beta + \gamma = 60^\circ, \qquad \text{whence} \qquad \beta + \gamma = 60^\circ - \alpha.$$

Thus

$$\angle YZU = 60^\circ - \alpha \qquad \text{and} \qquad \angle XZU = 120^\circ - \alpha.$$

Our next step is to mark off $BY' = BX$ on BA, and $CZ' = CX$ on CA. We now have

$$\triangle BZX \cong \triangle BZY' \qquad \text{and} \qquad \triangle CYX \cong \triangle CYZ',$$

so that

$$Y'Z = ZX = ZY = YX = YZ'.$$

Before we can apply the lemma, we still have to evaluate $\angle YZY'$ and $\angle Z'YZ$. However, this is a simple matter. Since the equal angles BZY' and BZX have equal supplements,

$$\angle UZY' = \angle XZU = 120^\circ - \alpha$$

and

$$\angle YZY' = \angle YZU + \angle UZY' = (60^\circ - \alpha) + (120^\circ - \alpha)$$
$$= 180^\circ - 2\alpha.$$

Similarly, $\angle Z'YZ = 180^\circ - 2\alpha$; and of course $\alpha = \frac{1}{3}A < 60^\circ$.

Applying the lemma, we deduce that the five points Y', Z, Y, Z', A all lie on a circle. Since the equal chords $Y'Z$, ZY, YZ' subtend equal angles α at A, the lines AZ and AY trisect the angle A of $\triangle ABC$. In other words, the points X, Y, Z, which were artificially constructed so as to form an equilateral triangle, are in fact the points described in Morley's theorem. The proof is now complete.

EXERCISES

1. Let the angle trisectors AZ and CX (extended) meet at V, BX and AY at W. Then the three lines UX, VY, WZ are concurrent. (That is, in the language of projective geometry, UVW and XYZ are *perspective* triangles. In general, UVW is *not* equilateral.)

2. For what kind of triangle ABC will the pentagon $AY'ZYZ'$ be regular?

3. When $\triangle ABC$ is equilateral, the four points Y', Z, Y, Z' occur among the vertices of a regular enneagon (9-gon) in which A is the vertex opposite to the side ZY.

4. For a triangle with angles 3α, 3β, 3γ and circumradius R, Morley's triangle has sides $8R \sin \alpha \sin \beta \sin \gamma$.

5. If $Z'Y = YZ = ZY'$ on the side $Z'Y'$ of a rectangle $BCZ'Y'$ whose center X forms an equilateral triangle with Y and Z, then BX and BZ trisect the right angle at B.

CHAPTER III

THE STRAIGHT LINE

1. *Collinearity of three points, concurrency of three straight lines*

We have already used the formula $z = 1 + ju$ for the straight line, passing through the point 1 in the direction of the vector j. If we wish to represent the line passing through the point z_1 in the direction of the vector z_2, we can generalize the above formula to $z = z_1 + z_2 u$.

The equation of the line passing through two given points z_1 and z_2, is however, more often required. Point P lying on this line in such a way that the distances from P to z_1 and z_2 are in the proportion u to 1 is given by: (fig. 28):

$$z = \frac{z_1 + uz_2}{1 + u}.$$ [illegible]

For $u = 0$, P coincides with z_1, for $u = \infty$, P coincides with z_2. Positive values of u occur between z_1 and z_2, negative values on both sides outside the stretch $z_1 z_2$; the point at infinity of the line is characterized by the parameter value $u = -1$.

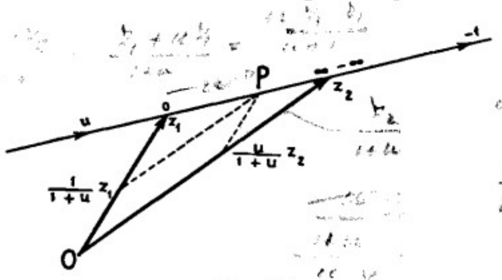

Fig. 28

Calculating u from the equation gives:

$$-u = \frac{z - z_1}{z - z_2}$$

and from this equation we see at once that the three points lie in one line as the reality of either side means that the vectors $z - z_1$ and $z - z_2$ have the same direction.

We can bring the criterion for collinearity of three points z_1, z_2 and z_3 in a more symmetrical form. The argument factor of

$$\frac{z_3 - z_1}{z_3 - z_2}$$

must equal ± 1; in formula:

$$\frac{z_3 - z_1}{z_3 - z_2} \cdot \frac{z_3^* - z_2^*}{z_3^* - z_1^*} = 1$$

and this can be written in the symmetrical form:

$$(z_1 z_2^* - z_1^* z_2) + (z_2 z_3^* - z_2^* z_3) + (z_3 z_1^* - z_3^* z_1) = 0$$

or, in the form of a determinant, the criterion of collinearity becomes:

$$\begin{vmatrix} 1 & 1 & 1 \\ z_1 & z_2 & z_3 \\ z_1^* & z_2^* & z_3^* \end{vmatrix} = 0.$$

We now proceed to calculate the point of intersection of the two lines passing through z_1 and z_2 and through z_3 and z_4 respectively. The two lines are:

$$z = \frac{z_1 + u z_2}{1 + u} \quad \text{and} \quad z = \frac{z_3 + v z_4}{1 + v}.$$

For the point of intersection these two expressions are equal, hence

$$(1 + v)\ (z_1 + u z_2) = (1 + u)\ (z_3 + v z_4)$$

For the conjugate values a similar equation must be valid:

$$(1 + v)\,(z_1^* + u z_2^*) = (1 + u)\,(z_3^* + v z_4^*)$$

and from these two equations u and v of the point of intersection can be calculated. Substituting these values into the line equations yields for the point of intersection:

$$z = \frac{(z_1 z_2^* - z_1^* z_2)\,(z_3 - z_4) - (z_3 z_4^* - z_3^* z_4)\,(z_1 - z_2)}{(z_1 - z_2)\,(z_3^* - z_4^*) - (z_1^* - z_2^*)\,(z_3 - z_4)}.$$

If the vectors $z_1 - z_2$ and $z_3 - z_4$ are parallel, the denominator equals zero by the criterion of parallellity and then $z=\infty$, as was to be expected.

If we cut the line $z_3 z_4$ by a third line $z_5 z_6$, we create a second point of intersection, the place of which is given by the last equation, if only we add 2 to each index. If the three lines have to pass through one point (in a technical term, if the lines are *concurrent*), the two expressions for the points of intersection have to be put equal to each other and the condition resulting from this equality can be brought into the symmetrical form of a determinant:

3 lignes [illegible]

$$\begin{vmatrix} z_1-z_2 & z_3-z_4 & z_5-z_6 \\ \dot{z}_1-\dot{z}_2 & \dot{z}_3-\dot{z}_4 & \dot{z}_5-\dot{z}_6 \\ z_1\dot{z}_2-\dot{z}_1 z_2 & z_3\dot{z}_4-\dot{z}_3 z_4 & z_5\dot{z}_6-\dot{z}_5 z_6 \end{vmatrix}=0.$$

We can check this formula by laying the origin in the common point of intersection. Each element of the third row is proportional to the area of the parallelograms on the vectors z_1z_2, z_3z_4 and z_5z_6 respectively and all three must vanish if the origin is on the lines z_1z_2, z_3z_4 and z_5z_6, but then the determinant is also zero.

2. *The theorems of Ceva, Menelaos and Desargues*

As applications of the general theory let us prove the theorems of Menelaos and Ceva.

Menelaos (58 A. D.): the three points P, Q, R, each lying on a side of the triangle ABC (fig. 29) in such a way that

$$\frac{AP.BQ.CR}{PB.QC.RA}=-1 \text{ are collinear.}$$

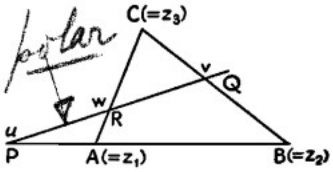

Fig. 29

Let the three points be:

$$z_P=\frac{z_1+uz_2}{1+u};\quad z_Q=\frac{z_2+vz_3}{1+v};\quad z_R=\frac{z_3+wz_1}{1+w}.$$

The condition is then equivalent to $u\cdot v\cdot w=-1$. The determinant occurring in the criterion for collinearity is

$$\begin{vmatrix} 1+u & 1+v & 1+w \\ z_1+uz_2 & z_2+vz_3 & z_3+wz_1 \\ \dot{z}_1+u\dot{z}_2 & \dot{z}_2+v\dot{z}_3 & \dot{z}_3+w\dot{z}_1 \end{vmatrix}.$$

[illegible]

[illegible]

Add the first row and $-u$ times the second to $-1/w=uv$ times the third row. The members of this row then become zero from which it follows that the determinant is zero and hence that the points PQR are collinear, q.e.d.

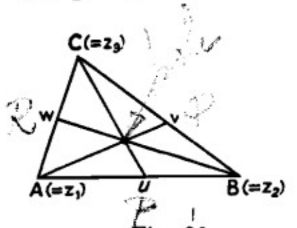

Fig. 30

CEVA (1700): the three lines joining the vertices of a triangle with the points PQR, each lying on one side so that

$$\frac{AP.BQ.CR}{PB.QC.RA}=1 \text{ are concurrent.}$$

Let the three points be:

$$z_P=\frac{z_1+uz_2}{1+u};\quad z_Q=\frac{z_2+vz_3}{1+v};\quad z_R=\frac{z_3+wz_2}{1+w},$$

then the condition leads to $u\cdot v\cdot w=1$. The determinant of the criterion of concurrency is:

$$\begin{vmatrix} (1+u)z_3-(z_1+uz_2) & (1+v)z_1-(z_2+vz_3) & (1+w)z_2-(z_3+wz_1) \\ (1+u)z_3^{\bullet}-(z_1^{\bullet}+uz_2^{\bullet}) & (1+v)z_1^{\bullet}-(z_2^{\bullet}+vz_3^{\bullet}) & (1+w)z_2^{\bullet}-(z_2^{\bullet}+wz_1^{\bullet}) \\ (1+u)\{z_3(z_1^{\bullet}+uz_2^{\bullet})-z_3^{\bullet}(z_1+uz_2)\} & \text{cycl.} & \text{cycl.} \end{vmatrix}.$$

The sum of v times the first column, the second column and $1/w=uv$ times the third is zero; therefore the determinant is zero, which proves the concurrency of the three lines.

Each Ceva's point characterized by three definite values of u, v and w is correlated to one Meneloas' line, characterized by $-u$, $-v$, $-w$. They are taken together as *trilinear pole* and *trilinear polar*. The polar of the centre of gravity of the triangle $(u=v=w=1)$ is the straight line at infinity.

Another important theorem is Desargues' *theorem*, stating that corresponding sides of two perspective triangles intersect in three collinear points, ($\pm$1650), and we may see as follows, that it is a consequence of the theorems of MENELAOS and CEVA. Draw

[illegible] $\triangle ABC$ + [illegible] → $\triangle$ [illegible]

(fig. 31) the triangle ABC and mark the points u, v and w on its sides. By Ceva's theorem the triangles ABC and vwu are perspective if $u \cdot v \cdot w = 1$. Mark the points $-u$, $-v$ and $-w$ and draw the straight line m through these points, which is possible because of Menelaos' theorem. Now as $uvw = 1$, the points w, u, $-v$ must be collinear and also the points v, u, $-w$.... and also the points w, v, $-u$. We see thus that the corresponding sides of the triangles ABC and vwu intersect in three points of the line m, q.e.d. ([illegible] $\triangle uvw$ [illegible])

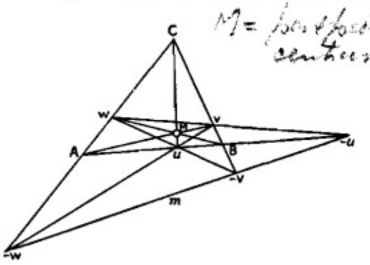

Fig. 31

M = [illegible] centrum.

3. *Line coordinates*

If in the criterion of collinearity of three points we substitute z for z_3, it becomes:

$$\begin{vmatrix} 1 & 1 & 1 \\ z_1 & z_2 & z \\ z_1^* & z_2^* & z^* \end{vmatrix} = 0$$

and this can be considered as the equation of the line passing through z_1 and z_2; written in one line the equation is:

$$(z_1^* - z_2^*)\, z + (z_2 - z_1)\, z^* + (z_1 z_2^* - z_2 z_1^*) = 0.$$

and this can be brought into the simple form:

$$p^* z + p z^* - 2 = 0 \qquad (\text{or } \operatorname{Re}(p^* z) = 1)$$

by introducing:

$$p = 2\,\frac{z_2 - z_1}{z_1^* z_2 - z_1 z_2^*}; \quad p^* = 2\,\frac{z_2^* - z_1^*}{z_1 z_2^* - z_1^* z_2}.$$

The straight line appears to be completely determined by the choice of p. p is called the vector of the line and its components are called the line coordinates. A point is determined by one vector or by two coordinates and we see that the same applies to a straight line.

The use of the line vector appears at once, if we introduce it

incident met

[illegible] →

[illegible] 3 [illegible]

[illegible]

into the formula for the point of intersection of two lines, deduced in a former section. Let the line z_1z_2 be characterized by p_1 and the line z_3z_4 by p_2, where

$$p_1 = 2\,\frac{z_2 - z_1}{\overset{\bullet}{z}_1 z_2 - z_1 \overset{\bullet}{z}_2}\,; \quad p_2 = 2\,\frac{z_4 - z_3}{\overset{\bullet}{z}_3 z_4 - z_3 \overset{\bullet}{z}_4}\,.$$

After introducing this in the formula for the point of intersection z it becomes:

$$z = 2\,\frac{p_2 - p_1}{\overset{\bullet}{p}_1 p_2 - p_1 \overset{\bullet}{p}_2}$$

and there exists a remarkable reciprocity between the point of intersection z of the two lines determined by the vectors p_1 and p_2 and the line p connecting the two points determined by the vectors z_1 and z_2.

Let us also introduce the notion of the line vector into the condition for the concurrency of three lines. This takes then the form:

$$\begin{vmatrix} 1 & 1 & 1 \\ p_1 & p_2 & p_3 \\ \overset{\bullet}{p}_1 & \overset{\bullet}{p}_2 & \overset{\bullet}{p}_3 \end{vmatrix} = 0$$

which is formally identical with the condition for the collinearity of three points. Indeed we may say that three lines are concurrent, if their p's are collinear.

We shall now investigate the geometrical nature of the vector p, defining the point P (fig. 32). As in the definition of p the denominator is purely imaginary, we conclude that the vector from the origin to P is normal to the vector $z_2 - z_1$, that means normal to the

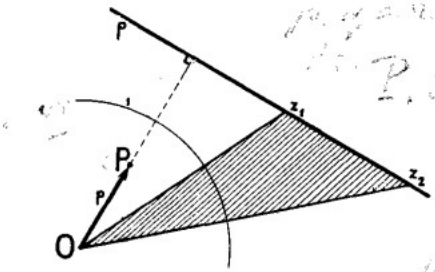

Fig. 32

[illegible]

dualität.

line z_1z_2. As, furthermore, the absolute value of the denominator equals twice the area of the triangle $O z_1 z_2$, of which z_1z_2 is the base, we easily conclude that the modulus of p is the inverse of the length of the perpendicular let down from O on to the line. Point P is the inversion of the base of this perpendicular.

From now on we shall take point P and the corresponding line together as *pole* and *polar* with respect to the unit circle; both the pole and the line will be characterized by the letter p. As we have seen above, by the transformation of pole and polar a pencil of rays passing through one point is transformed into a point assemblage on a straight line. We can prove that this line is the polar of the point which carries the pencil of rays. Let this point be Q with coordinate q. The condition that Q shall lie on an arbitrary member p of the pencil is:

$$p^* q + p q^* - 2 = 0$$

but owing to the symmetry between p and q this is also the condition that P shall fall on the polar q of Q, q.e.d.

The polar of the point of intersection R of the lines p and q (fig. 33) must be the line PQ. PQR is a so-called *polar triangle.*

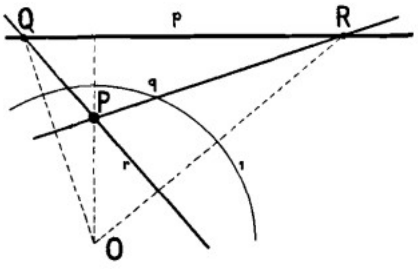

Fig. 33

By the transformation of pole and polar it is transformed into itself.

4. *Polar transformation, dual conceptions*

By the transformation of pole and polar a curve considered as a collection of points is transformed into a collection of straight lines. These lines will envelop a second curve which, therefore, may be considered as the transform of the original curve. A secant

[illegible]

of the original curve, intersecting it in n (= the order) points will be transformed into a point carrying n lines from the collection that envelops the second curve. As these lines are tangents to this curve, the transform will be of the class n. Conversely the class of the original curve will equal the order of the transform. As conics are both of second order and second class, the transformation of pole and polar will transform conics into conics. We know that the inversion transforms circles into circles, but this is not the case with the transformation of pole and polar. By way of example we shall transform the circle, but first we have to indicate the general way of finding the formula of the polar transform.

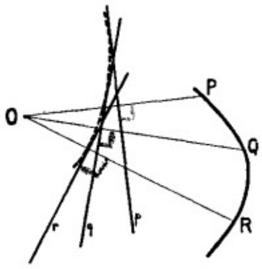

Fig. 34

The point of intersection of the lines p and q which are the transforms of the points P with coordinate p and Q with coordinate q is:

$$z = 2\,\frac{q-p}{p^{\cdot}q - pq^{\cdot}}.$$

Now let Q approach to P, then the line PQ will approach to a limiting position which is a tangent of the original curve. In the transform the point of intersection of p and q will approach a limiting position which by definition will be considered as a point of the transformed curve. Now if $q-p=dp$,

$$p^{\cdot}q - pq^{\cdot} = p^{\cdot}(p+dp) - p\,(p^{\cdot}+dp^{\cdot}) = p^{\cdot}dp - p\,dp^{\cdot}$$

and the point of the transformed curve is:

$$z = 2\,\frac{dp}{p^{\cdot}dp - p\,dp^{\cdot}}.$$

Performing the polar transformation for a second time that is, finding $2\,\dfrac{dz}{z^{\cdot}dz - z\,dz^{\cdot}}$ gives of course again the original curve p, as may be verified by actually performing the calculation.

We shall now apply this general result to the circle (fig. 35)

$$p = a + \exp(ju)$$
$$dp = j \exp(ju)\, du$$
$$dp^{*} = -j \exp(-ju)\, du$$

The transform is therefore:

$$z = \frac{\exp ju}{a \cos u + 1}$$

hyperbool

and this is not a circle, but a hyperbola (fig. 35).

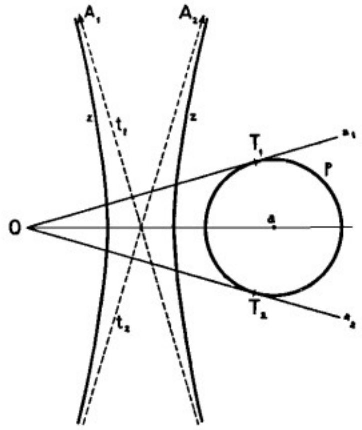

Fig. 35

Any property of the original figure will be found again in the transform, but in the so-called dual form (Poncelet). Dual expressions are point and line; collinearity of points and concurrency of lines; order and class; point on a curve and tangent. As examples of dual theorems we may consider the theorems C of Menelaos and Ceva. Another example is supplied by Pappos' theorems (300 A.D., fig. 36):

Take three points u_1, u_2, u_3 on one line and three points v_1, v_2, v_3 on a second line. The lines u_1v_2 and u_2v_1 intersect in C, the lines u_2v_3 and u_3v_2 in A, the lines u_3v_1 and u_1v_3 in B. The theorem says that A, B and C are collinear. It can be proved with the methods of the preceding sections.

The dual theorem is (fig. 37):

Take three lines u_1, u_2, u_3 through one point U and three lines v_1, v_2, v_3 through a second point V.

The points u_1v_2 and u_2v_1 determine the straight line c, the points u_2v_3 and u_3v_2 determine the line a, the points u_3v_1 and u_1v_3 determine the line b. According to the theorem the lines a, b and c are concurrent.

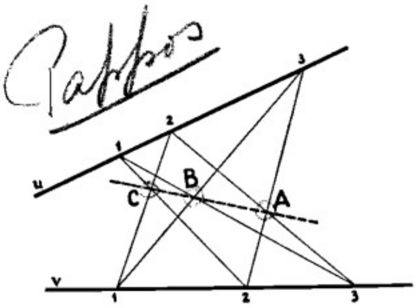

Fig. 36

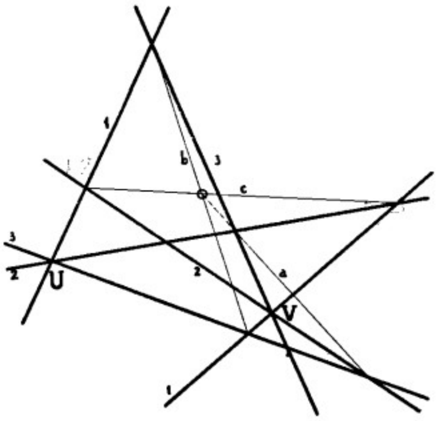

Fig. 37

Although this theorem too can be proved by means of the methods of the previous sections, it is not necessary to do so, once the dual theorem has been proved. More than that, the analytical proof of one of the theorems is identical with that of the second. We have merely to interpret the symbols in the dual way. Finally we may remind that Desargues' theorem is dual with itself.

5. *Projective point assemblages and ray pencils*

The point assemblage on the straight line:

$$z = \frac{z_1 + z_2u}{1+u} \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1)$$

may be compared with that on the arbitrary other straight line:

$$z' = \frac{z_3 + z_4u}{m+nu} \qquad (m \text{ and } n \text{ are real}). \quad . \quad . \quad . \quad . \quad (2)$$

The latter equation is of a more general character than the former. We remark here, that z_3 and z_4 are no longer points of the straight line; it passes through the points z_3/m $(u=0)$ and z_4/n $(n=\infty)$. We shall show that the transition from (1) to (2) can be accomplished by a combination of parallel translations, rotations and perspective projections.

By way of introduction we may remark that two lines:

$$z_A=\frac{z_1+z_2u}{m+nu} \quad \text{and} \quad z_B=\frac{z_1+z_2u}{p+qu}$$

are perspective with respect to the origin, by which we mean, that the points on the two lines with equal values of u lie on one straight line passing through O. Indeed, the quotient

$$\frac{z_A}{z_B}=\frac{p+qu}{m+nu}$$

is real and that means that z_A and z_B have the same direction.

The construction of the scale of (2)

$$z'=\frac{z_3+z_4u}{m+nu}$$

is shown in fig. 38. We first construct the line z_3+z_4u which is perspective with (2) and has a uniform scale (unit=modulus of z_4). Fig. 39 shows in the same way the construction of (1):

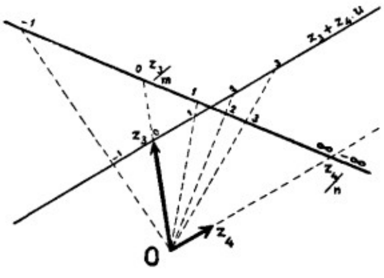

Fig. 38

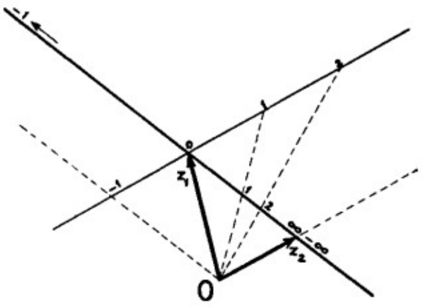

Fig. 39

Now move one of the here mentioned uniform scales until both are parallel and at the same time perspective and the chain of operations leading from (1) to (2) is closed. In general two point assemblages of the type (2) will not be perspective, but we call them *projective*.

Perspective projection leaves certain properties intact; these are called *projective properties*, other properties may be lost in the projection; as opposed to the projective properties they are called *metric properties*.

Examples of projective properties are; incidence of point and line, collinearity of points, concurrency of lines, order and class of a curve, character of tangent, double point, inflection point, cusp. We shall now add one important example more to this collection: the cross ratio of four points *on a straight line* is invariant. To prove this, take four points $u_1 u_2 u_3 u_4$ on the line (2) and calculate the cross ratio. We find:

$$D = \frac{z'(u_1) - z'(u_3)}{z'(u_1) - z'(u_4)} \div \frac{z'(u_2) - z'(u_3)}{z'(u_2) - z'(u_4)} = \frac{u_1 - u_3}{u_1 - u_4} \div \frac{u_2 - u_3}{u_2 - u_4}$$

and this is entirely independent of z_3, z_4, m and n.

The projective character of the cross ratio was already known to Pappos (300 A.D.).

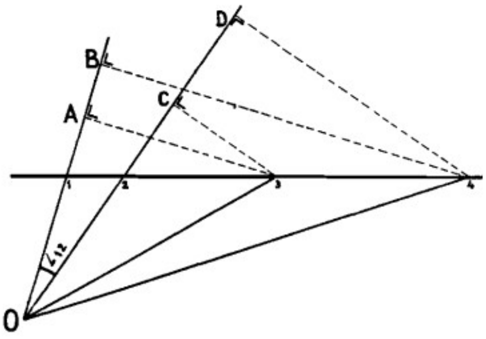

Fig 40

The cross ratio is, so to say, picked up by a projecting pencil of rays and transferred to a second line. We expect that it can be expressed in the angles of the pencil without the help of a secant. Indeed (fig. 40)

$$\frac{z_1-z_3}{z_1-z_4}=\frac{\mathrm{A}\,3}{\mathrm{B}\,4}=\frac{\mathrm{O}\,3\sin\angle 13}{\mathrm{O}\,4\sin\angle 14}$$

In the same way:

$$\frac{z_2-z_3}{z_2-z_4}=\frac{\mathrm{C}\,3}{\mathrm{D}4}=\frac{\mathrm{O}\,3\sin\angle 23}{\mathrm{O}\,4\sin\angle 24}$$

and the cross ratio:

$$\boxed{D=\frac{\sin\angle 13}{\sin\angle 14}\div\frac{\sin\angle 23}{\sin\angle 24},}$$ 2/

where $\angle$ 12 is the angle between the two rays from O to the points z_1 and z_2 etc.; as the choice of O however is entirely arbitrary we have left O out of the expression for D.

A ray pencil projecting a linear point assemblage will be called projective with it. Two pencils projecting projective point assemblages will be called mutually projective; if, more in particular, corresponding rays of these two pencils intersect all on one straight line, we shall call them *perspective*. „Perspective pencils of lines" is the dual conception of „perspective point assemblages".

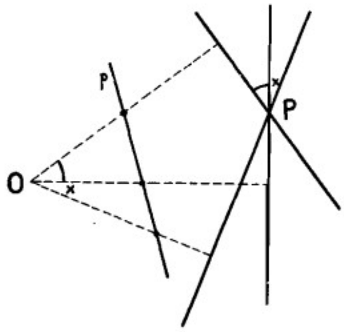

Fig. 41

The poles of a ray pencil lie on the polar of the carrier point of the pencil and as the pole of each member is situated on the perpendicular let down from O on the line concerned, the arguments of the poles differ by the same amounts as the slopes of the lines of the original pencil (fig. 41). We come therefore, to the conclusion that the cross ratio is also invariant with respect to the transformation of pole and polar.

6. *Projective geometry*

As a rule projective properties of figures are much more easily proved by direct projective methods than by analytical calculation.

*crossratio van een [illegible] [illegible] [illegible] in (3) [illegible]

We shall give a number of examples of theorems proved by the former methods.

a. Harmonic point quadruples in the complete quadrangle.

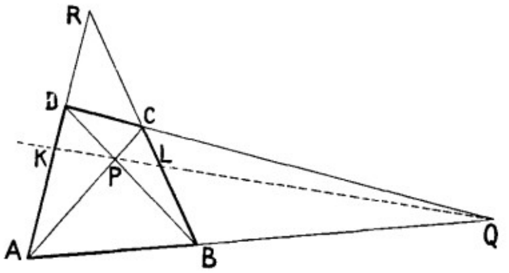

Fig. 42

The complete quadrangle ABCD has six sides and three diagonal points, P, Q and R (fig. 42). Connect P and Q by a line which intersects the two remaining sides in K and L, then the points P, Q, K and L are lying *harmonically* ($D = -1$). The proof is as follows:

$$D(\text{PQKL}) = (\text{projected from A on RB})) = D(\text{CBRL}).$$

D

$$= (\text{projected from D on KQ}) = D(\text{QPKL}).$$

Now P and Q have changed places, but from the definition of the cross ratio it follows that it is inverted by changing two elements. So D must be either $+1$ or -1, and from the figure we see, that in this case it is -1.

b. Desargues' theorem was proved analytically in a previous section. The projective proof is as follows: (fig. 31). The point quadruples $-w\text{A}w\text{C}$ and $-v\text{B}v\text{C}$ are both harmonic ($D = -1$) and as they have one point in common (C) they must be perspective, so that w $-v$ and $-w$ v must intersect on the side AB (in the point u); for the same reason w v and $-w$ v must meet on AB.; q.e.d.

c. Pappos' theorem I follows from the fact, that in fig. 43, where the lines u_2C and u_3B are parallel and so on, defining three points v_1, v_2 and v_3 on the straight line at infinity, A, B and C are collinear for elementary reasons. By a collineation this figure is transformed into fig. 36 of page 42, but the three points A, B and C will remain collinear, and this is what the theorem states.

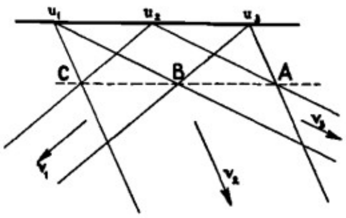

Fig. 43

7. *Involution*

We shall now return to the study of the point assemblage:

$$z = \frac{z_1 + z_2 u}{1 + u}$$

lying on the straight line through the two points z_1 and z_2, and try to find the point which lies harmonically with the point u with respect to z_1 and z_2. This point u' has to be determined from

$$D(z_1 z_2 z(u) z(u')) = -1.$$

or, as $u = 0$ for z_1, $u = \infty$ for z_2, from:

$$\frac{u-0}{u'-0} \div \frac{u-\infty}{u'-\infty} = -1; \text{ hence } u' = -u.$$

The transformation transforming each point into the fourth harmonic with respect to two fixed points, is called the *involution*, its analytical expression is simply:

$$u' = -u.$$

Evidently the relation is reciprocal, the points u and $-u$ form a *pair of the involution*. There are two points which coincide with their partners, namely $u=0$ and $u=\infty$; these are precisely the points z_1 and z_2. Because of this property they are called the *double points* of the involution. The middle of the section $z_1 z_2$ $(u=1)$ is the partner of the infinite point of the line $(u=-1)$.

The harmonic mean of the distances of two partners of the involution to one of the double points is constant;

$$z(u)-z_1=(z_2-z_1)\frac{u}{1+u}; \qquad z(-u)-z_1=(z_1-z_2)\frac{u}{1-u},$$

hence

$$\frac{1}{z(u)-z_1}+\frac{1}{z(-u)-z_1}=\frac{2}{z_2-z_1}=\text{constant}=\frac{1}{f}$$

and as all vectors involved are in the same direction, the same relation holds for the absolute values. With respect to the second double point (z_2) we come to the same result with opposite sign:

$$\frac{1}{z(u)-z_2}+\frac{1}{(z-u)-z_2}=\frac{2}{z_1-z_2}=\text{constant}.$$

Another theorem states that the product of the distances of the partners of a pair to the „*centre*" of the involution, that is the point $\frac{1}{2}(z_1+z_2)$, is constant. Indeed:

$$\left(z(u)-\frac{z_1+z_2}{2}\right)\left(z(-u)-\frac{z_1+z_2}{2}\right)=$$

$$=\left(\frac{z_1+z_2u}{1+u}-\frac{z_1+z_2}{2}\right)\left(\frac{z_1-z_2u}{1-u}-\frac{z_1+z_2}{2}\right)=\left(\frac{z_1-z_2}{2}\right)^2=\text{constant}$$

and as all vectors involved are in the same direction the same holds for the absolute values.

This theorem provides us with a second definition of the involution: The involution transforms a point into its partner in such a way that the product of the distances of the two partners to a fixed centre is constant.

This definition is more general than the original one. If the two partners are situated on the same side of the centre, as was the case up to now, the product is positive, if, however, we choose the points on opposite sides of the center, the product is negative and there exist no real double points of the involution. We distinguish *hyperbolic* (product positive, real double points) from *elliptic* (product negative, imaginary double points) and *parabolic* (product zero, two coinciding double points) involutions. In the case of the parabolic involution one of the points of each pair coincides always with the double point.

Now the point $1/u$ lies symmetrical with the point u with respect to the centre $\frac{1}{2}(z_1 + z_2)$:

$$z(u) - \frac{z_1 + z_2}{2} = \frac{u-1}{u+1} \cdot \frac{z_2 - z_1}{2}; \; z\left(\frac{1}{u}\right) - \frac{z_1 + z_2}{2} = \frac{1-u}{1+u} \cdot \frac{z_2 - z_1}{2};$$

and, as the pairs $(u, -u)$ form a hyperbolic involution, the pairs of points $(u, -1/u)$, form an elliptic involution. The basic points $z_1 (u = +0)$ and $z_2 (u = -\infty)$ are no longer double points, but form a pair. The double points are imaginary $(u = \pm i)$ and with respect to these imaginary double points the harmonic configuration of the pairs is maintained.

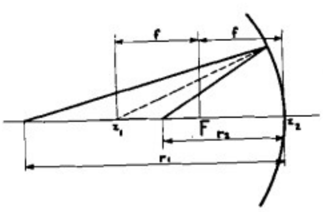

Fig. 44

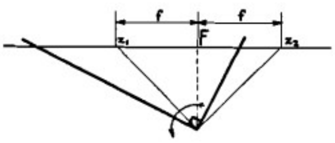

Fig 45

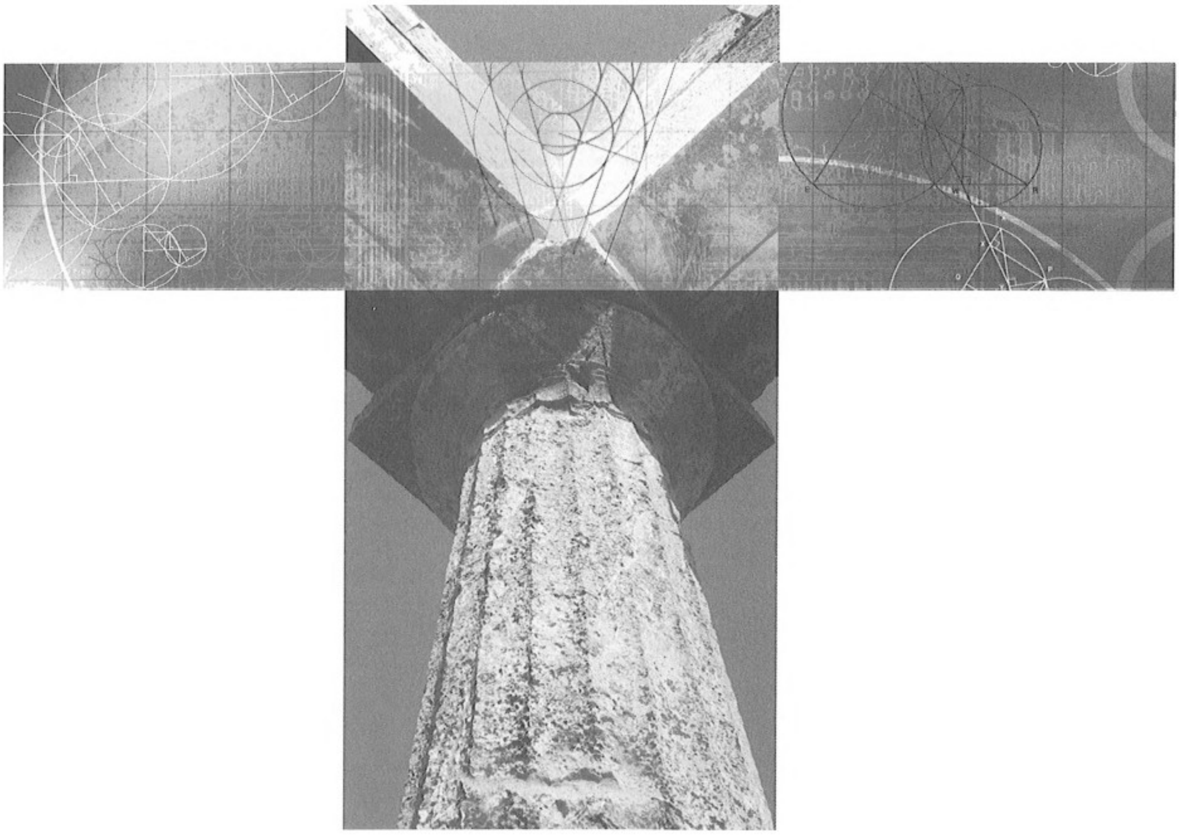
An example of a hyperbolic involution is provided by the pairs of objects and images in the case of reflection of light by a spherical mirror, for which the equation $1/r_1 + 1/r_2 = 1/f$ holds. This case is depicted in fig. 44; the mirror is placed in the point z_2, the centre of the spherical surface is placed in z_1.

An example of an elliptic involution is provided by the pairs of points of insersection of the sides of a right angle with a straight line, if the right angle is rotated round its vertex, fig. 45.

A point involution can be picked up by a projecting ray pencil and projected on a second line. If in particular, as is the case in fig. 45, the rays of each pair of the ray involution are at right angles we speak of an *orthogonal involution.* In projecting an involution on an other line carrier, the double points are perspective, but the centre is not projected as the centre of the new involution; the centre is not a projective but a metric characteristic of the involution.

CHAPTER TWO



CONCURRENCY OF LINES IN A TRIANGLE

INTRODUCTION

In spite of its importance, the concept of concurrency of lines (i.e., three or more lines containing a common point) usually gets a light treatment in an elementary geometry course because of higher priorities. Acquiring a truly good facility with the concept would require that more theorems be explored than time permits in the first geometry course. Familiar concurrencies such as the medians, angle bisectors, and altitudes of a triangle are mentioned but not often established by proof. Introducing a few new theorems makes the topic of concurrency quite simple and presents a new vista in Euclidean geometry. This chapter begins by demonstrating the importance of establishing concurrency. With the help of an important theorem, first published by Giovanni Ceva in 1678, we present a variety of interesting relationships and theorems. You will soon see how simply some previously difficult theorems can be proved.

Because we want to show the importance of concurrency, let us consider the following problem:

> Two wires are placed in straight lines meeting in an inaccessible region (Figure 2-1). How would you locate the proper placement for a wire that is to *bisect* the angle formed by the two wires without touching the inaccessible region?

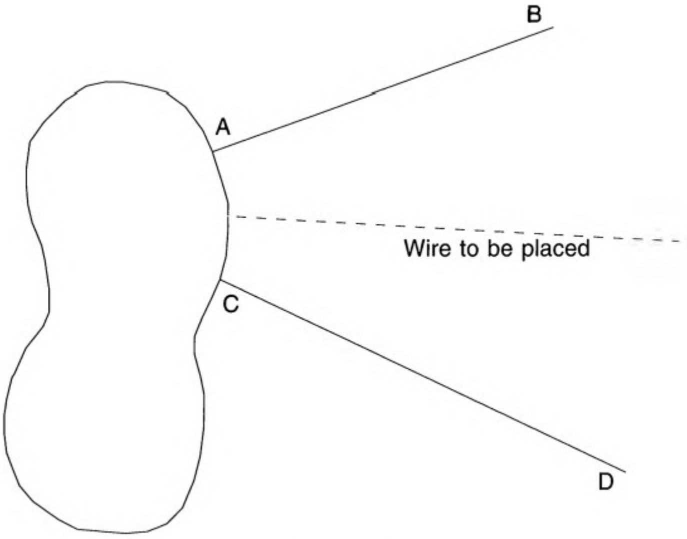


FIGURE 2-1

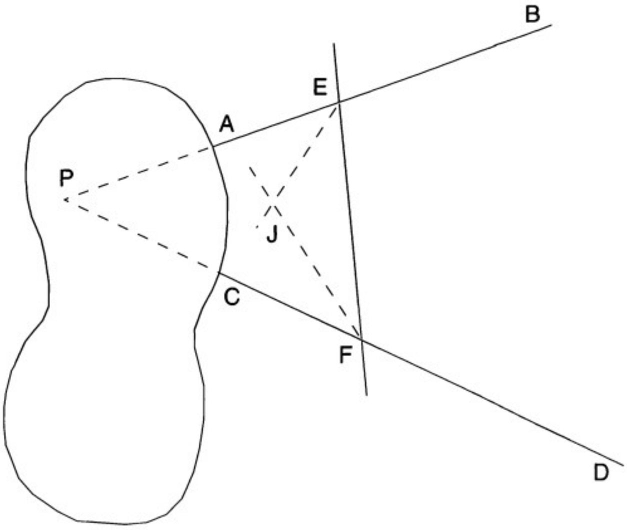

FIGURE 2-2

Although there are many possible methods of solution to this problem, we chose the following solution for a reason that will soon become clear.

Solution Draw any line through $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$, intersecting them at points E and F, respectively (see Figure 2-2). Construct the bisectors of $\angle AEF$ and $\angle CFE$, which meet at point J. Suppose $\triangle PEF$ were complete. The bisector of $\angle P$ would then have to contain point J because the angle bisectors of a triangle are concurrent.

Repeat this process for any other line $\overleftrightarrow{GH}$ that meets $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$ at points G and H, respectively (Figure 2-3). This time, bisect $\angle AGH$ and $\angle CHG$. These bisectors meet at point K. Once again, we notice that the required angle bisector (that of $\angle P$) must contain point K. Because this required angle bisector *must* contain both J and K, these two points determine our desired line, which is the location of the wire to be installed. ●

This solution relies heavily on the notion that the angle bisectors of a triangle are concurrent. As we have said, the topic of concurrency in a triangle deserves more attention than it usually gets in the elementary geometry course. In a very simple way, we will prove that the angle bisectors of a triangle are concurrent. First, we must establish an extremely useful relationship.

Recall from elementary geometry that there are many "centers" of a triangle. Some examples are:

- *centroid*—the center of gravity of the triangle, determined by the intersection of the medians;
- *orthocenter*—the point of intersection of the altitudes of the triangle;
- *incenter*—the center of the inscribed circle of the triangle, determined by the intersection of the angle bisectors of the triangle;

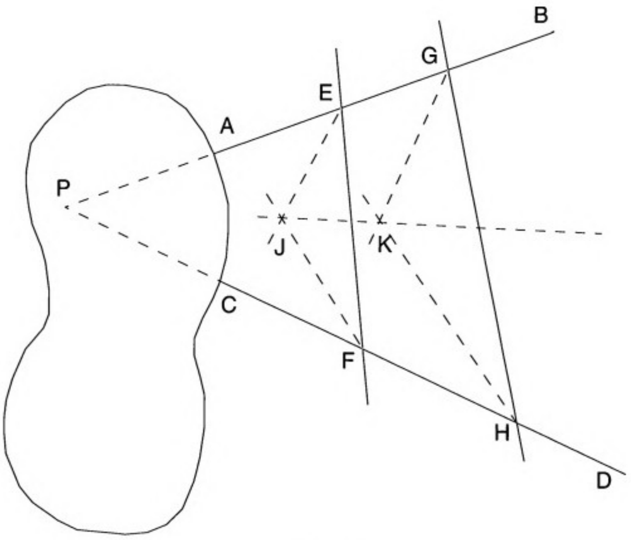

FIGURE 2-3

- *circumcenter*—the center of the circumscribed circle (or circumcircle), determined by the intersection of the perpendicular bisectors of the sides of the triangle.

Numerous applications of these triangle centers are considered in the elementary geometry course. On occasion, students will consider "practical" applications that rely on the concurrency property of these points. We offered one such application at the beginning of this chapter. Yet because the traditional proofs of these concurrency relationships are somewhat cumbersome, the relationships are frequently accepted without proof. With the help of the famous theorem first published* by the Italian mathematician Giovanni Ceva (1647–1734), which bears his name, we will produce simple proofs of the concurrency relationships named previously, as well as many others.

CEVA'S THEOREM

THEOREM 2.1 **(Ceva's Theorem)** The three lines containing the vertices A, B, and C of $\triangle ABC$ and intersecting the opposite sides at points L, M, and N, respectively, are concurrent if and only if $\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$.

---

* *De lineis se invicem secantibus statica constructio* (Milan, 1678).

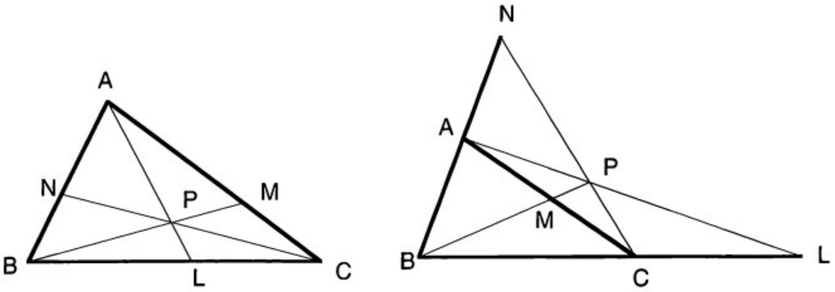

FIGURE 2-4

To prove this theorem, we must note that there are two possible situations in which the three lines drawn from the vertices may intersect the sides and still be concurrent. These situations are pictured in Figure 2-4. It is perhaps easier to follow the proof with the diagram on the left and verify the validity of the statements with the diagram on the right. In any case, the statements made in the proof hold for *both* diagrams.

Ceva's theorem is an equivalence (or biconditional) and therefore requires two proofs (one the converse of the other). We will first prove that *if the three lines containing the vertices of* $\triangle ABC$ *and intersecting the opposite sides at points L, M, and N, respectively, are concurrent, then* $\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$. We offer three proofs. The first (though not the simplest) requires no auxiliary lines.

Proof I In Figure 2-4, $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ meet at point *P*. Because $\triangle ABL$ and $\triangle ACL$ share the same altitude (i.e., from point *A*):

$$\frac{\text{area } \triangle ABL}{\text{area } \triangle ACL} = \frac{BL}{LC} \tag{I}$$

Similarly:

$$\frac{\text{area } \triangle PBL}{\text{area } \triangle PCL} = \frac{BL}{LC} \tag{II}$$

From (I) and (II):

$$\frac{\text{area } \triangle ABL}{\text{area } \triangle ACL} = \frac{\text{area } \triangle PBL}{\text{area } \triangle PCL}$$

A basic property of proportions $\left(\frac{w}{x} = \frac{y}{z} = \frac{w-y}{x-z}\right)$ provides that:

$$\frac{BL}{LC} = \frac{\text{area } \triangle ABL - \text{area } \triangle PBL}{\text{area } \triangle ACL - \text{area } \triangle PCL} = \frac{\text{area } \triangle ABP}{\text{area } \triangle ACP} \tag{III}$$

We now repeat the process, using $\overline{BM}$ instead of $\overline{AL}$:

$$\frac{CM}{MA} = \frac{\text{area } \triangle BMC}{\text{area } \triangle BMA} = \frac{\text{area } \triangle PMC}{\text{area } \triangle PMA}$$

It follows that:

$$\frac{CM}{MA} = \frac{\text{area } \triangle BMC - \text{area } \triangle PMC}{\text{area } \triangle BMA - \text{area } \triangle PMA} = \frac{\text{area } \triangle BCP}{\text{area } \triangle BAP} \qquad \text{(IV)}$$

Once again we repeat the process, this time using $\overline{CN}$ instead of $\overline{AL}$:

$$\frac{AN}{NB} = \frac{\text{area } \triangle ACN}{\text{area } \triangle BCN} = \frac{\text{area } \triangle APN}{\text{area } \triangle BPN}$$

This gives us:

$$\frac{AN}{NB} = \frac{\text{area } \triangle ACN - \text{area } \triangle APN}{\text{area } \triangle BCN - \text{area } \triangle BPN} = \frac{\text{area } \triangle ACP}{\text{area } \triangle BCP} \qquad \text{(V)}$$

We now simply multiply (III), (IV), and (V) to get the desired result:

$$\frac{BL}{LC} \cdot \frac{CM}{MA} \cdot \frac{AN}{NB} = \frac{\text{area } \triangle ABP}{\text{area } \triangle ACP} \cdot \frac{\text{area } \triangle BCP}{\text{area } \triangle BAP} \cdot \frac{\text{area } \triangle ACP}{\text{area } \triangle BCP} = 1 \; \bullet$$

By introducing an auxiliary line, we can produce a simpler proof.

Proof II Consider Figure 2-4, but add a line containing point A and parallel to $\overline{BC}$ that intersects $\overleftrightarrow{CP}$ at point S and $\overleftrightarrow{BP}$ at point R (see Figure 2-5). The parallel lines enable us to establish the following pairs of similar triangles:

$$\triangle AMR \sim \triangle CMB \Rightarrow \frac{AM}{MC} = \frac{AR}{CB} \qquad \text{(I)}$$

$$\triangle BNC \sim \triangle ANS \Rightarrow \frac{BN}{NA} = \frac{CB}{SA} \qquad \text{(II)}$$

$$\triangle CLP \sim \triangle SAP \Rightarrow \frac{CL}{SA} = \frac{LP}{AP} \qquad \text{(III)}$$

$$\triangle BLP \sim \triangle RAP \Rightarrow \frac{BL}{RA} = \frac{LP}{AP} \qquad \text{(IV)}$$

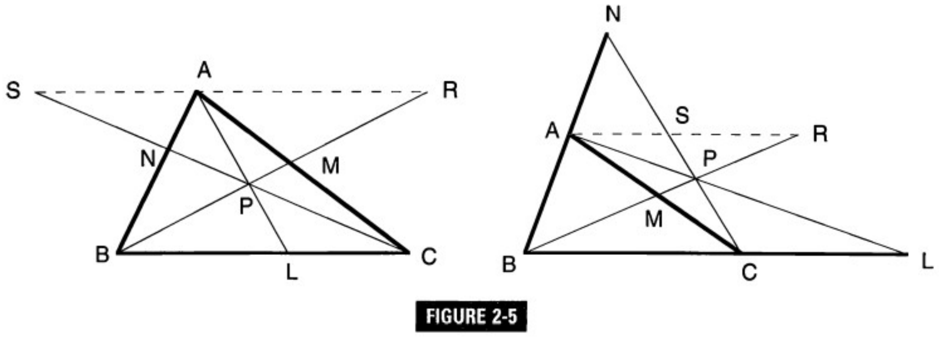

FIGURE 2-5

From (III) and (IV) we get:

$$\frac{CL}{SA} = \frac{BL}{RA}$$

This can be rewritten as:

$$\frac{CL}{BL} = \frac{SA}{RA} \qquad \text{(V)}$$

By multiplying (I), (II), and (V), we obtain our desired result:

$$\frac{AM}{MC} \cdot \frac{BN}{NA} \cdot \frac{CL}{BL} = \frac{AR}{CB} \cdot \frac{CB}{SA} \cdot \frac{SA}{RA} = 1$$

We rearrange the terms and invert the fractions to get:

$$\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1 \text{ (the same as the conclusion of Proof I)} \; \bullet$$

By adding two auxiliary lines to the diagrams in Figure 2-4, we are able to produce another proof, again using the properties of similar triangles.

Proof III We begin with the diagrams shown in Figure 2-4 but add two lines to each diagram. We draw a line through point A and a line through point C each parallel to $\overline{BP}$ and intersecting $\overleftrightarrow{CP}$ and $\overleftrightarrow{AP}$ at points S and R, respectively (see Figure 2-6).

$$\triangle ASN \sim \triangle BPN \Rightarrow \frac{AN}{NB} = \frac{AS}{BP} \qquad \text{(I)}$$

$$\triangle BPL \sim \triangle CRL \Rightarrow \frac{BL}{LC} = \frac{BP}{CR} \qquad \text{(II)}$$

$$\triangle PAM \sim \triangle RAC \Rightarrow \frac{CA}{MA} = \frac{RC}{PM}$$

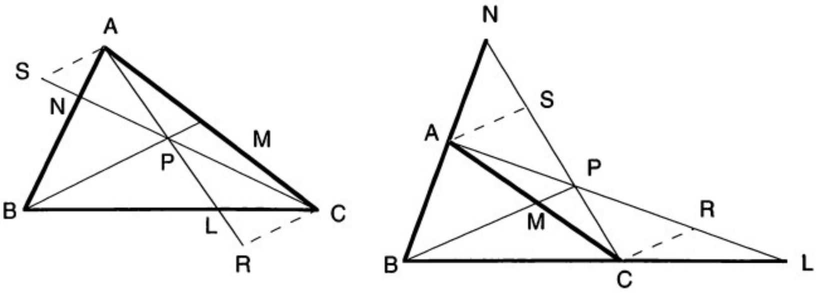

FIGURE 2-6

This can be written as:

$$CA = \frac{(RC)(MA)}{PM} \tag{III}$$

$$\triangle PCM \sim \triangle SCA \Rightarrow \frac{CM}{CA} = \frac{PM}{AS}$$

This can be written as:

$$CA = \frac{(AS)(CM)}{PM} \tag{IV}$$

From (III) and (IV):

$$\frac{(RC)(MA)}{PM} = \frac{(AS)(CM)}{PM}$$

This can be written as:

$$\frac{CM}{MA} = \frac{RC}{AS} \tag{V}$$

To obtain our desired result, we multiply (I), (II), and (V):

$$\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = \frac{AS}{BP} \cdot \frac{BP}{CR} \cdot \frac{RC}{AS} = 1$$ ●

To complete the proof of Ceva's theorem, we must now prove the converse of the implication proved above; that is, we will now prove that *if the lines containing the vertices of $\triangle ABC$ intersect the opposite sides in points L, M, and N, respectively, so that* $\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$, *then these lines,* $\overleftrightarrow{AL}$, $\overleftrightarrow{BM}$, *and* $\overleftrightarrow{CN}$, *are concurrent.*

Proof Suppose $\overleftrightarrow{BM}$ and $\overleftrightarrow{AL}$ intersect at point P. Draw $\overleftrightarrow{PC}$ and call its intersection with $\overleftrightarrow{AB}$ N'. Now that $\overleftrightarrow{AL}$, $\overleftrightarrow{BM}$, and $\overleftrightarrow{CN'}$ are concurrent, we can use the part of Ceva's theorem proved earlier to state the following:

$$\frac{AN'}{N'B} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$$

Our hypothesis stated that:

$$\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$$

Therefore $\frac{AN'}{N'B} = \frac{AN}{NB}$, so N and N' must coincide, proving concurrency. ●

APPLICATIONS OF CEVA'S THEOREM

One of the best ways to show the usefulness of Ceva's theorem is to apply it to the proof of the concurrency of the various line segments encountered in elementary geometry. The simplest application is to prove the concurrency of the medians of a triangle. To best appreciate the "power" of Ceva's theorem, you should first recall the conventional method of proving the medians of a triangle concurrent. Suffice it to say that it is quite long and complex. Compared to this rather cumbersome proof, the method we use here should provoke some excitement about Ceva's theorem.

Application 1 Prove that the medians of a triangle are concurrent. ●

Proof In $\triangle ABC$, $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are medians (see Figure 2-7). Therefore $AN = NB$, $BL = LC$, and $CM = MA$. Multiplying these equalities gives us:

$$(AN)(BL)(CM) = (NB)(LC)(MA) \quad \text{or} \quad \frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{CM}{MA} = 1$$

INTERACTIVE 2-7

Drag vertices *A*, *B*, and *C* to change the shape of the triangle and see that the medians always meet at one point.

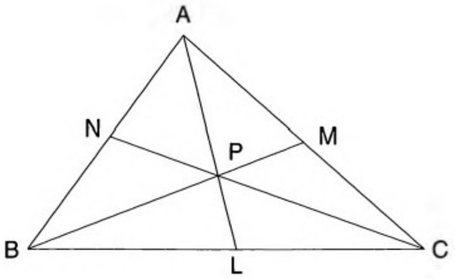

FIGURE 2-7

Thus by Ceva's theorem, $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent. ●

Again, it would be advisable to compare the conventional proof (that presented in the context of elementary geometry) for the concurrency of the altitudes of a triangle to the following proof, which uses Ceva's theorem.

Application 2 Prove that the altitudes of a triangle are concurrent. ●

Proof In $\triangle ABC$, $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are altitudes. You can follow this proof for both diagrams of Figure 2-8 because the same proof holds true for both an acute and an obtuse triangle.

$$\triangle ANC \sim \triangle AMB \Rightarrow \frac{AN}{MA} = \frac{AC}{AB} \qquad \text{(I)}$$

$$\triangle BLA \sim \triangle BNC \Rightarrow \frac{BL}{NB} = \frac{AB}{BC} \qquad \text{(II)}$$

$$\triangle CMB \sim \triangle CLA \Rightarrow \frac{CM}{LC} = \frac{BC}{AC} \qquad \text{(III)}$$

%/ AE 1 G // E 1

INTERACTIVE 2-8

Drag vertices *A*, *B*, and *C* to change the shape of the triangle and see that the altitudes always meet at one point.

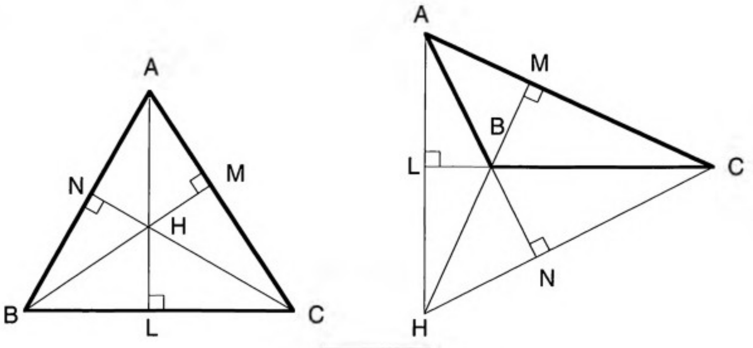

FIGURE 2-8

Multiplying (I), (II), and (III) gives us:

$$\frac{AN}{MA}\cdot\frac{BL}{NB}\cdot\frac{CM}{LC}=\frac{AC}{AB}\cdot\frac{AB}{BC}\cdot\frac{BC}{AC}=1$$

Therefore the altitudes are concurrent (by Ceva's theorem). ●

The proof that the three angle bisectors of a triangle are concurrent is left as an exercise. The following proof should be helpful in working that exercise.

Application 3 Prove that the bisector of any interior angle of a nonisosceles triangle and the bisectors of the two exterior angles at the other vertices are concurrent. ●

Proof In $\triangle ABC$, $\overleftrightarrow{AL}$ bisects $\angle BAC$ and meets $\overleftrightarrow{BC}$ at point L, $\overleftrightarrow{BM}$ bisects exterior $\angle ABE$ and meets $\overleftrightarrow{AC}$ at point M, and $\overleftrightarrow{CN}$ bisects exterior $\angle ACF$ and meets $\overleftrightarrow{AB}$ at point N (see Figure 2-9).

Because the bisector ($\overleftrightarrow{AL}$) of an interior angle of a triangle partitions the opposite side proportionally to the remaining two sides of the triangle:

$$\frac{BL}{LC}=\frac{AB}{AC} \tag{I}$$

An exterior angle bisector partitions the side that it intersects proportionally to the remaining sides of the triangle. This property produces the following proportions:

$$\text{For } \overleftrightarrow{BM}:\quad \frac{CM}{MA}=\frac{BC}{AB} \tag{II}$$

$$\text{For } \overleftrightarrow{CN}:\quad \frac{AN}{NB}=\frac{AC}{BC} \tag{III}$$

By multiplying (I), (II), and (III), we get:

$$\frac{BL}{LC}\cdot\frac{CM}{MA}\cdot\frac{AN}{NB}=\frac{AB}{AC}\cdot\frac{BC}{AB}\cdot\frac{AC}{BC}=1$$

INTERACTIVE 2-9

Drag vertices *A*, *B*, and *C* to change the shape of the triangle and see that the indicated bisectors of the angles (interior and exterior) always meet at one point.

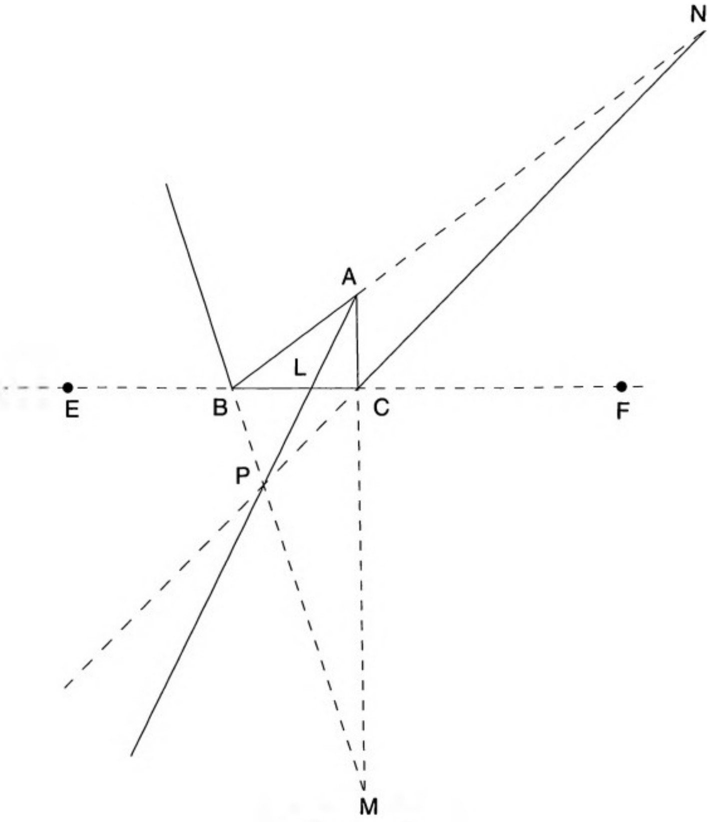

FIGURE 2-9

By Ceva's theorem, we may conclude that $\overleftrightarrow{AL}$, $\overleftrightarrow{BM}$, and $\overleftrightarrow{CN}$ are concurrent. ●

Sometimes the question of concurrency is a bit disguised, as in the following application.

Application 4 In $\triangle ABC$, $\overline{PQ} \parallel \overline{BC}$ and intersects $\overline{AB}$ and $\overline{AC}$ at points *P* and *Q*, respectively (see Figure 2-10). Prove that $\overline{PC}$ and $\overline{QB}$ intersect at a point on median $\overline{AM}$. ●

INTERACTIVE 2-10

Drag vertices *A*, *B*, and *C* to change the shape of the triangle; drag point *P* on $\overline{AB}$ and see that $\overline{PC}$ and $\overline{QB}$ always meet at a point on $\overline{AM}$.

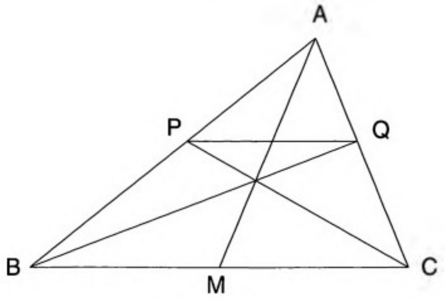

FIGURE 2-10

Proof Because $\overline{PQ} \parallel \overline{BC}$:

$$\frac{AP}{PB} = \frac{AQ}{QC} \quad \text{or} \quad \frac{AP}{PB} \cdot \frac{QC}{AQ} = 1 \qquad \text{(I)}$$

Because $\overline{AM}$ is a median, $BM = MC$. Therefore:

$$\frac{BM}{MC} = 1 \qquad \text{(II)}$$

By multiplying (I) and (II), we get:

$$\frac{AP}{PB} \cdot \frac{QC}{AQ} \cdot \frac{BM}{MC} = 1$$

Thus, by Ceva's theorem, $\overline{AM}$, $\overline{QB}$, and $\overline{PC}$ are concurrent, or $\overline{QB}$ and $\overline{PC}$ intersect at a point on $\overline{AM}$. ●

Up to this point, all our applications have been used to prove concurrency. The following application demonstrates a somewhat different use of Ceva's theorem.

Application 5 In $\triangle ABC$, where $\overline{CD}$ is the altitude to $\overline{AB}$ and P is any point on $\overline{DC}$, $\overline{AP}$ intersects $\overline{CB}$ at point Q and $\overline{BP}$ intersects $\overline{CA}$ at point R (see Figure 2-11). Prove that $\angle RDC \cong \angle QDC$. ●

Proof Let $\overrightarrow{DR}$ and $\overrightarrow{DQ}$ intersect the line containing C and parallel to $\overline{AB}$, at points G and H, respectively.

$$\triangle CGR \sim \triangle ADR \Rightarrow \frac{CR}{RA} = \frac{GC}{AD} \qquad \text{(I)}$$

$$\triangle BDQ \sim \triangle CHQ \Rightarrow \frac{BQ}{QC} = \frac{DB}{CH} \qquad \text{(II)}$$

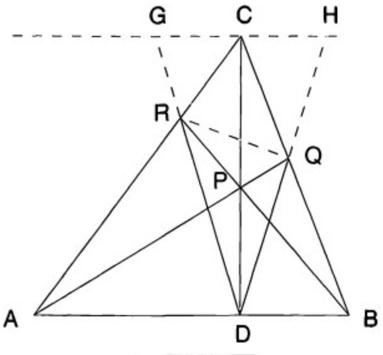

FIGURE 2-11

We now apply Ceva's theorem to $\triangle ABC$ to get:

$$\frac{CR}{RA}\cdot\frac{AD}{DB}\cdot\frac{BQ}{QC}=1 \tag{III}$$

Substituting (I) and (II) into (III) gives us:

$$\frac{GC}{AD}\cdot\frac{AD}{DB}\cdot\frac{DB}{CH}=1 \quad\text{or}\quad \frac{GC}{CH}=1$$

This implies that $GC = CH$. Thus $\overline{CD}$ is the perpendicular bisector of $\overline{GH}$. Hence $\triangle GCD \cong \triangle HCD$, and therefore $\angle RDC \cong \angle QDC$. ●

From the preceding applications, we have seen how Ceva's theorem easily enables us to prove theorems whose proofs would otherwise be quite complex. Ceva's theorem again demonstrates its usefulness in assisting us in proving an interesting point of concurrency in a triangle known as the *Gergonne point.*

THE GERGONNE POINT

A fascinating point of concurrency in a triangle was first established by French mathematician Joseph-Diaz Gergonne (1771–1859). Gergonne reserved a distinct place in the history of mathematics as the initiator (in 1810) of the first purely mathematical journal, *Annales des mathématiques pures et appliqués.* The journal appeared monthly until 1832 and was known as *Annales del Gergonne.* During the time of its publication, Gergonne published about two hundred papers, mostly on geometry. Gergonne's *Annales* played an important role in the establishment of projective and algebraic geometry by giving some of the greatest minds of the times an opportunity to share information. Here we consider a rather simple theorem established by Gergonne that exhibits concurrency and is easily proved using Ceva's theorem.

THEOREM 2.2 The lines containing a vertex of a triangle and the point of tangency of the opposite side with the inscribed circle are concurrent. (This point of concurrency is known as the **Gergonne point** of the triangle.)

Proof Circle O is tangent to sides $\overline{AB}$, $\overline{AC}$, and $\overline{BC}$ of $\triangle ABC$ at points N, M, and L, respectively (see Figure 2-12). It follows that $AN = AM$, $BL = BN$, and $CM = CL$. Each of these equalities can be written as:

$$\frac{AN}{AM}=1 \quad \frac{BL}{BN}=1 \quad \frac{CM}{CL}=1$$

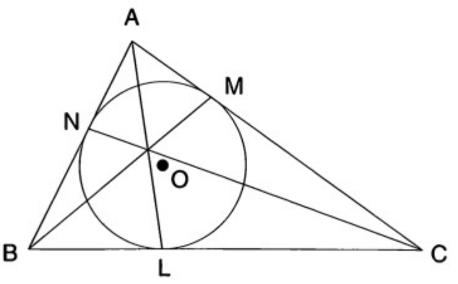

FIGURE 2-12

By multiplying these three fractions, we get:

$$\frac{AN}{AM} \cdot \frac{BL}{BN} \cdot \frac{CM}{CL} = 1$$

Therefore:

$$\frac{AN}{BN} \cdot \frac{BL}{CL} \cdot \frac{CM}{AM} = 1$$

By Ceva's theorem, this equality implies that $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent. The point of concurrency is the Gergonne point of $\triangle ABC$. ●

EXERCISES

1. Prove that the angle bisectors of a triangle are concurrent.

2. If point P is situated on $\overline{BC}$ so that $AB + BP = AC + CP$, point Q is situated on $\overline{AC}$ so that $BC + CQ = AB + AQ$, and point R is situated on $\overline{AB}$ so that $BC + BR = AC + AR$, prove that $\overline{AP}$, $\overline{BQ}$, and $\overline{CR}$ are concurrent (see Figure 2-13). (This point of concurrency is known as the *Nagel point** of $\triangle ABC$.)

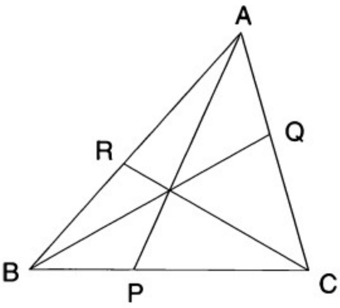

FIGURE 2-13

---

* Discovered by C. H. Nagel (1803–1882), the point can also be described as the intersection of the lines from the vertices of a triangle to the points of tangency of the opposite escribed circles.

3. $\triangle ABC$ cuts a circle at points E, E', D, D', F, and F', as in Figure 2-14. Prove that if $\overline{AD}$, $\overline{BF}$, and $\overline{CE}$ are concurrent, then $\overline{AD'}$, $\overline{BF'}$, and $\overline{CE'}$ are also concurrent.

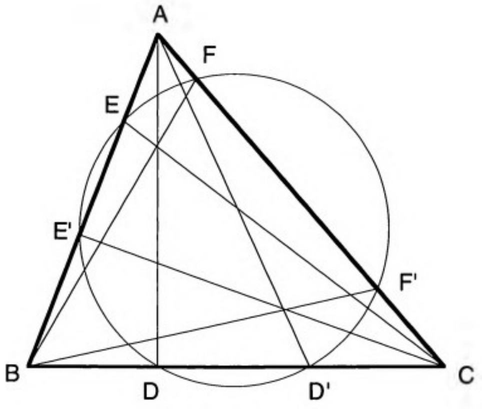

FIGURE 2-14

4. In $\triangle ABC$ (Figure 2-15), $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent at point P. Points R, S, and T are chosen on $\overline{BC}$, $\overline{AC}$, and $\overline{AB}$, respectively, so that $\overline{NR} \parallel \overline{AC}$, $\overline{LS} \parallel \overline{AB}$, and $\overline{MT} \parallel \overline{BC}$. Prove that $\overline{AR}$, $\overline{BS}$, and $\overline{CT}$ are concurrent (at point Q).

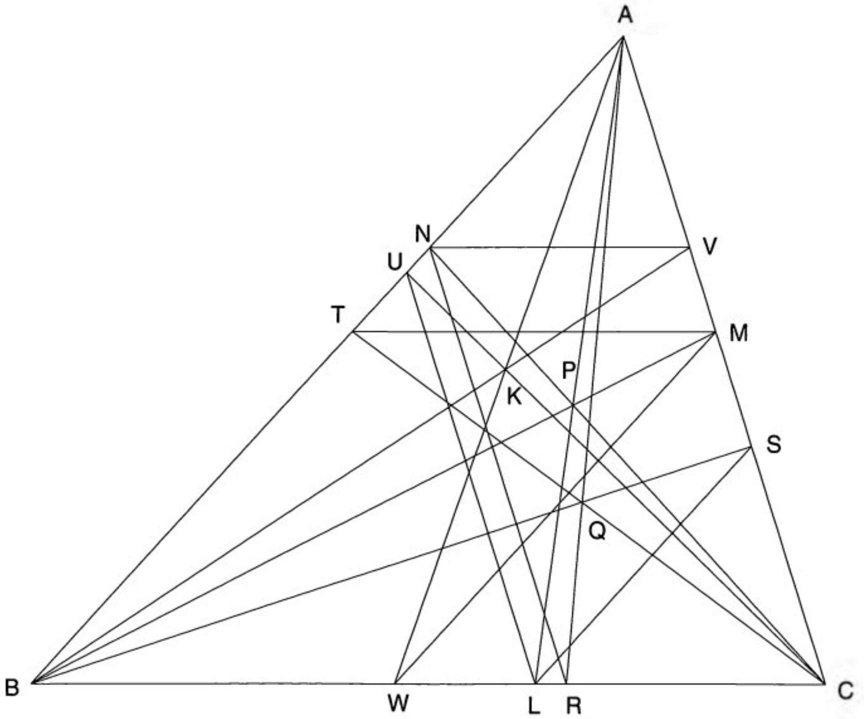

FIGURE 2-15

5. In $\triangle ABC$ (Figure 2-15), $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent at point P. Points U, V, and W are chosen on $\overline{AB}$, $\overline{AC}$, and $\overline{BC}$, respectively, so that $\overline{LU} \parallel \overline{AC}$, $\overline{NV} \parallel \overline{BC}$, and $\overline{MW} \parallel \overline{AB}$. Prove that $\overline{AW}$, $\overline{BV}$, and $\overline{CU}$ are concurrent (at point K).

6. In $\triangle ABC$ (Figure 2-16), $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent at point K and L, M, and N are points on $\overline{BC}$, $\overline{AC}$, and $\overline{AB}$, respectively. Points P, R, and Q are respective midpoints of $\overline{AL}$, $\overline{CN}$, and $\overline{BM}$. Prove that $\overline{DP}$, $\overline{EQ}$, and $\overline{FR}$ are concurrent if D, E, and F are respective midpoints of $\overline{BC}$, $\overline{AC}$, and $\overline{AB}$.

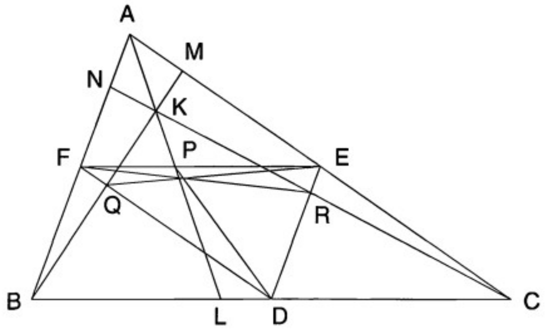

FIGURE 2-16

7. In $\triangle ABC$ (Figure 2-17), $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent at point P. Points S, Q, and R are midpoints of $\overline{MN}$, $\overline{ML}$, and $\overline{NL}$, respectively. Prove that $\overrightarrow{AS}$, $\overrightarrow{BR}$, and $\overrightarrow{CQ}$ are concurrent.

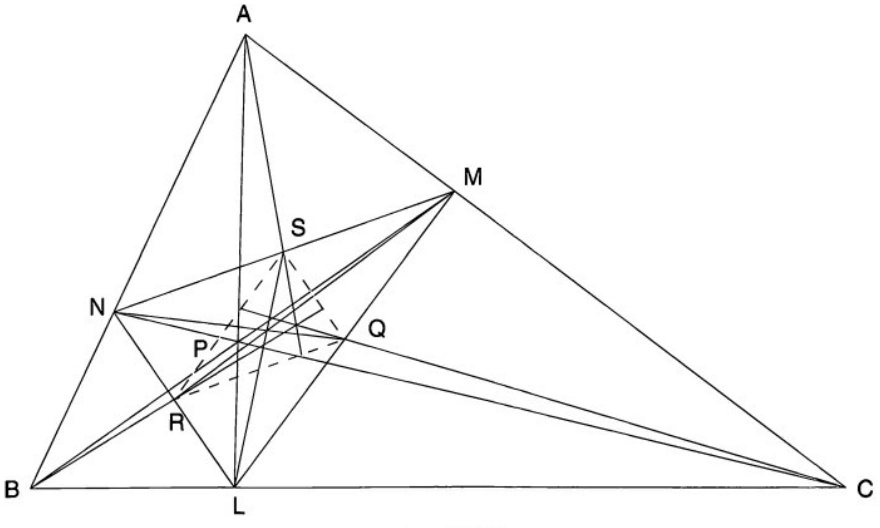

FIGURE 2-17

8. In $\triangle ABC$ (Figure 2-17), $\overline{AL}$, $\overline{BM}$, and $\overline{CN}$ are concurrent at point P. Points S, Q, and R are points on $\overline{MN}$, $\overline{ML}$, and $\overline{NL}$, respectively. If $\overline{LS}$, $\overline{MR}$, and $\overline{NQ}$ are concurrent, prove that $\overrightarrow{AS}$, $\overrightarrow{BR}$, and $\overrightarrow{CQ}$ are also concurrent.
9. Circles P, O, and Q are escribed circles of $\triangle ABC$, with the points of tangency indicated in Figure 2-18. Prove that $\overline{AD}$, $\overline{BE}$, and $\overline{CF}$ are concurrent.

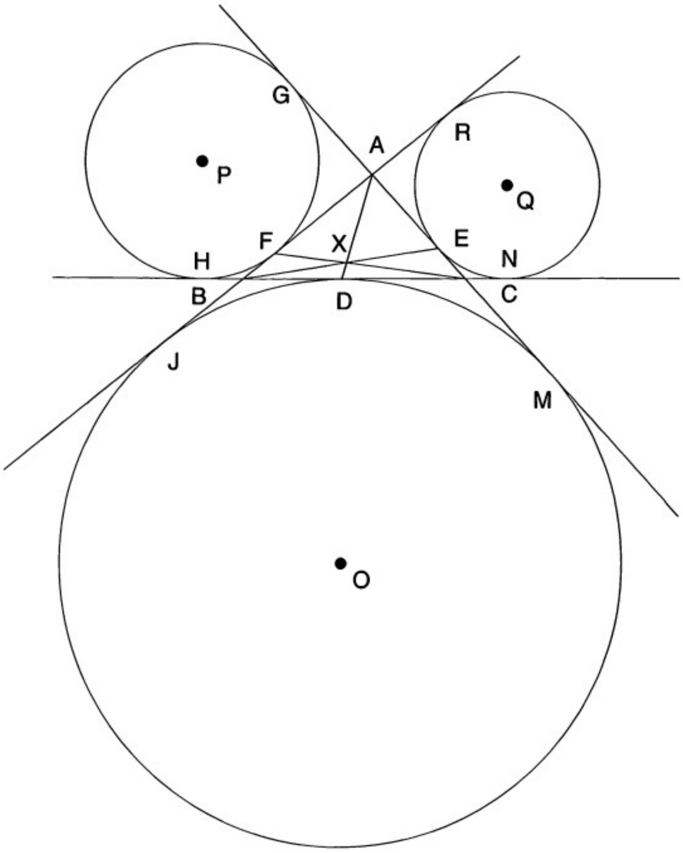

FIGURE 2-18

10. Given three circles, nonintersecting, mutually external, and with distinct radii, connect the intersection of internal common tangents of each pair of circles with the center of the other circle, as in Figure 2-19. Prove that the three resulting line segments are concurrent.

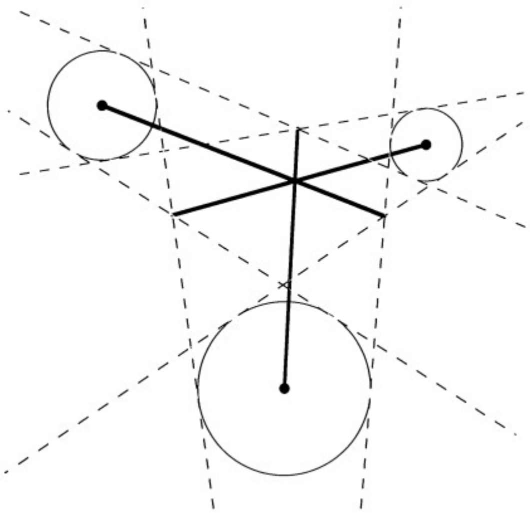

FIGURE 2-19

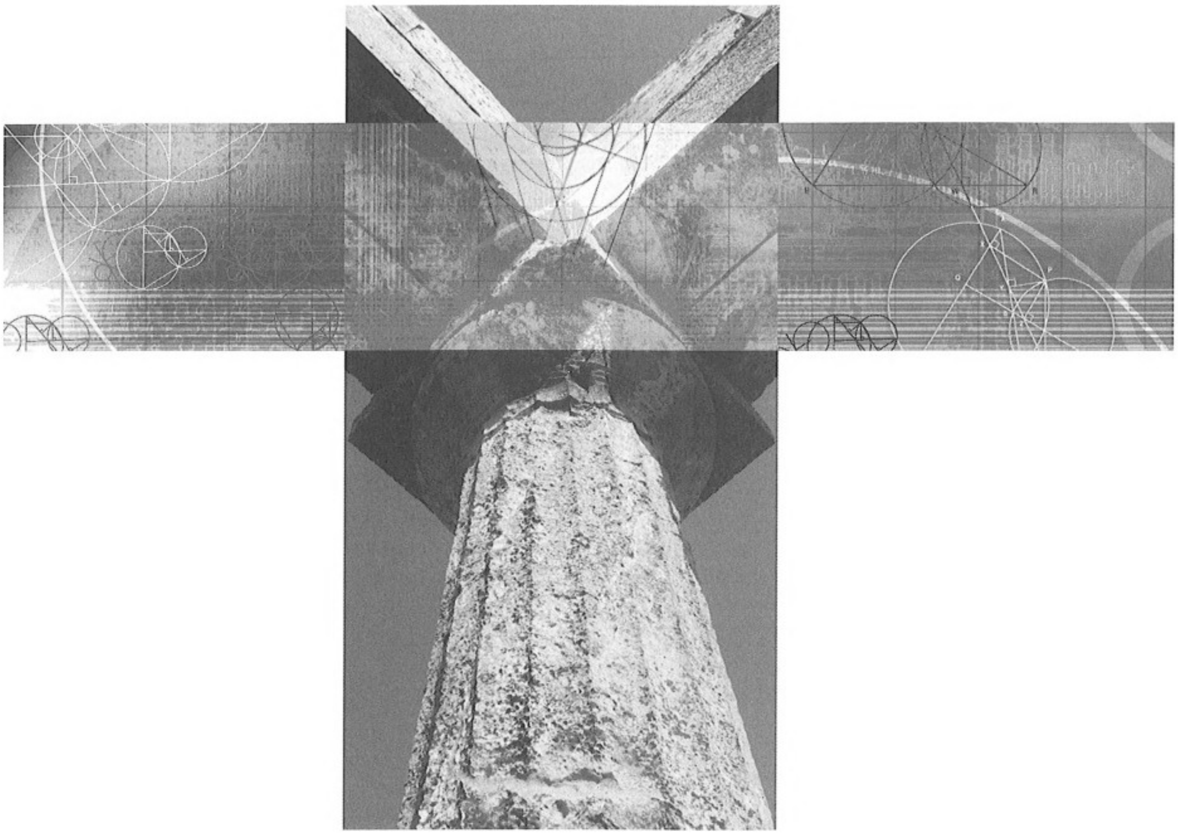
CHAPTER
THREE



COLLINEARITY OF POINTS

DUALITY

Many statements in geometry involve relationships between points and lines. In a statement concerning points and lines in a plane, when the word *point* is replaced by the word *line* and the word *line* is replaced by the word *point* each time these words are used in the statement, the newly formed statement is said to be the *dual* of the original statement. Occasionally, other modifications may need to be made in order to preserve proper sentence structure. This principle of duality was discovered by Charles Julien Brianchon (1785–1864) while using this relationship on a theorem by Blaise Pascal. We will visit these theorems later in this chapter. However, the transition from Chapter 2 to Chapter 3 follows the principle of duality because concurrency of lines is the dual of collinearity of points. The primary focus of this chapter is collinearity.

Let us first familiarize ourselves with the principle of duality. Consider the following examples of dual statements:

Statement	**Dual Statement**
1. Two distinct points determine a unique line.	1. Two distinct lines determine a unique point.
2. Any point contains an infinite number of lines.	2. Any line contains an infinite number of points.
3. Only one triangle is determined by three noncollinear points.	3. Only one trilateral is determined by three nonconcurrent lines.

This last example of duality demonstrates that related words also need to be changed when forming the dual of a statement. Specifically, note that *collinear* and *concurrent* are dual words, as are *triangle* and *trilateral.*

Recall Ceva's theorem (see Figure 3-1):

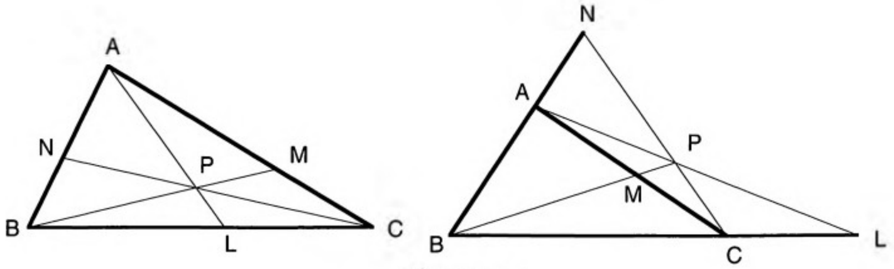


FIGURE 3-1

The three lines containing the vertices A, B, and C of $\triangle ABC$ and intersecting the opposite sides at points L, M, and N, respectively, are concurrent if and only if $\frac{AN}{NB}\cdot\frac{BL}{LC}\cdot\frac{CM}{MA}=1$.

For the most part, the dual of a postulate is also a postulate, and the dual of a definition is itself a definition. Thus, if a statement is a theorem, its dual is likely to be a theorem as well.* In any case, we would at least have a statement that would be a good candidate to be a theorem. A valid proof would be needed to establish the statement as a theorem.

This is precisely what we will now investigate. With our knowledge of duality, we will form the dual statement of Ceva's theorem. Actually, it was the rediscovery of Menelaus of Alexandria's famous but forgotten theorem,† which we will discuss in the next section, that led Giovanni Ceva in the first book of his *De lineis rectis se invicem secantibus statica constructio* (Milan, 1678) to produce his theorem by the principle of duality. Note the duality relationship between the two theorems.

The three points P, Q, and R on the sides $\overleftrightarrow{AC}$, $\overleftrightarrow{AB}$, and $\overleftrightarrow{BC}$, respectively, of $\triangle ABC$ (see Figure 3-2) are collinear if and only if $\frac{AQ}{QB}\cdot\frac{BR}{RC}\cdot\frac{CP}{PA}=-1$.‡ This statement is in fact a theorem, known as *Menelaus's theorem,* that is the subject of the next section.

INTERACTIVE 3-2

Drag vertices *A*, *B*, and *C* to change the shape of the triangle; drag points *P* and *Q* and see that Menelaus's theorem is always true.

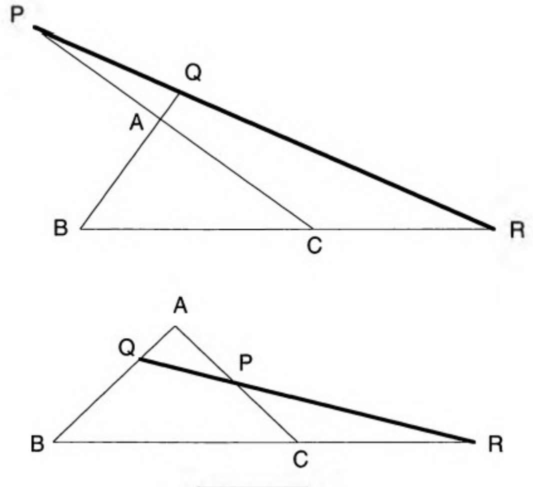

FIGURE 3-2

---

* In a geometric system exclusively based on postulates and definitions whose respective duals are all true, the dual of every theorem is also a theorem. This claim is easily justified by realizing that the proof of the dual of a theorem can be produced by simply replacing each statement of the proof of the original theorem by its dual.

† During the Dark Ages, much of classical Greek mathematics was lost and forgotten.

‡ The reason for the negative sign is explained in the proof of this theorem.

MENELAUS'S THEOREM

Menelaus of Alexandria, in about A.D. 100 in a work titled *Sphaerica,* produced the well-known plane version of the theorem that we will present here. He used the plane version to develop the spherical analogue,* which was the purpose of his treatise. As we have mentioned, this theorem, which today bears Menelaus's name, did not become popular until it was rediscovered by Giovanni Ceva as a part of his work in 1678.

THEOREM 3.1 **(Menelaus's theorem)** The three points P, Q, and R on the sides $\overleftrightarrow{AC}$, $\overleftrightarrow{AB}$, and $\overleftrightarrow{BC}$, respectively, of $\triangle ABC$ are collinear if and only if $\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = -1$.

Like Ceva's theorem, Menelaus's theorem is an equivalence and therefore requires proofs for each of the two statements (converses of each other) that comprise the entire theorem. We will first prove that *if the three points P, Q, and R on the sides $\overleftrightarrow{AC}$, $\overleftrightarrow{AB}$, and $\overleftrightarrow{BC}$,, respectively, of $\triangle ABC$ are collinear, then* $\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = -1$. We offer two proofs of this part of Menelaus's theorem.

Proof I Draw a line containing C, parallel to $\overleftrightarrow{AB}$ and intersecting $\overline{PQR}$ (or $\overline{QPR}$) at point D (see Figure 3-3).

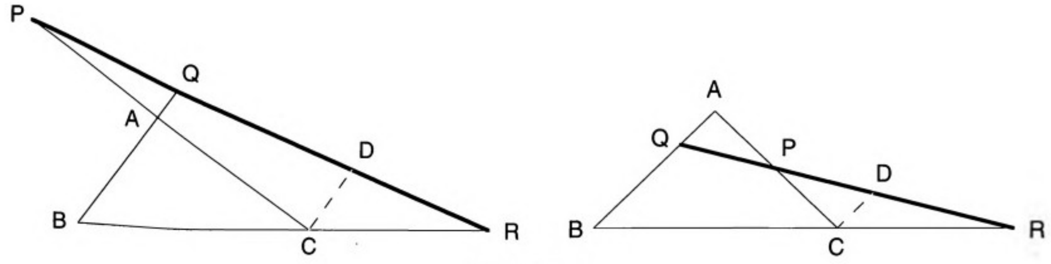

FIGURE 3-3

$$\triangle DCR \sim \triangle QBR \Rightarrow \frac{DC}{QB} = \frac{RC}{BR} \quad or \quad DC = \frac{(QB)(RC)}{BR} \qquad \text{(I)}$$

$$\triangle PDC \sim \triangle PQA \Rightarrow \frac{DC}{AQ} = \frac{CP}{PA} \quad or \quad DC = \frac{(AQ)(CP)}{PA} \qquad \text{(II)}$$

---

* The spherical analogue to Theorem 3.1 for spherical triangle ABC is $\frac{\sin \widehat{AQ}}{\sin \widehat{QB}} \cdot \frac{\sin \widehat{BR}}{\sin \widehat{RC}} \cdot \frac{\sin \widehat{CP}}{\sin \widehat{PA}} = -1$.

From (I) and (II), we get:

$$\frac{(QB)(RC)}{BR} = \frac{(AQ)(CP)}{PA} \quad \text{or} \quad (QB)(RC)(PA) = (AQ)(CP)(BR)$$

This gives us:

$$\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = 1$$

By taking direction into account in the left-hand diagram of Figure 3-3, we see that $\frac{AQ}{QB}$, $\frac{BR}{RC}$, and $\frac{CP}{PA}$ are each negative ratios; in the right-hand diagram of Figure 3-3, $\frac{BR}{RC}$ is a negative ratio, whereas $\frac{AQ}{QB}$ and $\frac{CP}{PA}$ are positive ratios. Because in each case there is an odd number of negative ratios:

$$\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = -1 \bullet$$

Proof II Once again we begin by assuming collinearity of P, Q, and R. Draw $\overline{BM} \perp \overleftrightarrow{PR}$, $\overline{AN} \perp \overleftrightarrow{PR}$, and $\overline{CL} \perp \overleftrightarrow{PR}$ (see Figure 3-4).

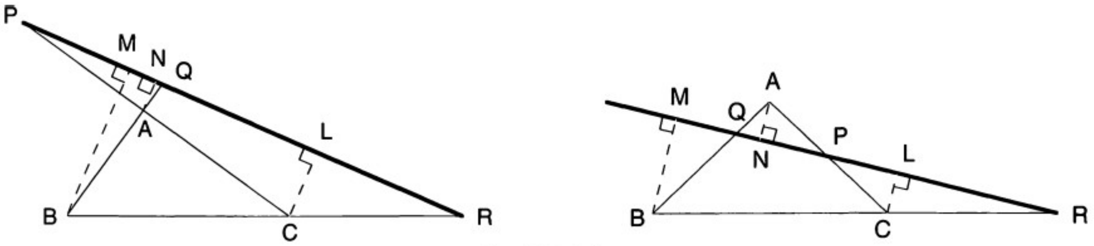

FIGURE 3-4

$$\triangle BMQ \sim \triangle ANQ \Rightarrow \frac{AQ}{QB} = \frac{AN}{BM} \qquad \text{(I)}$$

$$\triangle LCP \sim \triangle NAP \Rightarrow \frac{CP}{PA} = \frac{LC}{AN} \qquad \text{(II)}$$

$$\triangle MRB \sim \triangle LRC \Rightarrow \frac{BR}{RC} = \frac{BM}{LC} \qquad \text{(III)}$$

By multiplying (I), (II), and (III), we get, numerically:

$$\frac{AQ}{QB} \cdot \frac{CP}{PA} \cdot \frac{BR}{RC} = \frac{AN}{BM} \cdot \frac{LC}{AN} \cdot \frac{BM}{LC} = 1$$

From (I) and (II), we get:

$$\frac{(QB)(RC)}{BR} = \frac{(AQ)(CP)}{PA} \quad \text{or} \quad (QB)(RC)(PA) = (AQ)(CP)(BR)$$

This gives us:

$$\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = 1$$

By taking direction into account in the left-hand diagram of Figure 3-3, we see that $\frac{AQ}{QB}$, $\frac{BR}{RC}$, and $\frac{CP}{PA}$ are each negative ratios; in the right-hand diagram of Figure 3-3, $\frac{BR}{RC}$ is a negative ratio, whereas $\frac{AQ}{QB}$ and $\frac{CP}{PA}$ are positive ratios. Because in each case there is an odd number of negative ratios:

$$\frac{AQ}{QB} \cdot \frac{BR}{RC} \cdot \frac{CP}{PA} = -1 \; \bullet$$

Ⓟroof II Once again we begin by assuming collinearity of P, Q, and R. Draw $\overline{BM} \perp \overleftrightarrow{PR}$, $\overline{AN} \perp \overleftrightarrow{PR}$, and $\overline{CL} \perp \overleftrightarrow{PR}$ (see Figure 3-4).

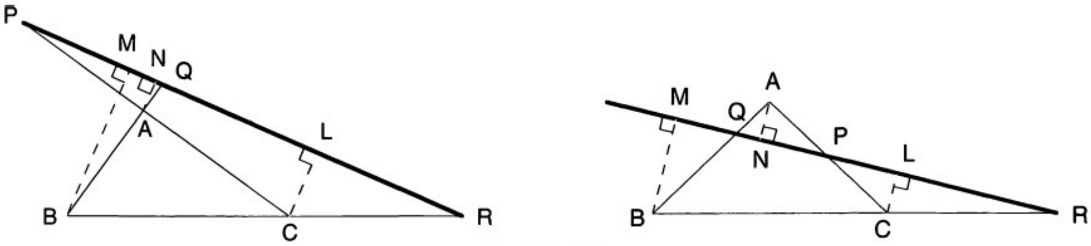

FIGURE 3-4

$$\triangle BMQ \sim \triangle ANQ \Rightarrow \frac{AQ}{QB} = \frac{AN}{BM} \tag{I}$$

$$\triangle LCP \sim \triangle NAP \Rightarrow \frac{CP}{PA} = \frac{LC}{AN} \tag{II}$$

$$\triangle MRB \sim \triangle LRC \Rightarrow \frac{BR}{RC} = \frac{BM}{LC} \tag{III}$$

By multiplying (I), (II), and (III), we get, numerically:

$$\frac{AQ}{QB} \cdot \frac{CP}{PA} \cdot \frac{BR}{RC} = \frac{AN}{BM} \cdot \frac{LC}{AN} \cdot \frac{BM}{LC} = 1$$

APPLICATIONS OF MENELAUS'S THEOREM

Before investigating other famous theorems that can be proved using Menelaus's theorem, we will consider a few applications of Menelaus's theorem. Each of these unnamed theorems presents some very interesting results that are very easily proved using Menelaus's theorem.

Application 1 Prove that the interior angle bisectors of two angles of a nonisosceles triangle and the exterior angle bisector of the third angle meet the opposite sides in three collinear points. ●

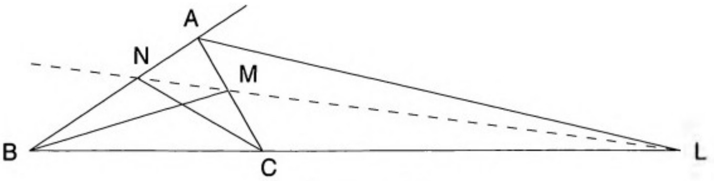

FIGURE 3-5

Proof In $\triangle ABC$, $\overline{BM}$ and $\overline{CN}$ are the interior angle bisectors, while $\overline{AL}$ bisects the exterior angle at point A (see Figure 3-5). Because the bisector of an angle (interior or exterior) of a triangle partitions the opposite side proportionally to the two remaining sides, we have:

$$\frac{AM}{MC}=\frac{AB}{BC}\quad\frac{BN}{NA}=\frac{BC}{AC}\quad\text{and}\quad\frac{CL}{BL}=\frac{AC}{AB}$$

Therefore, by multiplication:

$$\frac{AM}{MC}\cdot\frac{BN}{NA}\cdot\frac{CL}{BL}=\frac{AB}{BC}\cdot\frac{BC}{AC}\cdot\frac{AC}{AB}=1$$

However, because $\frac{CL}{BL}=\frac{-CL}{LB}$:

$$\frac{AM}{MC}\cdot\frac{BN}{NA}\cdot\frac{CL}{LB}=-1$$

Thus, by Menelaus's theorem, points N, M, and L must be collinear. ●

Application 2 Prove that the exterior angle bisectors of any nonisosceles triangle meet the opposite sides in three collinear points. ●

Proof In $\triangle ABC$, the bisectors of the exterior angles at A, B, and C meet the opposite sides (extended) at points N, L, and M, respectively (see Figure 3-6). Because the bisector of an angle (interior or exterior) of a triangle partitions the opposite side proportionally to the two remaining sides, we have:

$$\frac{CL}{AL} = \frac{BC}{AB} \quad \frac{AM}{BM} = \frac{AC}{BC} \quad \text{and} \quad \frac{BN}{CN} = \frac{AB}{AC}$$

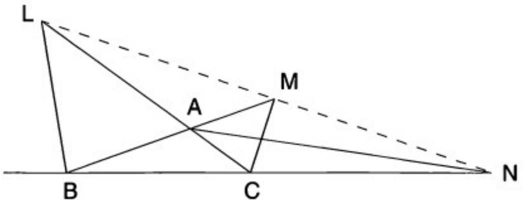

FIGURE 3-6

Therefore:

$$\frac{CL}{AL} \cdot \frac{AM}{BM} \cdot \frac{BN}{CN} = \frac{BC}{AB} \cdot \frac{AC}{BC} \cdot \frac{AB}{AC} = -1 \text{ (because all three ratios are negative)}$$

Thus, by Menelaus's theorem, points L, M, and N are collinear. ●

Application 3 A circle through vertices B and C of $\triangle ABC$ meets $\overline{AB}$ at point P and $\overline{AC}$ at point R. If $\overleftrightarrow{PR}$ meets $\overleftrightarrow{BC}$ at point Q, prove that $\frac{QC}{QB} = \frac{(RC)(AC)}{(PB)(AB)}$. ●

Proof Consider $\triangle ABC$ with transversal $\overline{QPR}$ (Figure 3-7). By Menelaus's theorem:

$$\frac{RC}{AR} \cdot \frac{AP}{PB} \cdot \frac{QB}{CQ} = -1$$

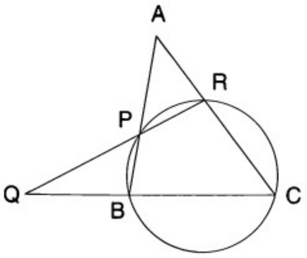

FIGURE 3-7

Then, considering absolute values, we have:

$$\frac{QC}{QB} = \frac{RC}{AR} \cdot \frac{AP}{PB} \tag{I}$$

However, $(AP)(AB) = (AR)(AC)$. (If two secant segments intersect outside the circle, the product of the lengths of one secant segment and its external segment equals the product of the lengths of the other secant segment and its external segment.) Therefore:

$$\frac{AP}{AR} = \frac{AC}{AB} \tag{II}$$

By substituting (II) into (I), we get our desired result:

$$\frac{QC}{QB} = \frac{(RC)(AC)}{(PB)(AB)} \bullet$$

Often, both Menelaus's theorem and its dual, Ceva's theorem, are needed to solve a problem or prove a theorem. The next applications demonstrate this.

Application 4 In right triangle ABC, points P and Q are on $\overline{BC}$ and $\overline{AC}$, respectively, such that $CP = CQ = 2$. Through R, the point of intersection of $\overline{AP}$ and $\overline{BQ}$, a line is drawn also passing through point C and meeting $\overline{AB}$ at point S. $\overleftrightarrow{PQ}$ meets $\overleftrightarrow{AB}$ at point T. If hypotenuse $AB = 10$ and $AC = 8$, find TS (Figure 3-8). ●

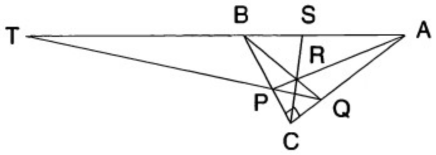

FIGURE 3-8

Solution In right triangle ABC, hypotenuse $AB = 10$ and $AC = 8$, so $BC = 6$ (by the Pythagorean theorem). In $\triangle ABC$, because $\overline{AP}$, $\overline{BQ}$, and $\overline{CS}$ are concurrent, by Ceva's theorem:

$$\frac{AQ}{QC} \cdot \frac{CP}{PB} \cdot \frac{BS}{SA} = 1$$

Substituting, we get:

$$\frac{6}{2} \cdot \frac{2}{4} \cdot \frac{BS}{10 - BS} = 1 \quad \text{or} \quad BS = 4$$

Now consider $\triangle ABC$ with transversal $\overline{QPT}$. By Menelaus's theorem:

$$\frac{AQ}{QC} \cdot \frac{CP}{PB} \cdot \frac{BT}{TA} = -1$$

Because we are not dealing with directed line segments, this may be restated as:

$$(AQ)(CP)(BT) = (QC)(PB)(AT)$$

Substituting, we get:

$$(6)(2)(BT) = (2)(4)(BT + 10)$$

Solving for BT gives us $BT = 20$, and thus $TS = 24$. ●

Application 5 In quadrilateral $ABCD$, $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$ meet at point P, while $\overleftrightarrow{AD}$ and $\overleftrightarrow{BC}$ meet at point Q. Diagonals $\overleftrightarrow{AC}$ and $\overleftrightarrow{BD}$ meet $\overleftrightarrow{PQ}$ at points X and Y, respectively. Prove that $\frac{PX}{XQ} = -\frac{PY}{YQ}$ (see Figure 3-9). ●

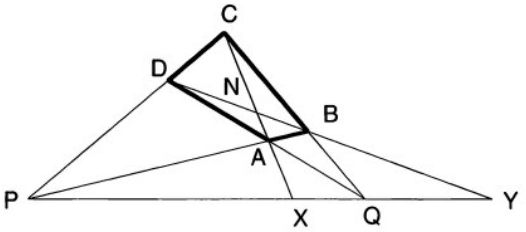

FIGURE 3-9

Proof Consider $\triangle PQC$ with $\overline{PB}$, $\overline{QD}$, and $\overline{CX}$ concurrent. By Ceva's theorem:

$$\frac{PX}{XQ} \cdot \frac{QB}{BC} \cdot \frac{CD}{DP} = 1 \qquad \text{(I)}$$

Now consider $\triangle PQC$ with $\overline{DBY}$ as a transversal. By Menelaus's theorem:

$$\frac{PY}{YQ} \cdot \frac{QB}{BC} \cdot \frac{CD}{DP} = -1 \qquad \text{(II)}$$

Therefore, from (I) and (II):

$$\frac{PX}{XQ} = -\frac{PY}{YQ}$$ ●

We will now consider some rather famous theorems that can be proved using Menelaus's theorem.

DESARGUES'S THEOREM

During his lifetime, Gérard Desargues (1591–1661) did not enjoy the important stature as a mathematician that he has attained in later years. This lack of popularity was in part due to the then recent development of analytic geometry by René Descartes (1596–1650) and to Desargues's introduction of many new and largely unfamiliar terms. (Incidentally, we make every effort in this book not to introduce any new terms in order to make it more reader-friendly—we want to learn from Desargues's misjudgment.)

In 1648, his pupil, Abraham Bosse, a master engraver, published a book titled *Manière universelle de M. Desargues, pour pratiquer la perspective,* which was not popularized until about two centuries later. This book contained a theorem that in the nineteenth century became one of the fundamental propositions of projective geometry. It is this theorem that is of interest to us here. It involves placing any two triangles in a position that will enable the three lines joining corresponding vertices to be concurrent. Remarkably, when this is achieved the pairs of corresponding sides meet in three collinear points. We will prove Desargues's theorem by using Menelaus's theorem.

THEOREM 3.2 **(Desargues's theorem)** If $\triangle A_1B_1C_1$ and $\triangle A_2B_2C_2$ are situated so that the lines joining the corresponding vertices, $\overleftrightarrow{A_1A_2}$, $\overleftrightarrow{B_1B_2}$, and $\overleftrightarrow{C_1C_2}$, are concurrent, then the pairs of corresponding sides intersect in three collinear points.

INTERACTIVE 3-10

Drag vertices A_1, B_1, C_1 and A_2, B_2, C_2 to change the shape of the triangles and point P and see that Desargues's theorem is true.

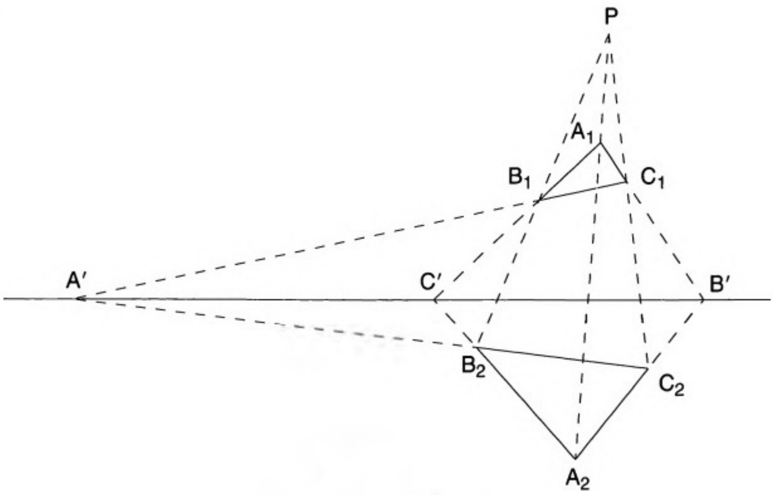

FIGURE 3-10

Proof In Figure 3-10, $\overleftrightarrow{A_1A_2}$, $\overleftrightarrow{B_1B_2}$, and $\overleftrightarrow{C_1C_2}$ all meet at point P, by hypothesis. $\overleftrightarrow{B_2C_2}$ and $\overleftrightarrow{B_1C_1}$ meet at A′; $\overleftrightarrow{A_2C_2}$ and $\overleftrightarrow{A_1C_1}$ meet at B′; $\overleftrightarrow{B_2A_2}$ and $\overleftrightarrow{B_1A_1}$ meet at C′.

Consider $\overline{A'B_1C_1}$ to be a transversal of $\triangle PB_2C_2$. Therefore, by Menelaus's theorem:

$$\frac{PB_1}{B_1B_2} \cdot \frac{B_2A'}{A'C_2} \cdot \frac{C_2C_1}{C_1P} = -1 \qquad \text{(I)}$$

Similarly, considering $\overline{C'B_1A_1}$ as a transversal of $\triangle PB_2A_2$:

$$\frac{PA_1}{A_1A_2} \cdot \frac{A_2C'}{C'B_2} \cdot \frac{B_2B_1}{B_1P} = -1 \text{ (Menelaus's theorem)} \qquad \text{(II)}$$

Now, taking $\overline{B'A_1C_1}$ as a transversal of $\triangle PA_2C_2$:

$$\frac{PC_1}{C_1C_2} \cdot \frac{C_2B'}{B'A_2} \cdot \frac{A_2A_1}{A_1P} = -1 \text{ (Menelaus's theorem)} \qquad \text{(III)}$$

By multiplying (I), (II), and (III), we get:

$$\frac{B_2A'}{A'C_2} \cdot \frac{A_2C'}{C'B_2} \cdot \frac{C_2B'}{B'A_2} = -1$$

Thus, by Menelaus's theorem, applied to $\triangle A_2B_2C_2$, we have points A', B', and C' collinear. ●

It should be noted that the converse of Desargues's theorem is also true. It is the dual of the original theorem. We leave the proof as an exercise.

To appreciate the value of Desargues's theorem, we will examine some applications. Although each may be proved in other ways, we will use the method employing Desargues's theorem.

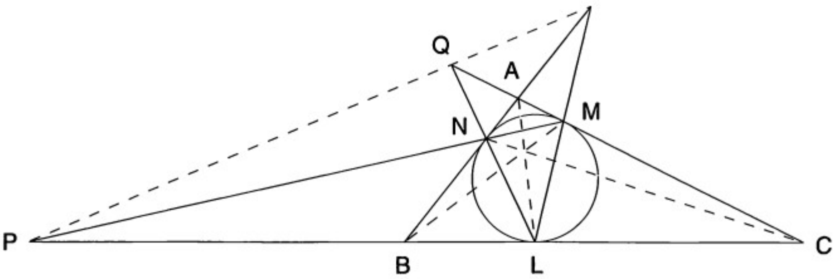

FIGURE 3-11

Application 6 A circle inscribed in $\triangle ABC$ is tangent to sides $\overline{BC}$, $\overline{CA}$, and $\overline{AB}$ at points L, M, and N, respectively. $\overleftrightarrow{MN}$ intersects $\overleftrightarrow{BC}$ at point P, $\overleftrightarrow{NL}$ intersects $\overleftrightarrow{AC}$ at point Q, and $\overleftrightarrow{ML}$ intersects $\overleftrightarrow{AB}$ at point R. Prove that points P, Q, and R are collinear (see Figure 3-11). ●

Proof Because the tangent segments from an external point to a circle are congruent:

$$AN = AM \quad NB = BL \quad MC = LC$$

Therefore:

$$\frac{AN}{NB} \cdot \frac{BL}{LC} \cdot \frac{MC}{AM} = 1$$

By Ceva's theorem, $\overleftrightarrow{AL}$, $\overleftrightarrow{BM}$, and $\overleftrightarrow{CN}$ are concurrent. Because these are the lines joining the corresponding vertices of $\triangle ABC$ and $\triangle LMN$, by Desargues's theorem the intersections of the corresponding sides are collinear; therefore points P, Q, and R are collinear. ●

Application 7 In $\triangle ABC$, points F, E, and D are the feet of the altitudes drawn from the vertices A, B, and C, respectively. The sides of pedal* triangle FED, $\overleftrightarrow{EF}$, $\overleftrightarrow{DF}$, and $\overleftrightarrow{DE}$, intersect the sides of $\triangle ABC$, $\overleftrightarrow{AB}$, $\overleftrightarrow{AC}$, and $\overleftrightarrow{BC}$, at points M, N, and L, respectively. Prove that points M, N, and L are collinear (see Figure 3-12). ●

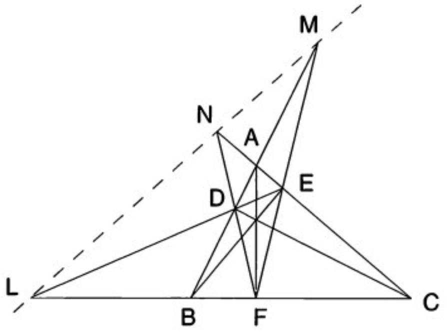

FIGURE 3-12

Proof Let A, B, C and F, E, D be corresponding vertices of $\triangle ABC$ and $\triangle FED$. Because $\overline{AF}$, $\overline{CD}$, and $\overline{BE}$ are concurrent (they are the altitudes of $\triangle ABC$), the intersections of the corresponding sides $\overleftrightarrow{DE}$ and $\overleftrightarrow{BC}$, $\overleftrightarrow{FE}$ and $\overleftrightarrow{BA}$, and $\overleftrightarrow{FD}$ and $\overleftrightarrow{CA}$ are collinear by Desargues's theorem. ●

---

* A pedal triangle (of a given triangle) is formed by joining the feet of the perpendiculars from any given point to the sides of the given triangle.

PASCAL'S THEOREM

Blaise Pascal (1623–1662), a contemporary of Desargues, is regarded today as one of the true geniuses in the history of mathematics. Although eccentricities kept him from achieving his true potential, he is considered one of the originators of the formalized study of probability (an outgrowth of his correspondences with Fermat), and he made many important contributions to other branches of mathematics. We concern ourselves here with one of his contributions to geometry.

In 1640, at the age of sixteen, Pascal published a one-page paper titled *Essay pour les coniques.* It contained a theorem that Pascal referred to as *mysterium hexagrammicum.* The work highly impressed Descartes, who couldn't believe it was the work of a boy. This theorem states that the intersections of the opposite sides of a hexagon inscribed in a conic section are collinear. For our purposes, we will consider only the case in which the conic section is a circle and the hexagon has no pair of opposite sides parallel.

THEOREM 3.3 **(Pascal's theorem)** If a hexagon with no pair of opposite sides parallel is inscribed in a circle, then the intersections of the opposite sides are collinear.

Proof Hexagon $ABCDEF$ is inscribed in a circle (see Figure 3-13). The pairs of opposite sides $\overleftrightarrow{AB}$ and $\overleftrightarrow{DE}$ meet at point L, $\overleftrightarrow{CB}$ and $\overleftrightarrow{EF}$ meet at point M, and $\overleftrightarrow{CD}$ and $\overleftrightarrow{AF}$ meet at point N. Also, $\overleftrightarrow{AB}$ meets $\overleftrightarrow{CN}$ at point X, $\overleftrightarrow{EF}$ meets $\overleftrightarrow{CN}$ at point Y, and $\overleftrightarrow{EF}$ meets $\overleftrightarrow{AB}$ at point Z.

Consider $\overleftrightarrow{BC}$ to be a transversal of $\triangle XYZ$. Then, by Menelaus's theorem:

$$\frac{ZB}{BX} \cdot \frac{XC}{CY} \cdot \frac{YM}{MZ} = -1 \tag{I}$$

Taking $\overleftrightarrow{AF}$ to be a transversal of $\triangle XYZ$:

$$\frac{ZA}{AX} \cdot \frac{YF}{FZ} \cdot \frac{XN}{NY} = -1 \quad \text{(Menelaus's theorem)} \tag{II}$$

Also, because $\overleftrightarrow{DE}$ is a transversal of $\triangle XYZ$:

$$\frac{XD}{DY} \cdot \frac{YE}{EZ} \cdot \frac{ZL}{LX} = -1 \quad \text{(Menelaus's theorem)} \tag{III}$$

By multiplying (I), (II), and (III), we get:

$$\frac{YM}{MZ} \cdot \frac{XN}{NY} \cdot \frac{ZL}{LX} \cdot \frac{(ZB)(ZA)}{(EZ)(FZ)} \cdot \frac{(XD)(XC)}{(AX)(BX)} \cdot \frac{(YE)(YF)}{(DY)(CY)} = -1 \tag{IV}$$

When two secant segments are drawn to a circle from an external point, the product of the lengths of one secant and its external segment equals the product of the lengths of the other secant and its external segment.

INTERACTIVE 3-13

Drag points *A, B, C, D, E,* and *F* on the circle to see that Pascal's theorem is true.

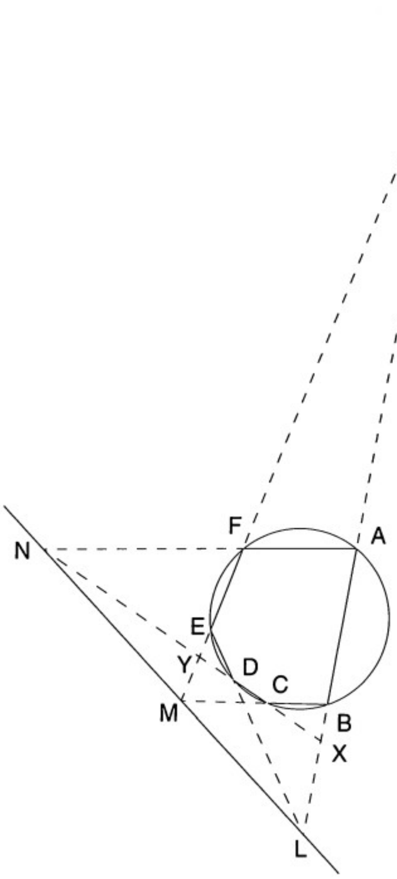

FIGURE 3-13

Therefore:

$$\frac{(ZB)(ZA)}{(EZ)(FZ)} = 1 \qquad \text{(V)}$$

$$\frac{(XD)(XC)}{(AX)(BX)} = 1 \qquad \text{(VI)}$$

$$\frac{(YE)(YF)}{(DY)(CY)} = 1 \qquad \text{(VII)}$$

By substituting (V), (VI), and (VII) into (IV), we get:

$$\frac{YM}{MZ} \cdot \frac{XN}{NY} \cdot \frac{ZL}{LX} = -1$$

Thus, by Menelaus's theorem, points *M, N,* and *L* must be collinear. ●

It is interesting to note that Pascal's theorem can be extended in the following manner.

INTERACTIVE 3-13

Drag points *A, B, C, D, E,* and *F* on the circle to see that Pascal's theorem is true.

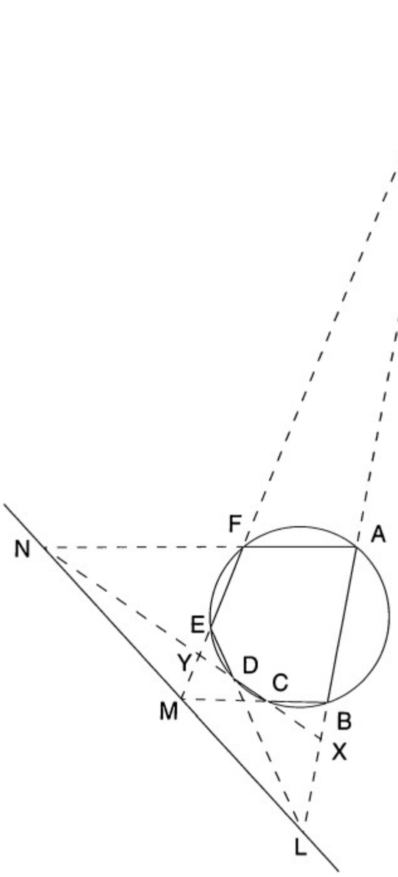

FIGURE 3-13

Therefore:

$$\frac{(ZB)(ZA)}{(EZ)(FZ)} = 1 \qquad \text{(V)}$$

$$\frac{(XD)(XC)}{(AX)(BX)} = 1 \qquad \text{(VI)}$$

$$\frac{(YE)(YF)}{(DY)(CY)} = 1 \qquad \text{(VII)}$$

By substituting (V), (VI), and (VII) into (IV), we get:

$$\frac{YM}{MZ} \cdot \frac{XN}{NY} \cdot \frac{ZL}{LX} = -1$$

Thus, by Menelaus's theorem, points *M, N,* and *L* must be collinear. ●

It is interesting to note that Pascal's theorem can be extended in the following manner.

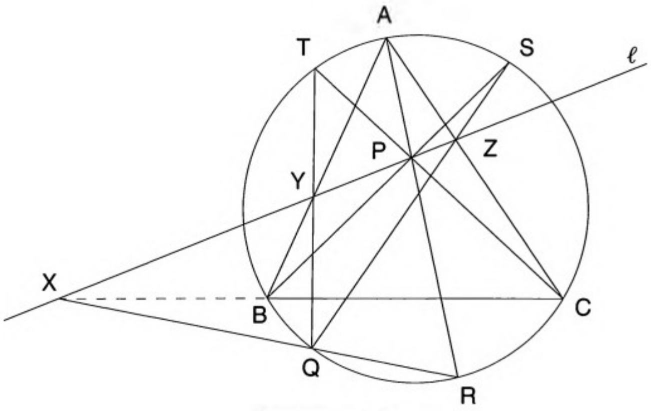

FIGURE 3-16

Application 9 Select any point P not on $\triangle ABC$ and a line ℓ containing P and intersecting sides $\overleftrightarrow{BC}$, $\overleftrightarrow{AB}$, and $\overleftrightarrow{AC}$ at points X, Y, and Z, respectively. Let $\overleftrightarrow{AP}$, $\overleftrightarrow{BP}$, and $\overleftrightarrow{CP}$ intersect the circumcircle of $\triangle ABC$ at points R, S, and T, respectively (see Figure 3-16). Prove that $\overleftrightarrow{RX}$, $\overleftrightarrow{SZ}$, and $\overleftrightarrow{TY}$ are concurrent. ●

Proof Let $\overleftrightarrow{RX}$ intersect the circumcircle at point Q. Consider hexagon $ARQTCB$ and apply Pascal's theorem to it. We notice that because $\overleftrightarrow{AR} \cap \overleftrightarrow{AB}$ at point P and $\overleftrightarrow{RQ} \cap \overleftrightarrow{CB}$ at point X, $\overleftrightarrow{TQ} \cap \overleftrightarrow{AB}$ at a point on ℓ, which must be Y (because $\overleftrightarrow{AB} \cap \ell$ at point Y).

Now consider hexagon $ARQSBC$. Because $\overleftrightarrow{AR} \cap \overleftrightarrow{SB}$ at P and $\overleftrightarrow{RQ} \cap \overleftrightarrow{CB}$ at X, $\overleftrightarrow{SQ} \cap \overleftrightarrow{AC}$ at a point on ℓ, which must be Z. Thus $\overleftrightarrow{RX}$, $\overleftrightarrow{SZ}$, and $\overleftrightarrow{TY}$ are and concurrent. ●

BRIANCHON'S THEOREM

In 1806, at the age of twenty-one, a student at the École Polytechnique, Charles Julien Brianchon (1785–1864), published an article in the *Journal de L'École Polytechnique* that was to become one of the fundamental contributions to the study of conic sections in projective geometry. His development led to a restatement of the somewhat forgotten theorem of Pascal and its extension, after which Brianchon stated a new theorem that now bears his name. Brianchon's theorem, which states "In any hexagon circumscribed about a conic section, the three diagonals cross each other in the same point,"* bears a curious resemblance to Pascal's theorem. They are, in fact, duals of each other. This can be easily seen by comparing the following versions of each theorem:

---

* *Source Book in Mathematics,* edited by D. E. Smith (New York: McGraw-Hill Book Co., 1929), p. 336.

Pascal's Theorem	**Brianchon's Theorem**
The points of intersection of the opposite sides of a hexagon inscribed in a conic section are collinear.	The lines joining the opposite vertices of a hexagon circumscribed about a conic section are concurrent.

Notice that the two statements above are alike except for the underlined words, which are duals of one another. As with Pascal's theorem, we will consider only the conic section that is a circle.

THEOREM 3.5 **(Brianchon's theorem)** If a hexagon is circumscribed about a circle (see Figure 3-17), the lines containing opposite vertices are concurrent.

INTERACTIVE 3-17

Drag points *A, B, C, D, E,* and *F* on the circle and see that Brianchon's theorem is true.

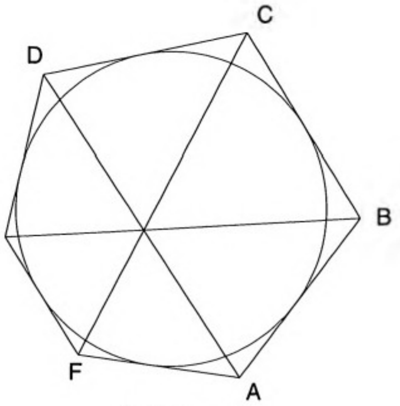

FIGURE 3-17

The simplest proofs of this theorem require knowledge of concepts from projective geometry. Although we are prepared at this point to prove this theorem by Euclidean methods, our proof will be more concise if we wait until we study radical axes later in this chapter on page 71.

Brianchon suggested the following application immediately after the statement of his new theorem.

Application 10 Pentagon *ABCDE* is circumscribed about a circle, with points of tangency at *F*, *M*, *N*, *R*, and *S*. If diagonals $\overline{AD}$ and $\overline{BE}$ intersect at point *P*, prove that points *C*, *P*, and *F* are collinear (see Figure 3-18). ●

Proof Consider the hexagon circumscribed about a circle (Figure 3-17) having its sides $\overline{AF}$ and $\overline{EF}$ merge into one line segment. Thus $\overline{AFE}$ is now a side of a circumscribed pentagon with *F* as one point of tangency (see Figure 3-18). Thus we can view the pentagon in Figure 3-18 as a degenerate hexagon. We then simply apply Brianchon's theorem to this degenerate hexagon to obtain our desired conclusion. That is, $\overline{AD}$, $\overline{BE}$, and $\overline{CF}$ are concurrent at point *P*, or points *C*, *P*, and *F* are collinear. ●

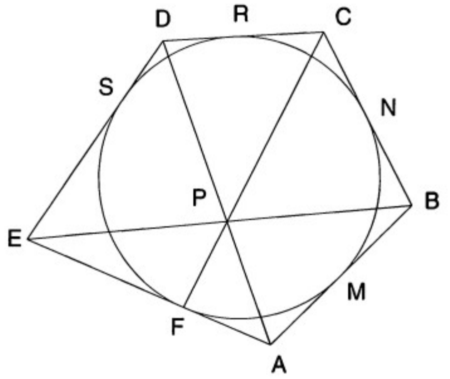

FIGURE 3-18

PAPPUS'S THEOREM

Consider the vertices of a hexagon $AB'CA'BC'$ (Figure 3-19) located alternately on two lines (see Figure 3-20). Suppose we now draw the lines that were the opposite sides of the hexagon to locate their point of intersection. We find that the three points of intersection of these pairs of "opposite sides" are collinear. This conclusion was first published by Pappus of Alexandria in his *Mathematical Collection* circa A.D. 300.

For the purpose of providing a proof, we will restate Pappus's theorem. You will notice once again that the proof uses Menelaus's theorem repeatedly.

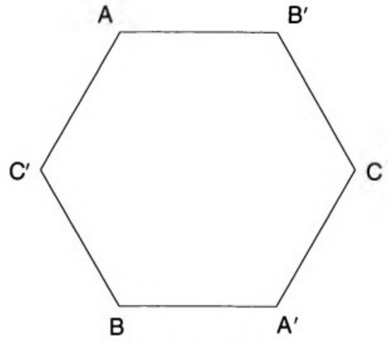

FIGURE 3-19

INTERACTIVE 3-20

Drag points *A′, B′, C′, A, B,* and *C* and see that Pappus's theorem is true.

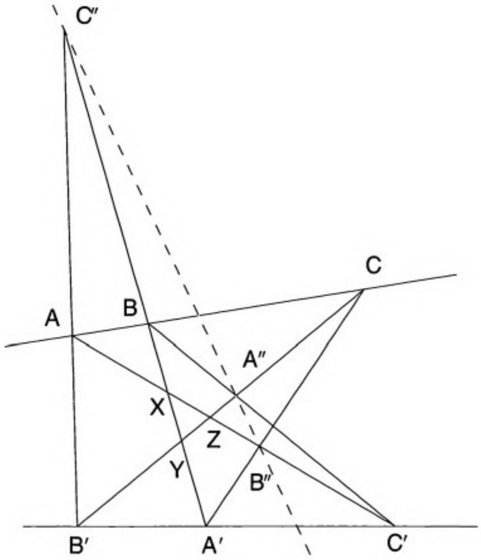

FIGURE 3-20

THEOREM 3.6 **(Pappus's theorem)** Points A, B, and C are on one line, and points A', B', and C' are on another line (in any order). If $\overleftrightarrow{AB'}$ and $\overleftrightarrow{A'B}$ meet at C'', $\overleftrightarrow{AC'}$ and $\overleftrightarrow{A'C}$ meet at B'', and $\overleftrightarrow{BC'}$ and $\overleftrightarrow{B'C}$ meet at A'', then points A'', B'', and C'' are collinear.

Proof In Figure 3-20, $\overline{B'C}$ meets $\overline{A'B}$ at point Y, $\overline{AC'}$ meets $\overline{A'B}$ at point X, and $\overline{B'C}$ meets $\overline{AC'}$ at point Z. Consider $\overline{C''AB'}$ as a transversal of $\triangle XYZ$. By Menelaus's theorem:

$$\frac{ZB'}{YB'} \cdot \frac{XA}{ZA} \cdot \frac{YC''}{XC''} = -1 \qquad \text{(I)}$$

Taking $\overline{A'B''C}$ as a transversal of $\triangle XYZ$:

$$\frac{YA'}{XA'} \cdot \frac{XB''}{ZB''} \cdot \frac{ZC}{YC} = -1 \text{ (Menelaus's theorem)} \qquad \text{(II)}$$

PAPPUS'S THEOREM

Consider the vertices of a hexagon $AB'CA'BC'$ (Figure 3-19) located alternately on two lines (see Figure 3-20). Suppose we now draw the lines that were the opposite sides of the hexagon to locate their point of intersection. We find that the three points of intersection of these pairs of "opposite sides" are collinear. This conclusion was first published by Pappus of Alexandria in his *Mathematical Collection* circa A.D. 300.

For the purpose of providing a proof, we will restate Pappus's theorem. You will notice once again that the proof uses Menelaus's theorem repeatedly.

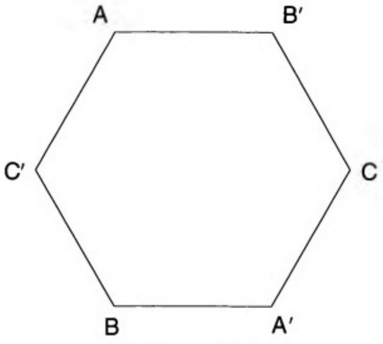

FIGURE 3-19

INTERACTIVE 3-20

Drag points A', B', C', A, B, and C and see that Pappus's theorem is true.

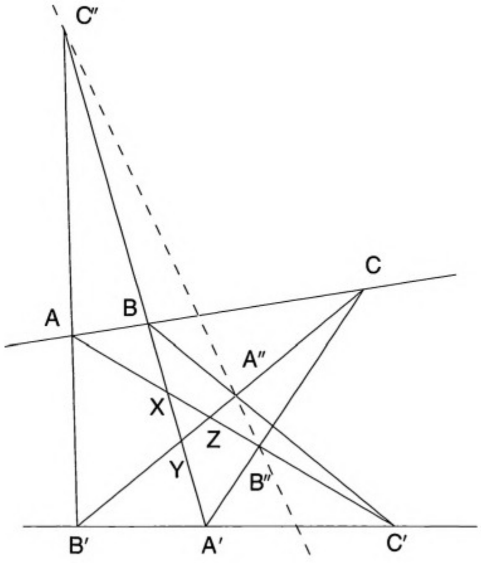

FIGURE 3-20

THEOREM 3.6 **(Pappus's theorem)** Points A, B, and C are on one line, and points A', B', and C' are on another line (in any order). If $\overleftrightarrow{AB'}$ and $\overleftrightarrow{A'B}$ meet at C'', $\overleftrightarrow{AC'}$ and $\overleftrightarrow{A'C}$ meet at B'', and $\overleftrightarrow{BC'}$ and $\overleftrightarrow{B'C}$ meet at A'', then points A'', B'', and C'' are collinear.

Proof In Figure 3-20, $\overline{B'C}$ meets $\overline{A'B}$ at point Y, $\overline{AC'}$ meets $\overline{A'B}$ at point X, and $\overline{B'C}$ meets $\overline{AC'}$ at point Z. Consider $\overline{C''AB'}$ as a transversal of $\triangle XYZ$. By Menelaus's theorem:

$$\frac{ZB'}{YB'} \cdot \frac{XA}{ZA} \cdot \frac{YC''}{XC''} = -1 \qquad \text{(I)}$$

Taking $\overline{A'B''C}$ as a transversal of $\triangle XYZ$:

$$\frac{YA'}{XA'} \cdot \frac{XB''}{ZB''} \cdot \frac{ZC}{YC} = -1 \text{ (Menelaus's theorem)} \qquad \text{(II)}$$

INTERACTIVE 3-21

Drag vertices *A*, *B*, and *C* to change the shape of the triangle; drag point *P* on the circle and watch the Simson line.

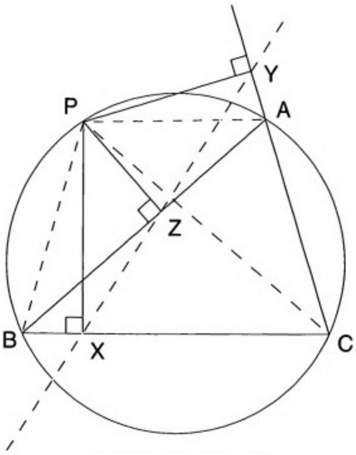

FIGURE 3-21

Proof I (See Figure 3-21.) Draw $\overline{PA}$, $\overline{PB}$, and $\overline{PC}$.

$$m\angle PBA = \frac{1}{2} m\,\widehat{AP}$$

$$m\angle PCA = \frac{1}{2} m\,\widehat{AP}$$

Therefore $m\angle PBA = m\angle PCA = a$. Thus:

$$\frac{BZ}{PZ} = \cot a = \frac{CY}{PY} \text{ (in } \triangle PZB \text{ and } \triangle PYC) \quad \text{or} \quad \frac{BZ}{PZ} = \frac{CY}{PY}$$

This implies:

$$\frac{BZ}{CY} = \frac{PZ}{PY} \tag{I}$$

Similarly, $m\angle PAB = m\angle PCB = b$ (both are $\frac{1}{2}m\widehat{PB}$). Therefore:

$$\frac{AZ}{PZ} = \cot b = \frac{CX}{PX} \text{ (in } \triangle PAZ \text{ and } \triangle PCX) \quad \text{or} \quad \frac{AZ}{PZ} = \frac{CX}{PX}$$

This implies:

$$\frac{CX}{AZ} = \frac{PX}{PZ} \tag{II}$$

Because $\angle PBC$ and $\angle PAC$ are opposite angles of an inscribed (cyclic) quadrilateral, they are supplementary. However, $\angle PAY$ is also supplementary to $\angle PAC$. Therefore:

$$m\angle PBC = m\angle PAY = c$$

Thus:

$$\frac{BX}{PX} = \cot c = \frac{AY}{PY}\,(\text{in } \triangle PBX \text{ and } \triangle PAY) \quad \text{or} \quad \frac{BX}{PX} = \frac{AY}{PY}$$

This implies:

$$\frac{AY}{BX} = \frac{PY}{PX} \tag{III}$$

By multiplying (I), (II), and (III), we obtain:

$$\frac{BZ}{CY} \cdot \frac{CX}{AZ} \cdot \frac{AY}{BX} = \frac{PZ}{PY} \cdot \frac{PX}{PZ} \cdot \frac{PY}{PX} = 1 \text{ (or } -1\text{, had we considered direction)}$$

Thus, by Menelaus's theorem, points X, Y, and Z are collinear. These three points determine the Simson line of $\triangle ABC$ with respect to point P. ●

Proof II (See Figure 3-21.) Because $\angle PYA$ is supplementary to $\angle PZA$, quadrilateral $PZAY$ is cyclic. Draw $\overline{PA}$, $\overline{PB}$, and $\overline{PC}$. Therefore:

$$m\angle PYZ = m\angle PAZ \tag{I}$$

Similarly, because $\angle PYC$ is supplementary to $\angle PXC$, quadrilateral $PXCY$ is cyclic, and therefore:

$$m\angle PYX = m\angle PCB \tag{II}$$

However, quadrilateral $PACB$ is also cyclic because it is inscribed in the given circumcircle, and therefore:

$$m\angle PAZ (m\angle PAB) = m\angle PCB \tag{III}$$

From (I), (II), and (III), $m\angle PYZ = m\angle PYX$, and thus points X, Y, and Z are collinear. ●

For other proofs of Simson's theorem, see *Challenging Problems in Geometry* by A. S. Posamentier and C. T. Salkind (New York: Dover, 1996), pages 43–45.

There are many simple applications of the Simson line. We will consider a few of them.

Application 11 Sides $\overleftrightarrow{AB}$, $\overleftrightarrow{BC}$, and $\overleftrightarrow{CA}$ of $\triangle ABC$ are cut by a transversal at points Q, R, and S, respectively. The circumcircles of $\triangle ABC$ and $\triangle SCR$ intersect at point P. Prove that quadrilateral $APSQ$ is cyclic. ●

Proof Draw perpendiculars $\overline{PX}$, $\overline{PY}$, $\overline{PZ}$, and $\overline{PW}$ to $\overleftrightarrow{AB}$, $\overleftrightarrow{AC}$, $\overleftrightarrow{QR}$, and $\overleftrightarrow{BC}$, respectively, as in Figure 3-22.

Because point P is on the circumcircle of $\triangle ABC$, points X, Y, and W are collinear (Simson's theorem). Similarly, because point P is on the circumcircle of $\triangle SCR$, points Y, Z, and W are collinear. It then follows that points X, Y, and Z are collinear.

Thus point P must lie on the circumcircle of $\triangle AQS$ (the converse of Simson's theorem, whose proof we leave as an exercise). Therefore quadrilateral $APSQ$ is cyclic. ●

INTERACTIVE 3-22

Drag vertices *A*, *B*, and *C* to change the shape of the triangle and note that *APSQ* is always cyclic.

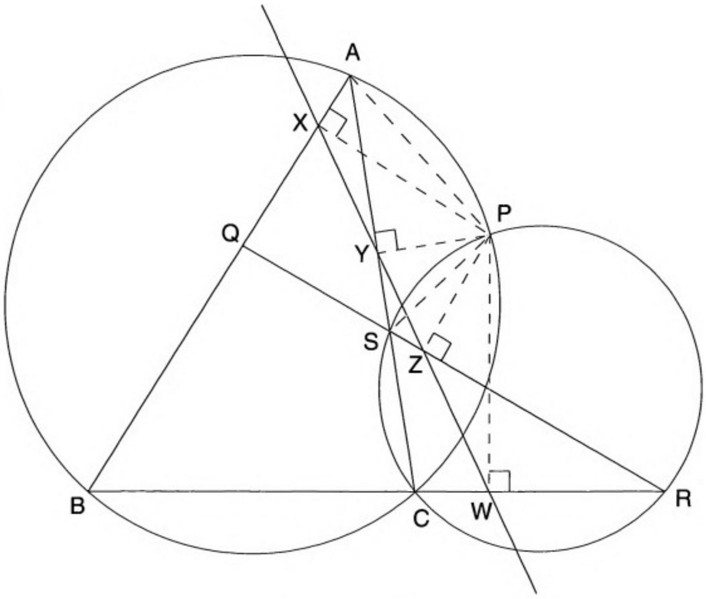

FIGURE 3-22

Application 12 $\overline{AB}$, $\overline{BC}$, $\overline{EC}$, and $\overline{ED}$ form triangles *ABC*, *FBD*, *EFA*, and *EDC*. Prove that the four circumcircles of these triangles meet at a common point. ●

Proof Consider the circumcircles of △*ABC* and △*FBD*, which meet at points *B* and *P*. From point *P* draw perpendiculars $\overline{PX}$, $\overline{PY}$, $\overline{PZ}$, and $\overline{PW}$ to $\overline{BC}$, $\overline{AB}$, $\overline{ED}$, and $\overline{EC}$, respectively (see Figure 3-23). Because point *P* is on the circumcircle of △*ABC*, points *X*, *Y*, and *W* are collinear. Therefore points *X*, *Y*, *Z*, and *W* are collinear.

Because points *Y*, *Z*, and *W* are collinear, point *P* must lie on the circumcircle of △*EFA* (the converse of Simson's theorem). By the same reasoning, because points *X*, *Z*, and *W* are collinear, point *P* lies on the circumcircle of △*EDC*. Thus all four circles pass through point *P*. ●

The Simson line has many interesting properties; we present a few here.

THEOREM 3.8 **(Simson line property I)** If the altitude $\overline{AD}$ of △*ABC* meets the circumcircle at point *P*, then the Simson line of *P* with respect to △*ABC* is parallel to the line tangent to the circle at point *A*.

INTERACTIVE 3-23

Drag vertices *A, B, C, D,* and *E* to change the shape of the triangles and see that the circles always meet at a point.

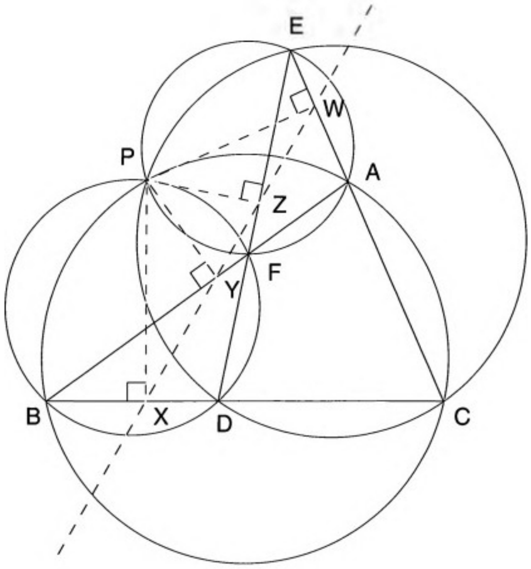

FIGURE 3-23

Proof Because $\overline{PX}$ and $\overline{PZ}$ are perpendicular, respectively, to sides $\overleftrightarrow{AC}$ and $\overleftrightarrow{AB}$ of $\triangle ABC$, points X, D, and Z determine the Simson line of point P with respect to $\triangle ABC$.

Draw $\overline{PB}$ (see Figure 3-24). Consider quadrilateral $PDBZ$, where $m\angle PDB = m\angle PZB = 90°$, thus making quadrilateral $PDBZ$ a cyclic quadrilateral.* In quadrilateral $PDBZ$:

$$m\angle DZB = m\angle DPB \qquad \text{(I)}$$

INTERACTIVE 3-24

Drag vertices *A, B,* and *C* to change the shape of the triangle and see that the required lines are parallel.

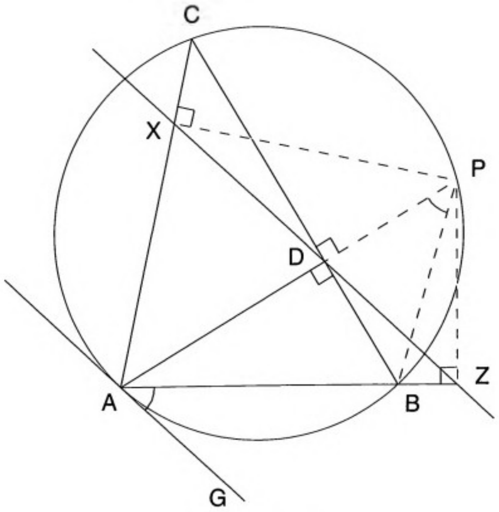

FIGURE 3-24

---

* Because opposite angles are supplementary.

However, in the circumcircle of $\triangle ABC$, $m\angle GAB = \frac{1}{2}(m\overset{\frown}{AB})$, and $m\angle DPB(m\angle APB) = \frac{1}{2}(m\overset{\frown}{AB})$. Therefore:

$$m\angle GAB = m\angle DPB \qquad \text{(II)}$$

From (I) and (II), by transitivity, $m\angle DZB = m\angle GAB$, and thus Simson line $\overleftrightarrow{XDZ}$ is parallel to tangent $\overleftrightarrow{GA}$. ●

THEOREM 3.9 **(Simson line property II)** From point P on the circumcircle of $\triangle ABC$, if perpendiculars $\overline{PX}$, $\overline{PY}$, and $\overline{PZ}$ are drawn to sides $\overleftrightarrow{AC}$, $\overleftrightarrow{AB}$, and $\overleftrightarrow{BC}$, respectively, then $(PA)(PZ) = (PB)(PX)$ (see Figure 3-25).

Proof Because $m\angle PYB = m\angle PZB = 90°$, quadrilateral $PYZB$ is cyclic.* Therefore:

$$m\angle PBY = m\angle PZY \qquad \text{(I)}$$

Likewise, because $m\angle PXA = m\angle PYA = 90°$, quadrilateral $PXAY$ is cyclic, and:

$$m\angle PXY = m\angle PAY \qquad \text{(II)}$$

Points X, Y, and Z are collinear (the Simson line). Therefore, from (I) and (II):

$$\triangle PAB \sim \triangle PXZ \Rightarrow \frac{PA}{PX} = \frac{PB}{PZ} \quad \text{or} \quad (PA)(PZ) = (PB)(PX)$$ ●

INTERACTIVE 3-25

Drag vertices *A*, *B*, and *C* to change the shape of the triangle; drag point *P* on the circle and see that the products are equal.

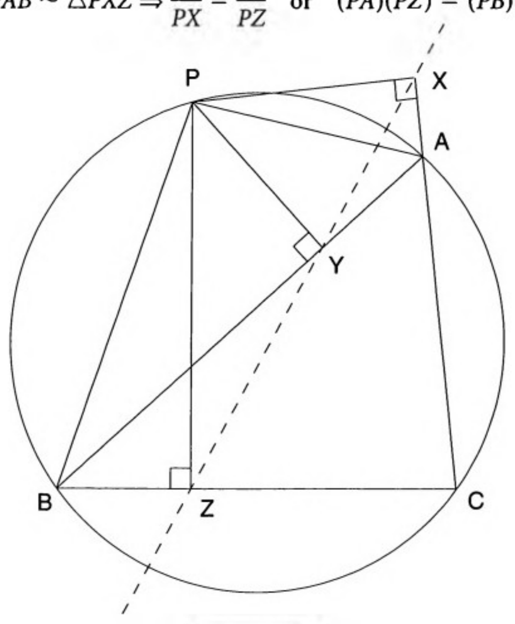

FIGURE 3-25

---

* A quadrilateral is cyclic (i.e., may be inscribed in a circle) if one side subtends congruent angles at the two opposite vertices.

THEOREM 3.10 **(Simson line property III)** The measure of the angle determined by the Simson line of two given points on the circumcircle of a given triangle is equal to one-half the measure of the arc determined by the two points.

Proof In Figure 3-26, $\overleftrightarrow{XYZ}$ is the Simson line for point P and $\overleftrightarrow{UVW}$ is the Simson line for point Q. Extend $\overline{PX}$ and $\overline{QW}$ to meet the circle at points M and N, respectively. Then draw $\overline{AM}$ and $\overline{AN}$. Because $m\angle PZB = m\angle PXB = 90°$, quadrilateral $PZXB$ is cyclic, and:

$$m\angle ZXP = m\angle ZBP \qquad \text{(I)}$$

$$m\angle ABP = m\angle AMP \quad \text{or} \quad m\angle ZBP = m\angle AMP \qquad \text{(II)}$$

From (I) and (II), $m\angle ZXP = m\angle AMP$. Therefore:

$$\overleftrightarrow{XYZ} \parallel \overline{AM}$$

In a similar fashion, it may be shown that $\overleftrightarrow{UVW} \parallel \overline{AN}$.

Hence, if T is the point of intersection of the two Simson lines, then $m\angle XTW = m\angle MAN$ because their corresponding sides are parallel. Now, $m\angle MAN = \frac{1}{2}(m\overset{\frown}{MN})$, but because $\overline{PM} \parallel \overline{QN}$, we have $m\overset{\frown}{MN} = m\overset{\frown}{PQ}$ and therefore $m\angle MAN = \frac{1}{2}(m\overset{\frown}{PQ})$. Thus $m\angle XTW = \frac{1}{2}(m\overset{\frown}{PQ})$. ●

INTERACTIVE 3-26

Drag vertices *A*, *B*, and *C* to change the shape of the triangle; drag points *P* and *Q* on the circle, and the angle is one-half the measure of the arc.

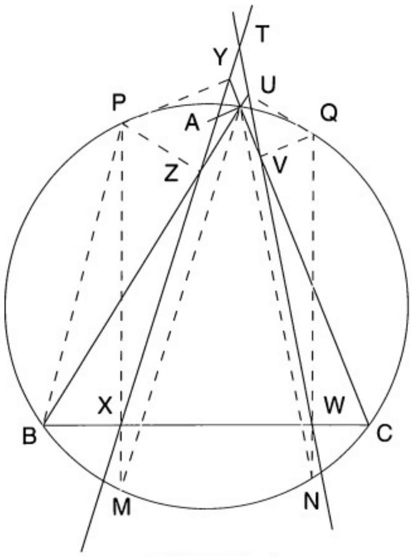

FIGURE 3-26

Here is an interesting application of Simson's theorem to an earlier dilemma. Recall the proof of the fallacy that all scalene triangles are isosceles in Chapter 1. Perpendiculars were drawn from point G to $\overleftrightarrow{AC}$, $\overleftrightarrow{BC}$, and $\overleftrightarrow{AB}$, meeting these lines at points D, F, and E, respectively. Because point G is on the circumcircle of $\triangle ABC$, Simson's theorem establishes that points D, E, and

F are collinear. The famous postulate by Moritz Pasch (1843–1930) states that a straight line intersecting one side of a triangle (internally) must intersect exactly one of the other two sides (internally) except if the line contains a vertex of the triangle. Euclid had quietly assumed this idea. Yet with this postulate available to us, we are assured that the two critical perpendiculars can neither both fall inside nor both fall outside the triangle, which enables us to avoid the fallacious proof previously offered.

RADICAL AXES

Earlier in this chapter, we stated Brianchon's theorem as the dual of Pascal's theorem. At that juncture we deferred the proof because we needed some more knowledge about a radical axis. We will now establish some important properties of radical axes and then use them to prove Brianchon's theorem.

Consider two circles R and Q (see Figure 3-27) intersecting at points A and B. P is any point on $\overleftrightarrow{AB}$ not between points A and B. $\overline{PT}$ and $\overline{PS}$ are tangents to circles R and Q at points T and S, respectively.

INTERACTIVE 3-27

Drag points Q, R, and P and note the radical axis.

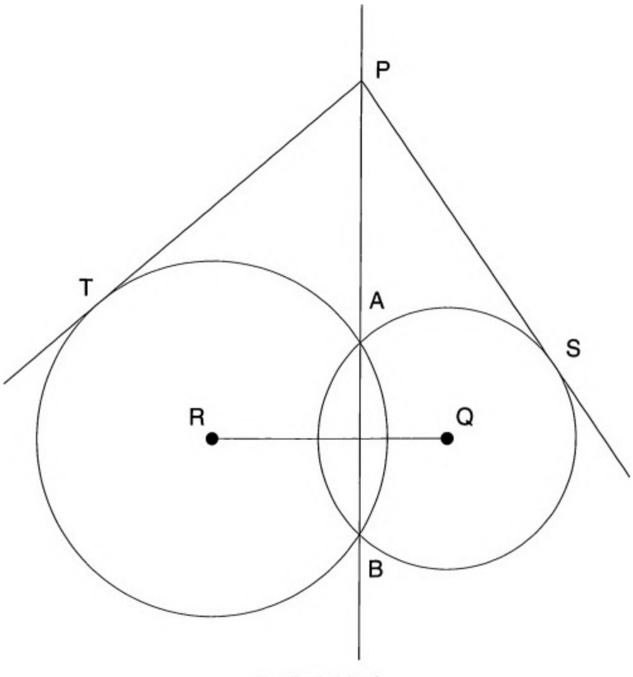

FIGURE 3-27

From our study of elementary geometry, we know that PT is the mean proportional between PB and PA. Therefore $(PT)^2 = (PB)(PA)$. Similarly, for circle Q, $(PS)^2 = (PB)(PA)$. It then follows that $PT = PS$.

Because point P was selected as *any* external point on $\overleftrightarrow{AB}$, we can conclude that from any external point on $\overleftrightarrow{AB}$, tangent segments to circles R and Q are congruent. Before we can state this as a locus theorem, we must prove that any point P that generates congruent tangents to circles R and Q must lie on $\overleftrightarrow{AB}$.

Suppose P is any point where tangent segments $\overline{PT}$ and $\overline{PS}$ are congruent. Let $\overrightarrow{PA}$ intersect circle R at point B and circle Q at point B'. As before, $(PB)(PA) = (PT)^2$ and $(PB')(PA) = (PS)^2$. Because $PT = PS$, $PB = PB'$. Therefore B and B' must coincide, and P lies on the common secant, $\overleftrightarrow{PA}$, of the two circles. We call the line consisting of points that are common endpoints of congruent tangent segments to two circles the *radical axis* of the two circles.

We now state this result as our next theorem.

THEOREM 3.11 The radical axis of two intersecting circles is their common secant.

It follows immediately that the radical axis of two tangent circles is their common tangent. Before we can investigate the radical axis of two nonintersecting circles, we need to consider the following theorem.

THEOREM 3.12 The locus of a point the difference of whose distances squared from two fixed points is a constant is a line perpendicular to the segment determined by the two fixed points.

Proof Let R and Q be the fixed points and let P be a point on the locus (see Figure 3-28). Draw $\overline{PR}$ and $\overline{PQ}$. Construct $\overline{PN} \perp \overline{RQ}$. We use the Pythagorean theorem to get:

$$(PR)^2 - (RN)^2 = (PN)^2 \quad \text{and} \quad (PQ)^2 - (QN)^2 = (PN)^2$$

Therefore:

$$(PR)^2 - (RN)^2 = (PQ)^2 - (QN)^2 \quad \text{or} \quad (PR)^2 - (PQ)^2 = (RN)^2 - (QN)^2 = k$$

Let $RQ = d$. Then, by factoring the last equality, we have:

$$(RN + QN)(RN - QN) = k$$

$$d(RN - QN) = k$$

$$RN - QN = \frac{k}{d} \qquad \text{(I)}$$

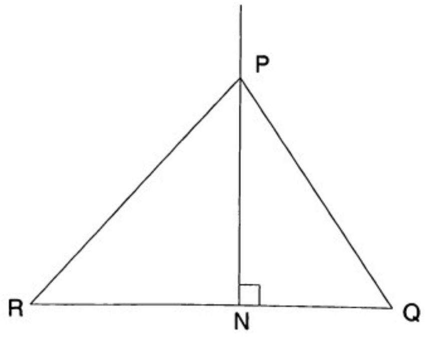

FIGURE 3-28

Remember that:

$$RN + QN = d \tag{II}$$

Solving equations (I) and (II) simultaneously, we get:

$$RN = \frac{d^2 + k}{2d} \quad \text{and} \quad QN = \frac{d^2 - k}{2d}$$

This fixes the position of point N.

Because d and k are constant for any given situation, point P must lie on the line perpendicular to $\overline{RQ}$ at point N, which divides $\overline{RQ}$ in the ratio:

$$\frac{RN}{QN} = \frac{d^2 + k}{d^2 - k}$$

We can conclude this locus proof by showing that any point on $\overleftrightarrow{PN}$ satisfies the given conditions. This is left to the reader. ●

Theorem 3.12 enables us to continue our study of radical axes. We must now determine the radical axis of two nonintersecting circles. Our intuition would probably predict the next theorem.

THEOREM 3.13 The radical axis of two nonintersecting circles is a line perpendicular to their line of centers.

Proof Begin by letting r and q be the radii of circles R and Q, respectively. Let P be a point on the required locus, that is, so that tangent segments $\overline{PT}$ and $\overline{PS}$ are congruent (see Figure 3-29).

By applying the Pythagorean theorem to $\triangle PTR$ and $\triangle PSQ$, we get:

$$(PR)^2 - r^2 = (PT)^2 \quad \text{and} \quad (PQ)^2 - q^2 = (PS)^2$$

But $PT = PS$; therefore:

$$(PR)^2 - r^2 = (PQ)^2 - q^2 \quad \text{or} \quad (PR)^2 - (PQ)^2 = r^2 - q^2$$

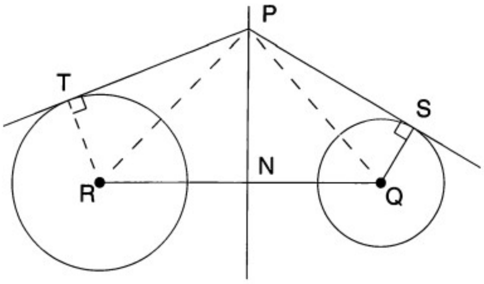

FIGURE 3-29

Because the right-hand side of this equality is a constant, we can conclude (by Theorem 3.12) that the locus of P is the line containing point P, which is perpendicular to the line of centers $\overleftrightarrow{RQ}$. ●

In a manner similar to that used in the previous proof, we can determine the location of point N in terms of the radii and the distance between the centers. As a direct consequence of Theorem 3.13, we have the following theorem.

THEOREM 3.14 The radical axes of three given circles whose centers are not collinear are concurrent.

Proof Let us consider circles R, Q, and U whose radical axes are $\overleftrightarrow{AB}$, $\overleftrightarrow{CD}$, and $\overleftrightarrow{EF}$ (see Figure 3-30).

Let point P be the intersection of $\overleftrightarrow{AB}$ and $\overleftrightarrow{CD}$. Using radical axis $\overleftrightarrow{AB}$ of circles R and Q, we have $PT = PS$. Using radical axis $\overleftrightarrow{CD}$ of circles Q and U, we have $PV = PS$. (Note: $\overleftrightarrow{PT}$, $\overleftrightarrow{PS}$, and $\overleftrightarrow{PV}$ are tangents to the given circles.)

Thus $PT = PV$, which indicates that point P must lie on the radical axis, $\overleftrightarrow{EF}$, of circles R and U. This proves that the radical axes are concurrent at point P. ●

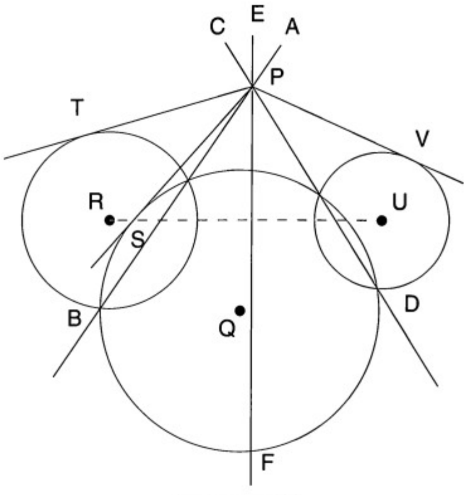

FIGURE 3-30

We are now ready to prove Brianchon's theorem, which we discussed earlier in the chapter (on page 58). The proof we will use is by A. S. Smogorzhevskii (*The Ruler in Geometrical Constructions,* New York: Blaisdell Publishing Company, 1961, pp. 33–35).

THEOREM 3.5 **(Brianchon's theorem)** If a hexagon is circumscribed about a circle, the lines containing opposite vertices are concurrent.

Proof As seen in Figure 3-31, the sides of hexagon $ABCDEF$ are tangent to a circle at points T, N, L, S, M, and K. Points K', L', N', M', S', and T' are chosen on $\overrightarrow{FA}$, $\overrightarrow{DC}$, $\overrightarrow{BC}$, $\overrightarrow{FE}$, $\overrightarrow{DE}$, and $\overrightarrow{BA}$, respectively, so that:

$$KK' = LL' = NN' = MM' = SS' = TT'$$

Now construct circle P tangent to $\overrightarrow{BA}$ and $\overrightarrow{DE}$ at points T' and S', respectively (the existence of this circle is easily justified). Similarly, construct circle Q tangent to $\overrightarrow{FA}$ and $\overrightarrow{DC}$ at points K' and L', respectively. Then construct circle R tangent to $\overrightarrow{FE}$ and $\overrightarrow{BC}$ at points M' and N', respectively.

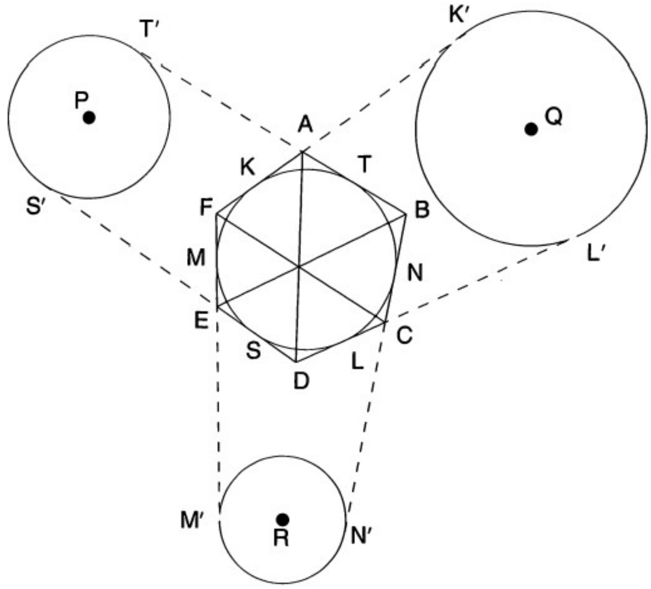

FIGURE 3-31

Because two tangent segments to a circle from an external point have the same length, $FM = FK$. We already know that $MM' = KK'$. Therefore, by addition:

$$FM' = FK'$$

Similarly:

$$CL = CN \quad \text{and} \quad LL' = NN'$$

By subtraction:

$$CL' = CN'$$

We now notice that points F and C are each endpoints of a pair of congruent tangent segments to circles R and Q. Thus these points determine the radical axis, $\overleftrightarrow{CF}$, of circles R and Q. Using the same technique, we can easily show that $\overleftrightarrow{AD}$ is the radical axis of circles P and Q and that $\overleftrightarrow{BE}$ is the radical axis of circles P and R.

We proved that the radical axes of three circles with noncollinear centers (taken in pairs) are concurrent (Theorem 3.14). Therefore $\overleftrightarrow{CF}$, $\overleftrightarrow{AD}$, and $\overleftrightarrow{BE}$ are concurrent.

We should note that the only way in which these circles would have had collinear centers is if the diagonals were to have coincided, which is impossible.

EXERCISES

1. Sides $\overleftrightarrow{AB}$, $\overleftrightarrow{BC}$, $\overleftrightarrow{CD}$, and $\overleftrightarrow{DA}$ of quadrilateral $ABCD$ are intersected by a straight line at points K, L, M, and N, respectively. Prove that $\frac{BL}{LC} \cdot \frac{AK}{KB} \cdot \frac{DN}{NA} \cdot \frac{CM}{MD} = 1$.

2. Side $\overline{AB}$ of square $ABCD$ is extended to point P so that $BP = 2(AB)$. With M the midpoint of $\overline{DC}$, $\overline{BM}$ intersects $\overline{AC}$ at point Q. Also, $\overline{PQ}$ intersects $\overline{BC}$ at point R. Use Menelaus's theorem to find the numerical value of $\frac{CR}{RB}$.

3. Points P and R are on sides $\overline{AB}$ and $\overline{AC}$, respectively, of $\triangle ABC$ so that $\overline{AP} \cong \overline{AR}$. Prove that median $\overline{AM}$ partitions $\overline{PR}$ into segments proportional to $\overline{AB}$ and $\overline{AC}$.

4. Prove that the tangents to the circumcircle of a triangle at its vertices intersect the opposite sides in three collinear points.

5. Prove that if a line contains the centroid, G, of $\triangle ABC$ and intersects sides $\overleftrightarrow{AB}$ and $\overleftrightarrow{AC}$ at points M and N, respectively, then $(AM)(NC) + (AN)(MB) = (AM)(AN)$.

6. A circle is tangent to side $\overline{BC}$ of $\triangle ABC$ at M, its midpoint, and intersects $\overleftrightarrow{AB}$ and $\overleftrightarrow{AC}$ at points R, R' and S, S', respectively. If $\overline{RS}$ and $\overline{R'S'}$ are each extended to meet $\overleftrightarrow{BC}$ at points P and P', respectively, prove that $(BP)(BP') = (CP)(CP')$ (see Figure 3-32).

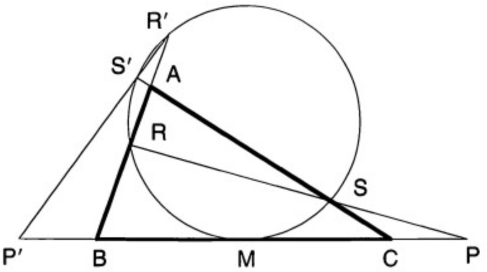

FIGURE 3-32

7. In $\triangle ABC$, P, Q, and R are the midpoints of sides $\overline{AB}$, $\overline{BC}$, and, $\overline{AC}$ respectively. $\overleftrightarrow{AN}$, $\overleftrightarrow{BL}$, and $\overleftrightarrow{CM}$ are concurrent, meeting the opposite sides at points N, L, and M, respectively. If $\overleftrightarrow{PL}$ meets $\overleftrightarrow{BC}$ at point J, $\overleftrightarrow{MQ}$ meets $\overleftrightarrow{AC}$ at point I, and $\overleftrightarrow{RN}$ meets $\overleftrightarrow{AB}$ at point H, prove that points H, I, and J are collinear (see Figure 3-33).

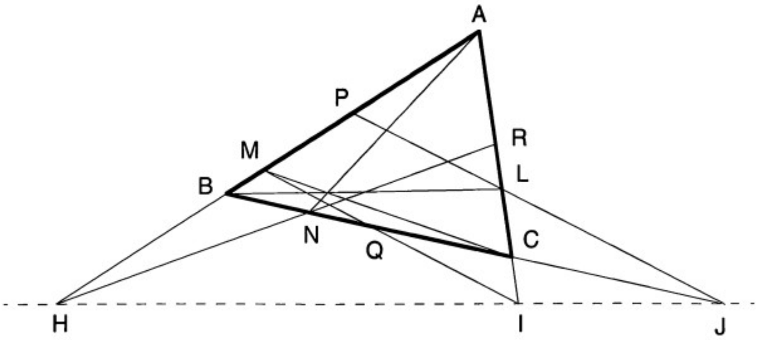

FIGURE 3-33

8. Prove that the three pairs of common external tangents to three circles (no two of which are equal or concentric), taken two at a time, intersect in three collinear points.

9. Prove that the perpendicular bisectors of the interior angle bisectors of any triangle meet the sides opposite the angles being bisected in three collinear points.

10. Provide a proof for Application 6, using Menelaus's theorem.

11. How can Brianchon's theorem be used to prove the existence of the Gergonne point of a triangle?

12. Compare Pappus's theorem to Pascal's theorem.

13. State and prove the converse of Desargues's theorem.

14. State and prove the converse of Simson's theorem.

15. In Figure 3-34, $\triangle ABC$, with right angle at A, is inscribed in circle O. The Simson line of point P with respect to $\triangle ABC$ meets $\overline{PA}$ at point M. Prove that $\overline{MO}$ is perpendicular to $\overline{PA}$ at point M.

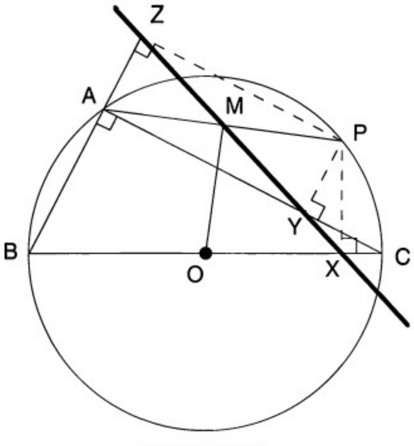

FIGURE 3-34

16. From a point P on the circumference of circle O, three chords are drawn meeting the circle at points A, B, and C. Prove that the three points of intersection of the three circles with $\overline{PA}$, $\overline{PB}$, and $\overline{PC}$ as diameters are collinear.

17. If two triangles are inscribed in the same circle, a single point on the circumcircle determines a Simson line for each triangle. Prove that the angle formed by these two Simson lines is constant, regardless of the position of the point.

18. Prove that the common tangent segments (if they exist) of two given circles are bisected by their radical axis.

19. Prove that the radical axis of the two circles whose diameters are the diagonals of a trapezoid contains the point of intersection of the nonparallel sides of the trapezoid.

20. Prove that the four points determined by the intersections of two secants drawn from a point on the radical axis of two circles with the two circles lie on a third circle.

CHAPTER 5

HISTORY OF THE PARALLEL POSTULATE

> Like the goblin "Puck," [the feat of proving Euclid V] has led me "up and down, up and down," through many a wakeful night: but always, just as I thought I had it, some unforeseen fallacy was sure to trip me up, and the tricksy sprite would "leap out, laughing ho, ho, ho!"
>
> C. L. DODGSON (LEWIS CARROLL)

Let us summarize what we have done so far. We have discovered certain gaps in Euclid's definitions and postulates for plane geometry. We filled in these gaps and firmed up the foundations for this geometry by presenting (a modified version of) Hilbert's definitions and axioms. We then built a structure of theorems on these foundations. However, the structure thus far erected does not rest on the parallel postulate, and we called that structure "neutral geometry." One reason we postponed building on the parallel postulate is that we have less confidence in it than in the other axioms.

You may feel that to deny the Euclidean parallel postulate would go against common sense. Albert Einstein once said that "common sense is, as a matter of fact, nothing more than layers of preconceived notions stored in our memories and emotions for the most part before age eighteen."

That Euclid himself did not quite trust this postulate is shown by the fact that he postponed using it in a proof for as long as possible — until his 29th proposition. In this chapter, we will examine a few illuminating attempts to prove Euclid's parallel postulate (many other attempts are presented in Bonola, 1955; Gray, 1989; and Rosenfeld, 1988). It should be emphasized that most of these attempts were made by outstanding mathematicians, not incompetents. And even though each attempt was flawed, the effort was usually not wasted; for, assuming that all but one step can be justified, when we detect the flawed step, we find another statement which to our surprise is equivalent[1] to the parallel postulate. You have the opportunity to do this enjoyable detective work in Exercises 8 through 13.

PROCLUS

Proclus (A.D. 410–485), whose commentary is one of the main sources of information on Greek geometry, criticized the parallel postulate as follows: "This ought even to be struck out of the Postulates altogether; for it is a theorem involving many difficulties, which Ptolemy, in a certain book, set himself to solve. . . . The statement that since [the two lines] converge more and more as they are produced, they will sometime meet is plausible but not necessary." Proclus offers the example of a hyperbola that approaches its asymptotes as closely as you like without ever meeting them (see Figure 5.1). This example shows that the opposite of Euclid's conclusions can at least be imagined.[2] Proclus says: "It is then clear from this that we must seek a proof of the present theorem, and that it is alien to the special character of postulates."

For over two thousand years some of the best mathematicians tried to prove Euclid's fifth postulate. What does it mean, according to our terminology, to have a proof? It should not be necessary to *assume* the parallel postulate as an axiom; we should be able to prove it *from the other axioms.* If we were able to prove Euclid V in this way, it would become a theorem in neutral geometry and neutral geometry would encompass all of Euclidean geometry.

The first known attempted proof was by Ptolemy. Without going through the details of his argument (see Heath, 1956, pp. 204–206), we might say that he assumed Hilbert's parallel postulate without

---

[1] Actually, the flawed argument only proves that the unjustified statement *implies* the parallel postulate; the converse requires further argument. I do not present any attempts that are uninformative.

[2] Students always object to Figure 5.1 on the grounds that the hyperbola is not "straight." We agreed not to use this word because we don't have a precise definition. A precise definition can be given in differential geometry. See Appendix A.

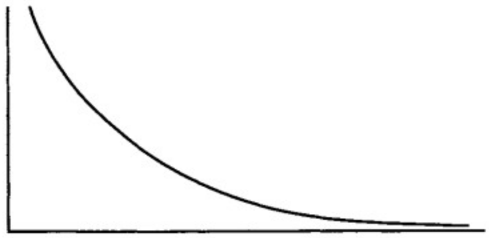

FIGURE 5.1

realizing it. We have seen in Chapter 4 that Hilbert's parallel postulate is logically equivalent to Euclid V (Theorem 4.5), so that Ptolemy was assuming what he was trying to prove; i.e., his reasoning was essentially circular.

Proclus attempted to prove the parallel postulate as follows (see Figure 5.2): Given two parallel lines *l* and *m*. Suppose line *n* cuts *m* at P. We wish to show *n* intersects *l* also (see Proposition 4.7). Let Q be the foot of the perpendicular from P to *l* (Corollary 1 to Theorem 4.1). If *n* coincides with $\overleftrightarrow{PQ}$, then it intersects *l* at Q. Otherwise, one ray $\overrightarrow{PY}$ of *n* lies between $\overrightarrow{PQ}$ and a ray $\overrightarrow{PX}$ of *m*. Take X to be the foot of the perpendicular from Y to *m*.

Now, as the point Y recedes endlessly from P on *n*, the segment XY increases indefinitely in size, and so eventually becomes greater than segment PQ. Therefore, Y must cross over to the other side of *l*, so that *n* must meet *l*.

The preceding paragraph is the heart of Proclus' argument; it is a rather sophisticated argument, involving motion and continuity. Moreover, every step in the argument can be shown to be correct—except that the conclusion doesn't follow! (In Exercise 6 you are asked to prove Aristotle's principle that XY increases indefinitely, where "indefinitely" means "without bound." For example, the sequence of numbers $\frac{1}{2}, \frac{3}{4}, \frac{7}{8}, \frac{15}{16}, \frac{31}{32}, \ldots$ increases but not "indefinitely" in the sense of "without bound," because 1 is a bound for these numbers.)

How could one justify the last step? Let us drop a perpendicular YZ from Y to *l*. You might then say that (1) X, Y, and Z are collinear, and (2) XZ $\cong$ PQ. Thus, when XY becomes greater than PQ, XY must also be greater than XZ, so that Y must be on the other side of *l*. Here the conclusion does indeed follow from statements 1 and 2. The trouble is that there is no justification for these statements!

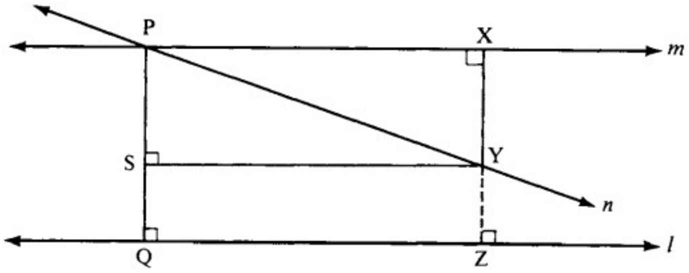

FIGURE 5.2

If this boggles your mind, it may be because Figure 5.2 makes statements 1 and 2 *seem* correct. You recall, however, that we are not allowed to use a diagram to justify a step in a proof. Each step must be proved from stated axioms or previously proven theorems. (We will show later that it is not possible in neutral geometry to prove statements 1 and 2. They can be proved only in Euclidean geometry and only by using the parallel postulate; this makes Proclus' argument circular.)

This analysis of Proclus' faulty argument illustrates how careful you must be in the way you think about parallel lines from now on. You probably visualize parallel lines as railroad tracks, everywhere equidistant from each other, and the ties of the tracks perpendicular to both parallels. This imagery is valid only in Euclidean geometry. Without the parallel postulate, the only thing we can say about two lines that are "parallel" is that, by definition of "parallel," they have no point in common. You can't assume they are equidistant; you can't even assume they have one common perpendicular segment. As Humpty Dumpty remarked: "When I use a word it means what I wish it to mean, neither more nor less."

WALLIS

The next important attempt to prove the parallel postulate was made by the Persian astronomer and mathematician Nasir Eddin al-Tusi (1201 – 1274). But since his attempted proof had several unjustified

John Wallis

assumptions, let us move ahead to John Wallis (1616–1703).[3] Wallis gave up trying to prove the parallel postulate in neutral geometry. Instead, he proposed a new axiom, which he felt was more plausible than the parallel postulate, and then proved the parallel postulate from his new axiom and the other axioms of neutral geometry.

WALLIS' POSTULATE. Given any triangle $\triangle ABC$ and given any segment DE. There exists a triangle $\triangle DEF$ (having DE as one of its sides) that is similar to $\triangle ABC$ (denoted $\triangle DEF \sim \triangle ABC$). (See Figure 5.3.)

---

[3] Wallis was the leading English mathematician before Isaac Newton. In his treatise *Arithmetica infinitorum* (which Newton studied), Wallis introduced the symbol ∞ for "infinity," developed formulas for certain integrals, and presented his famous infinite product formula

$$\frac{\pi}{2}=\frac{2\cdot 2\cdot 4\cdot 4\cdot 6\cdot 6\cdot 8\cdots}{1\cdot 3\cdot 3\cdot 5\cdot 5\cdot 7\cdot 7\cdots}$$

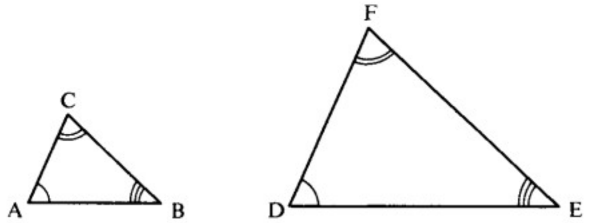

FIGURE 5.3

Similar triangles are triangles whose vertices can be put in one-to-one correspondence so that corresponding angles are congruent. In Euclidean geometry it is proved that corresponding sides of similar triangles are proportional (see Exercise 18); for example, each side of $\triangle$DEF might be twice as long as the corresponding side of $\triangle$ABC. Thus, the intuitive meaning of Wallis' postulate is that you can either magnify or shrink a triangle as much as you like, without distortion.

Using Wallis' postulate, the parallel postulate can be proved as follows (see Figure 5.4):

Proof:

Given a point P not on line *l*, construct one parallel *m* to *l* through P as before—by dropping a perpendicular $\overleftrightarrow{PQ}$ to *l* and erecting *m* perpendicular to $\overleftrightarrow{PQ}$. Let *n* be any other line through P. We must show that *n* meets *l*. As before, we consider a ray of *n* emanating from P that is between a ray of *m* and $\overrightarrow{PQ}$; for any point R on this ray, we drop $\overleftrightarrow{RS}$ perpendicular to $\overleftrightarrow{PQ}$ (see Proposition 3.16 and Corollary 1 to Theorem 4.1 for the existence and uniqueness of all our perpendiculars).

We now apply Wallis' postulate to $\triangle$PSR and segment PQ. It tells us that there is a point T such that $\triangle$PSR is similar to $\triangle$PQT.

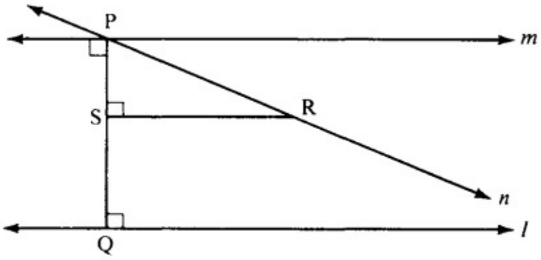

FIGURE 5.4

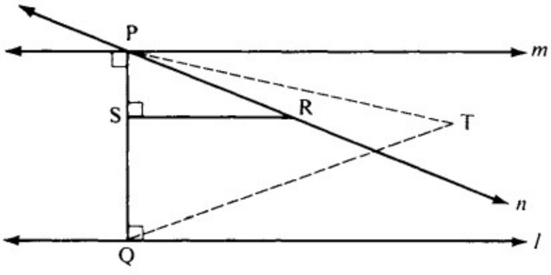

FIGURE 5.5

Assume T lies on the same side of $\overleftrightarrow{PQ}$ as R (Figure 5.5) — if not, reflect across $\overleftrightarrow{PQ}$.

By definition of similar triangles, $\sphericalangle TPQ \cong \sphericalangle RPS$. But since these angles have the ray $\overrightarrow{PQ} = \overrightarrow{PS}$ as a common side and since T lies on the same side of $\overleftrightarrow{PQ}$ as R, the only way they can be congruent is to be equal (Axiom C-4). Thus, $\overrightarrow{PR} = \overrightarrow{PT}$, so that T lies on n. Similarly, $\sphericalangle PQT \cong \sphericalangle PSR$, a right angle; hence, T lies on l. Thus, n and l meet at T; m is therefore the only line through P parallel to l. ■

There is no longer reason to consider Wallis' postulate any more plausible than Euclid V, because it turns out to be logically equivalent to Euclid V (see Exercise 7(a)).

SACCHERI

We next consider the remarkable work of the logician and Jesuit priest Girolamo Saccheri (1667 – 1733). Just before he died he published a little book entitled *Euclides ab omni naevo vindicatus (Euclid Freed of Every Flaw)*, which was not really noticed until a century and a half later, when Eugenio Beltrami rediscovered it.

Saccheri's idea was to use a reductio ad absurdum argument. He assumed the negation of the parallel postulate and tried to deduce a contradiction. Specifically, he studied certain quadrilaterals (Figure 5.6) whose base angles are right angles and whose base-adjacent sides

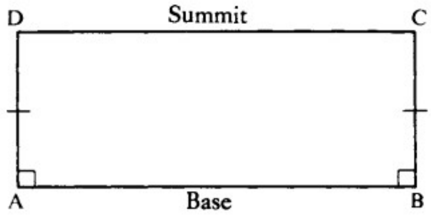

FIGURE 5.6 Saccheri quadrilateral.

are congruent to each other. These quadrilaterals have subsequently become known as *Saccheri quadrilaterals* (though they were studied many centuries earlier by the poet Omar Khayyám and by Nasir Eddin al-Tusi). It is easy to prove in neutral geometry that the summit angles are congruent (Exercise 1), i.e., $\sphericalangle C \cong \sphericalangle D$.

There are three possible cases:

Case 1: The summit angles are right angles.
Case 2: The summit angles are obtuse.
Case 3: The summit angles are acute.

Wanting to prove the first case, which is the case in Euclidean geometry, Saccheri tried to show that the other two cases led to contradictions. He succeeded in showing that case 2 leads to a contradiction: if the summit angles were obtuse, the angle sum of the quadrilateral would be more than 360°, contradicting Corollary 2 to the Saccheri-Legendre theorem (to verify the hypothesis of Corollary 2, see Exercise 17).

However hard he tried, he could not squeeze a contradiction out of case 3, "the inimical acute angle hypothesis," as he called it. He was able to deduce many strange results,[4] but not a contradiction. Finally, he exclaimed in frustration: "The hypothesis of the acute angle is absolutely false, because [it is] repugnant to the nature of the straight line!" It is as if a man had discovered a rare diamond, but, unable to believe what he saw, announced it was glass. Although he did not recognize it, Saccheri had discovered non-Euclidean geometry.

---

[4] See the translation of Saccheri's treatise by G. B. Halsted (Saccheri, 1970).

CLAIRAUT

Alexis Claude Clairaut (1713–1765) was a leading French geometer. Like Wallis, he did not try to prove the parallel postulate in neutral geometry but replaced it in his 1741 text *Éléments de géometrie* with another axiom.

CLAIRAUT'S AXIOM. Rectangles exist.

One can argue that Euclid V is not obvious because one might have to travel very far indeed to verify that the "physical lines" predicted to meet by that postulate actually do meet. According to Saccheri, it suffices to show the existence of one rectangle, which could be quite "small." Clairaut made that his axiom, arguing that "we observe rectangles all around us in houses, gardens, rooms, walls." So why didn't that settle the matter? Perhaps because the game of trying to prove Euclid V had been going on for so many centuries that it became a challenging obsession for mathematicians. Or did mathematicians finally recognize that geometry was not about "physical space"? After all, if you believe that a rectangle can be drawn on the ground, then you cannot also believe that the earth is spherical, because rectangles do not exist on a sphere. If you think you have drawn a "physical rectangle," you could be mistaken because exact measurements are physically impossible. Or did it finally dawn on mathematicians that any postulate proposed to replace Euclid V—no matter how intuitively appealing—was logically equivalent to Euclid V and therefore nothing was gained *logically* by the replacement?

Let us prove that *Clairaut's axiom is logically equivalent in neutral geometry to the parallel postulate.*

Proof:
If we assume the latter, then the existence of rectangles follows easily from Proposition 4.11 and Theorem 4.7. Conversely, assume Clairaut's axiom. Then by Theorem 4.7, all triangles have angle sum 180°, and by introducing a diagonal, all convex quadrilaterals have angle sum 360°. Return to Proclus' argument as illustrated in Figure 5.2. Let S be the foot of the perpendicular from Y to $\overleftrightarrow{PQ}$. S is on the same side of m as Y and Q because $\overleftrightarrow{SY}$ is parallel to m

(Corollary 1 to Theorem 4.1). Moreover, □PXYS, which has three right angles, is now known to be a rectangle. You can easily prove (Exercise 4) that opposite sides of a rectangle are congruent, so $PS \cong XY$. By Aristotle's axiom (Chapter 3), Y can be chosen on the given ray of n so that $XY > PQ$. Then $PS > PQ$ and $P * Q * S$. As above, Y is on the same side of l as S, hence on the opposite side of l from P. Therefore l meets n at some point between P and Y. ■

LEGENDRE

Legendre did not know of Saccheri's work and rediscovered Saccheri's theorems in neutral geometry that are our Theorems 4.4 and 4.7. Legendre certainly knew of Clairaut's text and rejected Clairaut's axiom. We already discussed, in Chapter 1, one of Legendre's attempts to prove the parallel postulate, whose flaw we ask you to detect in Exercise 8. Legendre published a collection of his many attempts as late as 1833, the year he died. Here is his attempt to prove that the angle sum of every triangle is 180°. (Using our modification of Proclus' argument above, we could then prove Hilbert's parallel postulate.)

Proof (see Figure 5.7):

Suppose, on the contrary, there exists a triangle $\triangle ABC$ having defect $d \neq 0$. By the Saccheri-Legendre Theorem 4.4, $d > 0$. One of the angles of the triangle—say $\sphericalangle A$—must then be acute (in fact, less than 60°). On the opposite side of $\overleftrightarrow{BC}$ from A, let D be the unique point such that $\sphericalangle DBC \cong \sphericalangle ACB$ and $BD \cong AC$ (Axioms

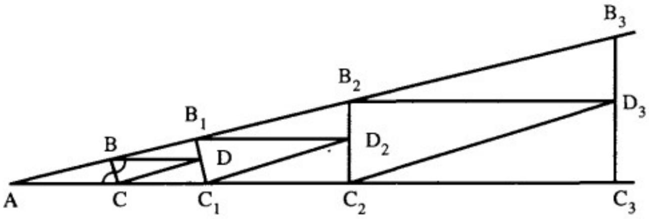

FIGURE 5.7

C-1 and C-4). Then $\triangle ACB \cong \triangle DBC$ (SAS). Also $\overleftrightarrow{BD} \parallel \overleftrightarrow{AC}$ and $\overleftrightarrow{BA} \parallel \overleftrightarrow{DC}$ (by the alternate interior angle theorem, Theorem 4.1), so that D lies in the interior of the acute $\sphericalangle A$. Hence there is a line l through D such that l intersects side $\overrightarrow{AB}$ in a point $B_1 \neq A$ and side $\overrightarrow{AC}$ in a point $C_1 \neq A$. Because of the parallel lines, we know that $B_1 \neq B$ and $C_1 \neq C$.

Suppose B_1 was on segment AB. Then A and B_1 would be on the same side of $\overleftrightarrow{BD}$. Since $\overleftrightarrow{BD} \parallel \overleftrightarrow{AC}$, A and C_1 are on the same side of $\overleftrightarrow{BD}$. Thus B_1 and C_1 are on the same side of $\overleftrightarrow{BD}$ (Axiom B-4). But since D lies in the interior of $\sphericalangle A$, $B_1 * D * C_1$ (Proposition 3.7). This contradiction shows that $A * B * B_1$. Similarly, we have $A * C * C_1$. Since $\triangle ACB \cong \triangle DBC$, the defect of $\triangle DBC$ is also d. Therefore, by the additivity of the defect applied to the four triangles into which $\triangle AB_1C_1$ has been decomposed, the defect of $\triangle AB_1C_1$ is greater than or equal to $2d$.

Repeating this construction for $\triangle AB_1C_1$, we obtain $\triangle AB_2C_2$ with defect greater than or equal to $4d$. Iterating the construction n times, we obtain a triangle with defect greater than or equal to $2^n d$, which can be made as large as we like by taking n sufficiently large. But the defect of a triangle cannot be more than 180°! This contradiction shows that every triangle $\triangle ABC$ has defect 0. ■

Can you see the flaw? It is easy, because we have justified every step but one, the sentence beginning with "Hence." That is the assumption you were warned in Chapter 3 not to make. Legendre made the same error as was made many centuries earlier by Simplicius (Byzantine, sixth century), al-Jawhari (Persian, ninth century), Nasir Eddin al-Tusi, and others. He has failed to prove in neutral geometry that the defect of every triangle is zero. Nevertheless, Legendre has succeeded in proving the following theorem in neutral geometry.

THEOREM 5.1. Hypothesis: For any acute $\sphericalangle A$ and any point D in the interior of $\sphericalangle A$, there exists a line through D and not through A which intersects both sides of $\sphericalangle A$. Conclusion: The angle sum of every triangle is 180°.

You will easily see from the Klein model in Chapter 7 that the hypothesis of Theorem 5.1 fails in non-Euclidean geometry (Figure 7.5). Let us show that *the hypothesis can be proved in Euclidean geometry* (hence this hypothesis is another statement equivalent to Euclid V). Drop a perpendicular from interior point D to one of the sides of ∢A, and let B be the foot of that perpendicular. Since ∢A is acute, $(\sphericalangle A)^\circ + (\sphericalangle DBA)^\circ = (\sphericalangle A)^\circ + 90^\circ < 180^\circ$. So $\overrightarrow{BD}$ meets the other side of ∢A, by Euclid V. ■

LAMBERT AND TAURINUS

Regarding Euclid V, Johann Heinrich Lambert (1728–1777) wrote:

> Undoubtedly, this basic assertion is far less clear and obvious than the others. Not only does it naturally give the impression that it should be proved, but to some extent it makes the reader feel that he is capable

Johann Heinrich Lambert

> of giving a proof, or that he should give it. However, to the extent to which I understand this matter, that is just a *first* impression. He who reads Euclid further is bound to be amazed not only at the rigor of his proofs but also at the delightful simplicity of his exposition. This being so, he will marvel all the more at the position of the fifth postulate when he finds out that Euclid proved propositions that could far more easily be left unproved.

Lambert studied quadrilaterals having at least three right angles, which are now named after him (though they were studied seven centuries earlier by the Egyptian scientist ibn-al-Haytham). You showed in Exercise 19, Chapter 4, that Lambert quadrilaterals exist. A Lambert quadrilateral can be "doubled" (by reflecting it across an included side of two right angles) to obtain a Saccheri quadrilateral. Like Saccheri, Lambert disproved the obtuse angle hypothesis and studied the implications of the "inimical" acute angle hypothesis. He observed that it implied that similar triangles must then be congruent, which in turn implied the existence of an absolute unit of length (see Theorem 6.2, Chapter 6). He called this consequence "exquisite" but did not want it to be true, worrying that the absence of similar, proportional figures "would result in countless inconveniences," especially for astronomers (he did not realize that an elegant non-Euclidean trigonometry could be developed).

He also noticed that the defect of a triangle was proportional to its area (see Chapter 10). He recalled that on a sphere in Euclidean space, the angle sum of a triangle formed by arcs of great circles was greater than 180°, and the excess over 180° of the angle sum of the triangle was proportional to the area of the triangle, the constant of proportionality being the square r^2 of the radius of the sphere (see Rosenfeld, 1988, Chapter 1). If r is replaced by ir ($i = \sqrt{-1}$), squaring introduces a minus sign that converts the excess into the defect in that proportionality. Lambert therefore speculated that the acute angle hypothesis described geometry on a "sphere of imaginary radius."[5]

---

[5] In fact, this idea can be explained in terms of a natural embedding of the non-Euclidean plane in *relativistic* three-space (see Chapter 7). Lambert is known for proving the irrationality of π and of e^x and tan x when x is rational, as well as for important laws he discovered in optics and astronomy. The quote is from B. A. Rosenfeld (1988), p. 100.

Fifty years passed before this brilliant idea was further elaborated in a booklet dated 1826 by F. A. Taurinus, who transformed the formulas of spherical trigonometry into formulas for what he called "log-spherical geometry" by substituting ir for r (his formulas are proved by a different method in Theorem 10.4, Chapter 10). Taurinus vacillated over whether such a geometry actually "existed." He sent a copy of his booklet to C. F. Gauss (see Chapter 6) and later burned the remaining copies in despair when Gauss did not respond.

Lambert cautiously did not submit his *Theory of Parallels* for publication (it was published posthumously in 1786). It contained an erroneous attempt to disprove the acute angle hypothesis. Given line l and distance d, let us call the locus m of all points on a given side of l at perpendicular distance d from l an *equidistant curve*. The flaw in many early attempts to prove the parallel postulate was the tacit assumption that m was a line. Lambert tried to prove this assumption, but he only succeeded in proving that an arc of m could not be a circular arc. Saccheri also erred using differential calculus in his attempt to prove that m was a line.[6]

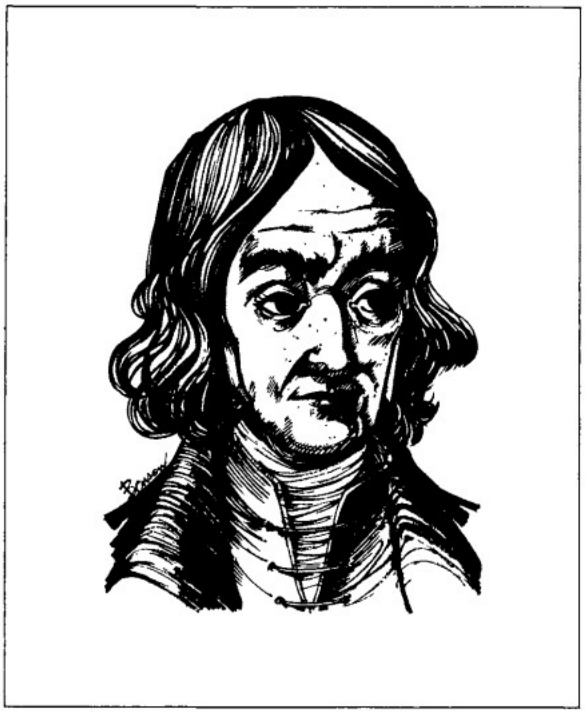
FARKAS BOLYAI

There were so many attempts to prove Euclid V that by 1763 G. S. Klügel was able to submit a doctoral thesis finding the flaws in 28 different supposed proofs of the parallel postulate, expressing doubt that it could be proved. The French encyclopedist and mathematician J. L. R. d'Alembert called this "the scandal of geometry." Mathematicians were becoming discouraged. The Hungarian Farkas Bolyai wrote to his son János:

> You must not attempt this approach to parallels. I know this way to its very end. I have traversed this bottomless night, which extinguished all light and joy of my life. I entreat you, leave the science of parallels alone. . . . I thought I would sacrifice myself for the sake of the truth. I was ready to become a martyr who would remove the flaw from

---

[6] As an example in elliptic geometry: If l is the equator of the sphere, the equidistant curves are the other circles of latitude.



Farkas Bolyai

> geometry and return it purified to mankind. I accomplished monstrous, enormous labors; my creations are far better than those of others and yet I have not achieved complete satisfaction. . . . I turned back when I saw that no man can reach the bottom of the night. I turned back unconsoled, pitying myself and all mankind.
>
> I admit that I expect little from the deviation of your lines. It seems to me that I have been in these regions; that I have traveled past all reefs of this infernal Dead Sea and have always come back with broken mast and torn sail. The ruin of my disposition and my fall date back to this time. I thoughtlessly risked my life and happiness — *aut Caesar aut nihil.*[7]

But the young Bolyai was not deterred by his father's warnings, for he had a completely new idea. He assumed that the negation of

---

[7] The correspondence between Farkas and János Bolyai is from Meschkowski (1964).

Euclid's parallel postulate was not absurd, and in 1823 was able to write to his father:

> It is now my definite plan to publish a work on parallels as soon as I can complete and arrange the material and an opportunity presents itself; at the moment I still do not clearly see my way through, but the path which I have followed gives positive evidence that the goal will be reached, if it is at all possible; I have not quite reached it, but I have discovered such wonderful things that I was amazed, and it would be an everlasting piece of bad fortune if they were lost. When you, my dear Father, see them, you will understand; at present I can say nothing except this: that *out of nothing I have created a strange new universe.* All that I have sent you previously is like a house of cards in comparison with a tower. I am no less convinced that these discoveries will bring me honor than I would be if they were completed.

We will explore this "strange new universe" in the following chapters. A century after János Bolyai wrote this letter, the English physicist J. J. Thomson remarked, somewhat facetiously:

> We have Einstein's space, de Sitter's space, expanding universes, contracting universes, vibrating universes, mysterious universes. In fact, the pure mathematician may create universes just by writing down an equation, and indeed if he is an individualist he can have a universe of his own.

In fact, in 1949 the renowned logician Kurt Gödel found a model of the universe that satisfies Einstein's gravitational equations, one in which it is theoretically possible to travel backward in time![8]

REVIEW EXERCISE

Which of the following statements are correct?

(1) Wallis' postulate implies that there exist two triangles that are similar but not congruent.

---

[8] To date, attempts to refute Gödel's model on either mathematical or philosophical grounds have failed. See "On the paradoxical time-structures of Gödel," by Howard Stein, *Journal of the Philosophy of Science*, v. 37, December 1970, p. 589.

(2) A "Saccheri quadrilateral" is a quadrilateral □ABDC such that ∢CAB and ∢DBA are right angles and AC ≅ BD.

(3) A "Lambert quadrilateral" is a quadrilateral having at least three right angles.

(4) A quadrilateral that is both a Saccheri and a Lambert quadrilateral must be a rectangle.

(5) A hyperbola comes arbitrarily close to its asymptotes without ever intersecting them.

(6) János Bolyai warned his son Farkas not to work on the parallel problem.

(7) Saccheri succeeded in disproving the "inimical" acute angle hypothesis.

(8) In trying to prove Euclid's fifth postulate, Ptolemy tacitly assumed what we have been calling Hilbert's parallel postulate.

(9) It is a theorem in neutral geometry that if $l \parallel m$ and $m \parallel n$, then $l \parallel n$.

(10) It is a theorem in neutral geometry that every segment has a unique midpoint.

(11) It is a theorem in neutral geometry that if a rectangle exists, then the angle sum of any triangle is 180°.

(12) It is a theorem in neutral geometry that if l and m are parallel lines, then alternate interior angles cut out by any transversal to l and m are congruent to each other.

(13) Legendre proved in neutral geometry that for any acute ∢A and any point D in the interior of ∢A, there exists a line through D and not through A which intersects both sides of ∢A.

(14) Clairaut showed that Euclid's fifth postulate could be replaced in the logical presentation of Euclidean geometry by the "more obvious" postulate that rectangles exist, yet mathematicians were not appeased by Clairaut's replacement and they continued to try to prove Euclid V.

EXERCISES

Again, in proofs in Exercises 1 – 17 you are allowed to use only our previous results from neutral geometry.

1. Let □ABDC be a Saccheri quadrilateral, so that ∢B and ∢A are right angles and CA ≅ DB (Figure 5.8). Prove that ∢C ≅ ∢D. (Hint: Prove △CAB ≅ △DBA, then △CDB ≅ △DCA.) Also prove that Saccheri quadrilaterals exist.

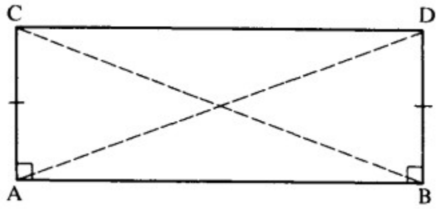


FIGURE 5.8

2. Let □ABDC be a quadrilateral whose base angles ∢A and ∢B are right angles. Prove that if AC < BD, then (∢D)° < (∢C)° (Figure 5.9). (Hint: If AC ≅ BE, with B * E * D, use Exercise 23, Chapter 4, to show that E is interior to ∢ACD, then apply Exercise 1 and the exterior angle theorem.)
3. With the same hypothesis as in Exercise 2, prove the converse, that if (∢D)° < (∢C)°, then AC < BD. (Hint: Assume the contrary, which involves the two cases AC ≅ BD and AC > BD. In each case, derive a contradiction.)
4. The Swiss-German mathematician Lambert considered quadrilaterals with at least three right angles, which are now named after him (Figure 5.10). Prove the following:
   (a) The fourth angle ∢D of a Lambert quadrilateral is never obtuse.
   (b) If ∢D is a right angle, then the opposite sides of □ABCD are congruent (use Exercise 2 and an RAA argument).

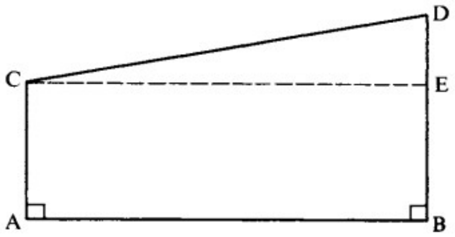

FIGURE 5.9

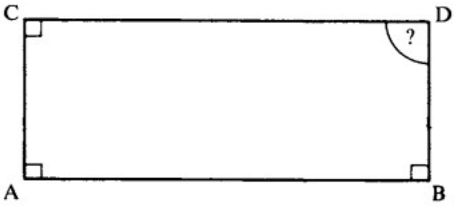

FIGURE 5.10 Lambert quadrilateral.

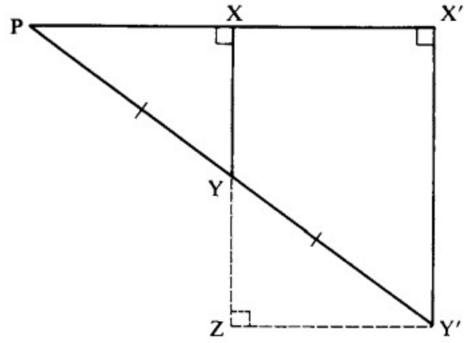

FIGURE 5.11

(c) If ∢D is acute, then each side adjacent to ∢D is greater than its opposite side, i.e., DB > CA and CD > AB (use Exercise 3).

(d) A quadrilateral is both a Lambert and a Saccheri quadrilateral if and only if it is a rectangle.

We can combine statements (a), (b), and (c) of this exercise into the following statement: a side adjacent to the fourth angle of a Lambert quadrilateral is greater than or congruent to its opposite side. As you know, case (b) always holds if the geometry is Euclidean; in the next chapter we will show that case (c) always holds if the geometry is hyperbolic. In elliptic geometry the fourth angle of a Lambert quadrilateral is always obtuse, and a side adjacent to the fourth angle is always smaller than its opposite side.

5. Given a right triangle △PXY with right angle at X, form a new right triangle △PX′Y′ that has acute angle ∢P in common with the given triangle but double the hypotenuse (prove that this can be done); see Figure 5.11. Prove that the side opposite the acute angle is *at least* doubled, whereas the side adjacent to the acute angle is *at most* doubled. (Hint: Extend side XY far enough to drop a perpendicular Y′Z to $\overleftrightarrow{XY}$. Prove that △PXY ≅ △Y′ZY, and apply Exercise 4 to the Lambert quadrilateral □XZY′X′.)
6. Use Exercise 5 to prove Aristotle's axiom (used in Proclus' argument) that as Y recedes endlessly from P, segment XY increases indefinitely (see p. 96). (Hint: Use Archimedes' axiom and the fact that $2^n \to \infty$ as $n \to \infty$.[9]) Does segment PX also increase indefinitely?
7. (a) Prove that Euclid's fifth postulate implies Wallis' postulate (see Figure 5.12). (Hint: Use Axiom C-4 and the fact that in Euclidean

---

[9] Euclid had a version of Archimedes' axiom in Book V, but he presented it as a "definition": If $a < b$, then there is a number n such that $2^n a > b$.

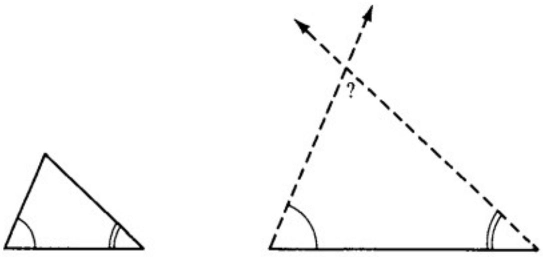

FIGURE 5.12

geometry the angle sum of a triangle is 180° — Proposition 4.11.)

(b) Suppose that in the statement of Wallis' postulate we add the assumption $AB \cong DE$ and replace the word "similar" by "congruent." Prove this new statement in neutral geometry.

8. Reread Legendre's attempted proof of the parallel postulate in Chapter 1. Find the flaw, and justify all the steps that are correct. Prove the flawed statement in Euclidean geometry.
9. Find the unjustified assumption in the following "proof" of the parallel postulate by Farkas Bolyai (see Figure 5.13). Given P not on line l, $\overleftrightarrow{PQ}$ perpendicular to l at Q, and line m perpendicular to $\overleftrightarrow{PQ}$ at P. Let n be any line through P distinct from m and $\overleftrightarrow{PQ}$. We must show that n meets l. Let A be any point between P and Q. Let B be the unique point such that

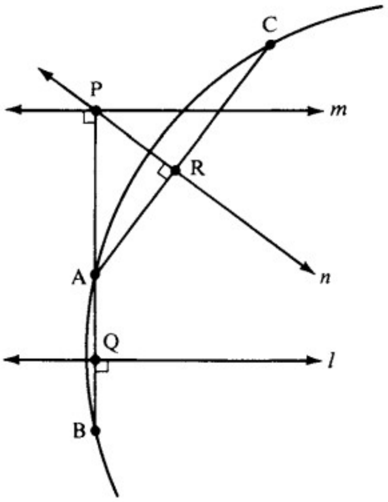

FIGURE 5.13

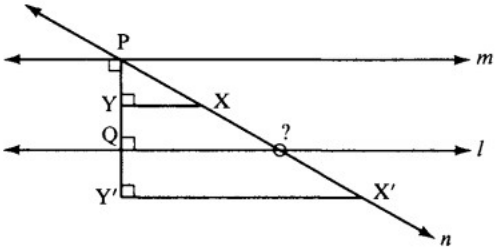

FIGURE 5.14

$A * Q * B$ and $AQ \cong QB$. Let R be the foot of the perpendicular from A to n. Let C be the unique point such that $A * R * C$ and $AR \cong RC$. Then A, B, and C are not collinear (else $R = P$); hence there is a unique circle γ passing through them. Since l is the perpendicular bisector of chord AB of γ and n is the perpendicular bisector of chord AC of γ, l and n meet at the center of γ (Exercise 17(b), Chapter 4).

10. The following attempted proof of the parallel postulate is similar to Proclus' but the flaw is different; detect the flaw with the help of Exercise 5. (See Figure 5.14.) Given P not on line l, $\overleftrightarrow{PQ}$ perpendicular to l at Q, and line m perpendicular to $\overleftrightarrow{PQ}$ at P. Let n be any line through P distinct from m and $\overleftrightarrow{PQ}$. We must show that n meets l. Let $\overrightarrow{PX}$ be a ray of n between $\overleftrightarrow{PQ}$ and a ray of m, and let Y be the foot of the perpendicular from X to $\overleftrightarrow{PQ}$. As X recedes endlessly from P, PY increases indefinitely. Hence, Y eventually reaches a position Y′ on $\overrightarrow{PQ}$ such that $PY' > PQ$. Let X′ be the corresponding position reached by X on line n. Now X′ and Y′ are on the same side of l because $\overleftrightarrow{X'Y'}$ is parallel to l. But Y′ and P are on opposite sides of l. Hence, X′ and P are on opposite sides of l, so that segment PX′ (which is part of n) meets l.
11. Find the flaw in the following attempted proof of the parallel postulate given by J. D. Gergonne (see Figure 5.15). Given P not on line l, $\overleftrightarrow{PQ}$ perpendicular to l at Q, line m perpendicular to $\overleftrightarrow{PQ}$ at P, and point $A \neq P$ on m. Let $\overrightarrow{PB}$ be the last ray between $\overrightarrow{PA}$ and $\overrightarrow{PQ}$ that intersects l, B being the point of intersection. There exists a point C on l such that $Q * B * C$ (Axioms B-1 and B-2). It follows that $\overrightarrow{PB}$ is not the last ray between $\overrightarrow{PA}$ and $\overrightarrow{PQ}$ that intersects l, and hence all rays between $\overrightarrow{PA}$ and $\overrightarrow{PQ}$ meet l. Thus m is the only parallel to l through P.
12. Legendre made another attempt to prove that the defect of every triangle is zero, as follows. In any triangle $\triangle ABC$, if we are given the numbers α, β that measure the angles at A and B, respectively, and the number x that measures the length of the included side AB, then by ASA the number γ that measures the third angle is uniquely determined, so we can write $\gamma = f(\alpha, \beta, x)$. Now if right angles are measured by the unit 1,

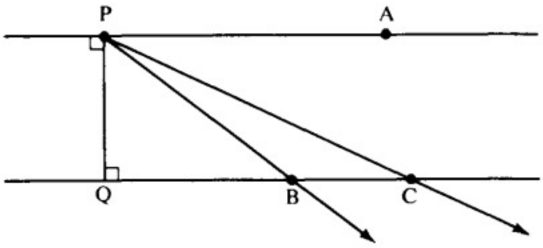

FIGURE 5.15

γ is some number between 0 and 2. But x is not a dimensionless number, since it depends on the arbitrary unit of length (e.g., inch, foot, or meter). Thus the formula for γ cannot actually contain x, and so $\gamma = f(\alpha, \beta)$. (If we knew that the geometry was Euclidean, we would have $f(\alpha, \beta) = 2 - \alpha - \beta$.) Now let D be the midpoint of AB. By Axiom C-4, there is a unique ray $\overrightarrow{DE}$ with E on the same side of $\overleftrightarrow{AB}$ as C such that $\sphericalangle ADE \cong \sphericalangle B$. Then $\overleftrightarrow{DE} \parallel \overleftrightarrow{BC}$, by corresponding angles (Exercise 32, Chapter 4), so, by Pasch's theorem, we can choose label E for a point on AC. Since $\gamma = f(\alpha, \beta)$ for any triangle, $\sphericalangle AED \cong \sphericalangle C$ (i.e., $\triangle ADE$ is similar to $\triangle ABC$). Hence $\square$CEDB has angle sum 360°, so $\triangle CEB$ and $\triangle BED$ have angle sum 180°. By Theorem 4.7, all triangles have defect zero. What is the flaw? (Hint: See the remarks following Theorem 6.2.)

13. It was stated at the beginning of this chapter that if all steps but one of an attempt to prove the parallel postulate are correct, then the flawed step yields another statement equivalent to Hilbert's parallel postulate. Show that for Proclus' attempt, that statement is: Given parallel lines l, m having a common perpendicular and a point Y not lying on l or m, if X (resp. Z) is the foot of the perpendicular from Y to l (resp. to m), then X, Y, and Z are collinear. (Hint: Use Exercise 4b.)
14. Prove that if the defect of every triangle is 0 then Hilbert's parallel postulate holds (this is the converse to Proposition 4.11). (Hint: See the discussion of Clairaut's axiom.)
15. You will show in Exercise 24 that the following statement can be proved in Euclidean geometry: If points P, Q, R lie on a circle with center O, and if $\sphericalangle PQR$ is acute, then $(\sphericalangle PQR)^\circ = \frac{1}{2}(\sphericalangle POR)^\circ$. In neutral geometry, show that this statement implies the existence of a triangle of defect zero (hence, by Prop. 4.7 and Clairaut's axiom, the geometry is Euclidean).
16. *(Difficult)* Here is Legendre's desperate attempt in the 12th and final edition of his geometry text to prove that the defect d of any triangle $\triangle ABC$ is zero. Label so that $\overline{AC} \geq \overline{AB}$. Then the method of Exercise 15,

Chapter 4 (invented by Legendre to prove Theorem 4.4), gives us $\triangle AEC$ having the same defect d (where $AE = 2AD$, D being the midpoint of BC). From $\overline{AC} \geq \overline{AB}$ it is not difficult to show that $\sphericalangle EAC \leq \sphericalangle EAB$, so that $\sphericalangle EAC \leq \frac{1}{2}\sphericalangle BAC$. If $\overline{AC} \geq \overline{AE}$, set $B_1 = E$ and $C_1 = C$; otherwise, reflect $\triangle AEC$ across the angle bisector of $\sphericalangle EAC$ to obtain $\triangle AB_1C_1$ with defect d, $\sphericalangle B_1AC_1 \leq \frac{1}{2}\sphericalangle BAC$, C_1 on ray $\overrightarrow{AC}$, and $\overline{AC_1} \geq \overline{AB_1}$. Iterate this construction n times to obtain $\triangle AB_nC_n$ with defect d, $\sphericalangle B_nAC_n \leq 2^{-n}\sphericalangle BAC$, and C_n on ray $\overrightarrow{AC}$. Let $n \to \infty$. Since $\sphericalangle B_nAC_n \to 0$, the triangles $\triangle AB_nC_n$ (which all have defect d) converge in the limit to a degenerate triangle on ray $\overrightarrow{AC}$ having angles 0°, 0°, and 180°. Hence $d = 0$. Criticize this argument (Hint: Show that B_n, $C_n \to \infty$.)

17. Prove that a Saccheri quadrilateral is convex. Prove that a Lambert quadrilateral is a parallelogram and that every parallelogram is convex.

The remaining exercises in this chapter are exercises in Euclidean geometry, which means you are allowed to use the parallel postulate and its consequences already established. We will refer to these results in Chapter 7. You are also allowed to use the following result, a proof of which is indicated in the Major Exercises:

PARALLEL PROJECTION THEOREM. Given three parallel lines l, m, and n. Let t and t' be transversals to these parallels, cutting them in points A, B, and C and in points A′, B′, and C′, respectively. Then $\overline{AB}/\overline{BC} = \overline{A'B'}/\overline{B'C'}$. (Figure 5.16.)

18. *Fundamental theorem on similar triangles.* Given $\triangle ABC \sim \triangle A'B'C'$, i.e., given $\sphericalangle A \cong \sphericalangle A'$, $\sphericalangle B \cong \sphericalangle B'$, and $\sphericalangle C \cong \sphericalangle C'$. Then corresponding sides are proportional, i.e., $\overline{AB}/\overline{A'B'} = \overline{AC}/\overline{A'C'} = \overline{BC}/\overline{B'C'}$. (See Figure 5.17.) Prove the theorem. (Hint: Let B″ be the point on $\overrightarrow{AB}$ such that $AB'' \cong A'B'$, and let C″ be the point on $\overrightarrow{AC}$ such that $AC'' \cong A'C'$. Use

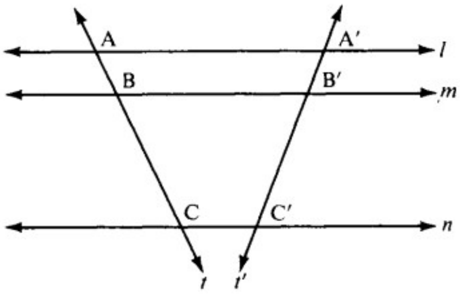

FIGURE 5.16

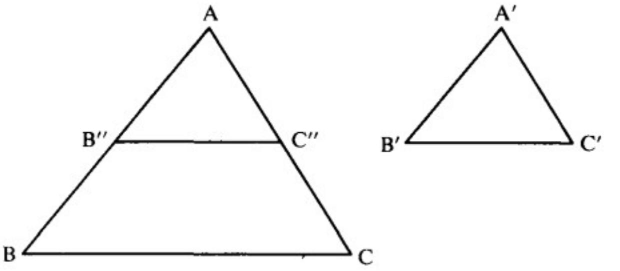

FIGURE 5.17

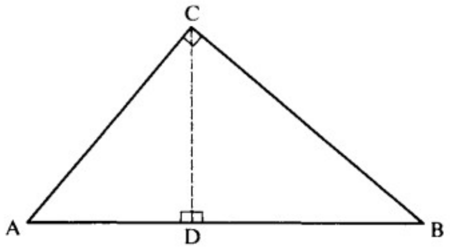
the hypothesis to show that $\triangle AB''C'' \cong \triangle A'B'C'$ and deduce from corresponding angles that $\overleftrightarrow{B''C''}$ is parallel to $\overleftrightarrow{BC}$. Now apply the parallel projection theorem.)

19. Prove the converse to the fundamental theorem on similar triangles. (Hint: Choose B″ as before. Use Pasch's theorem to show that the parallel to $\overleftrightarrow{BC}$ through B″ cuts AC at a point C″. Then use the hypothesis, Exercise 18, and the SSS criterion to show that $\triangle ABC \sim \triangle AB''C'' \cong \triangle A'B'C'$.)
20. *SAS similarity criterion.* If $\sphericalangle A \cong \sphericalangle A'$ and $\overline{AB}/\overline{A'B'} = \overline{AC}/\overline{A'C'}$, prove that $\triangle ABC \sim \triangle A'B'C'$. (Hint: Same method as in Exercise 19, but using SAS instead of SSS.)
21. Prove the Pythagorean theorem. (Hint: Let CD be the altitude to the hypotenuse; see Figure 5.18. Use the fact that the angle sum of a triangle equals 180° (Exercise 8, Chapter 4) to show that $\triangle ACD \sim \triangle ABC \sim \triangle CBD$. Apply Exercise 18 and a little algebra based on $\overline{AB} = \overline{AD} + \overline{DB}$ to get the result.)
22. The fundamental theorem on similar triangles (Exercise 18) allows the trigonometric functions such as sine and cosine to be defined. Namely, given an acute angle $\sphericalangle A$, make it part of a right triangle $\triangle BAC$ with right angle at C, and set

FIGURE 5.18



$$\sin \sphericalangle A = (\overline{BC})/(\overline{AB})$$
$$\cos \sphericalangle A = (\overline{AC})/(\overline{AB}).$$

These definitions are then independent of the choice of the right triangle used. If $\sphericalangle A$ is obtuse and $\sphericalangle A'$ is its supplement, set

$$\sin \sphericalangle A = +\sin \sphericalangle A'$$
$$\cos \sphericalangle A = -\cos \sphericalangle A'.$$

If $\sphericalangle A$ is a right angle, set

$$\sin \sphericalangle A = 1$$
$$\cos \sphericalangle A = 0.$$

Now, given any triangle $\triangle ABC$, if a and b are the lengths of the sides opposite A and B, respectively, prove the law of sines,

$$\frac{a}{b} = \frac{\sin \sphericalangle A}{\sin \sphericalangle B}.$$

(Hint: Drop altitude CD and use the two right triangles $\triangle ADC$ and $\triangle BDC$ to show that $b \sin \sphericalangle A = \overline{CD} = a \sin \sphericalangle B$; see Figure 5.19.) Similarly, prove the law of cosines,

$$c^2 = a^2 + b^2 - 2ab \cos \sphericalangle C,$$

and deduce the converse to the Pythagorean theorem.

23. Given A * B * C and point D not collinear with A, B, and C (Figure 5.20). Prove that

$$\frac{\overline{AB}}{\overline{BC}} = \frac{\overline{AD} \sin \sphericalangle ADB}{\overline{CD} \sin \sphericalangle CDB}$$
$$\frac{\overline{AC}}{\overline{BC}} = \frac{\overline{AD} \sin \sphericalangle ADC}{\overline{BD} \sin \sphericalangle BDC}$$

(Hint: Use the law of sines to compute $\overline{AB}/\overline{AD}$, $\overline{CD}/\overline{BC}$, and $\overline{BD}/\overline{BC}$, and remember that $\sin \sphericalangle ABD = \sin \sphericalangle CBD$.)

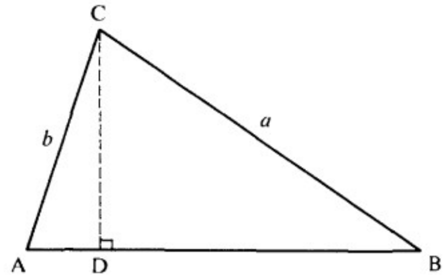


FIGURE 5.19

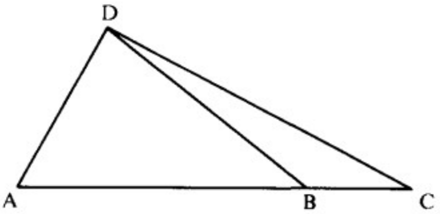

FIGURE 5.20

24. Let γ be a circle with center O, and let P, Q, and R be three points on γ. Prove that if P and R are diametrically opposite, then $\measuredangle$PQR is a right angle, and if O and Q are on the same side of $\overleftrightarrow{PR}$, then $(\measuredangle PQR)^\circ = \frac{1}{2}(\measuredangle POR)^\circ$. (Hint: Again use the fact that the triangular angle sum is 180°. There are four cases to consider, as in Figure 5.21.) State and prove the analogous result when O and Q are on opposite sides of $\overleftrightarrow{PR}$.
25. Prove that if two angles inscribed in a circle subtend the same arc, then they are congruent; see Figure 5.22. (Hint: Apply the previous exercise after carefully defining "subtend the same arc.")
26. Prove that if $\measuredangle$PQR is a right angle, then Q lies on the circle γ having PR as diameter. (Hint: Use uniqueness of perpendiculars and Exercise 24.)

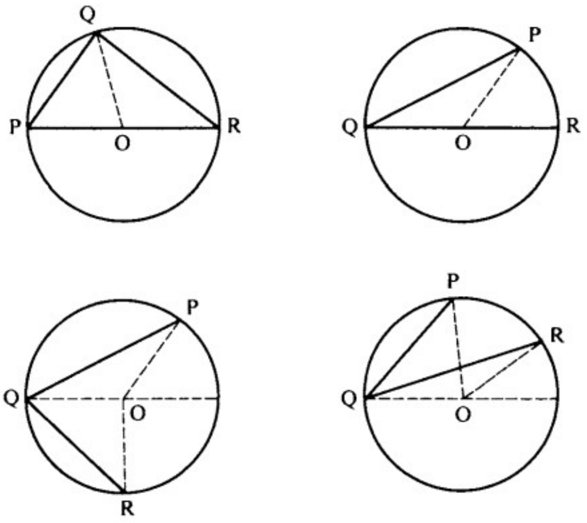

FIGURE 5.21

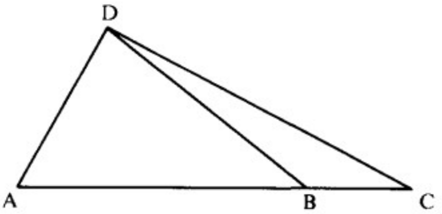

FIGURE 5.20

24. Let γ be a circle with center O, and let P, Q, and R be three points on γ. Prove that if P and R are diametrically opposite, then ∢PQR is a right angle, and if O and Q are on the same side of $\overleftrightarrow{PR}$, then $(∢PQR)^\circ = \frac{1}{2}(∢POR)^\circ$. (Hint: Again use the fact that the triangular angle sum is 180°. There are four cases to consider, as in Figure 5.21.) State and prove the analogous result when O and Q are on opposite sides of $\overleftrightarrow{PR}$.
25. Prove that if two angles inscribed in a circle subtend the same arc, then they are congruent; see Figure 5.22. (Hint: Apply the previous exercise after carefully defining "subtend the same arc.")
26. Prove that if ∢PQR is a right angle, then Q lies on the circle γ having PR as diameter. (Hint: Use uniqueness of perpendiculars and Exercise 24.)

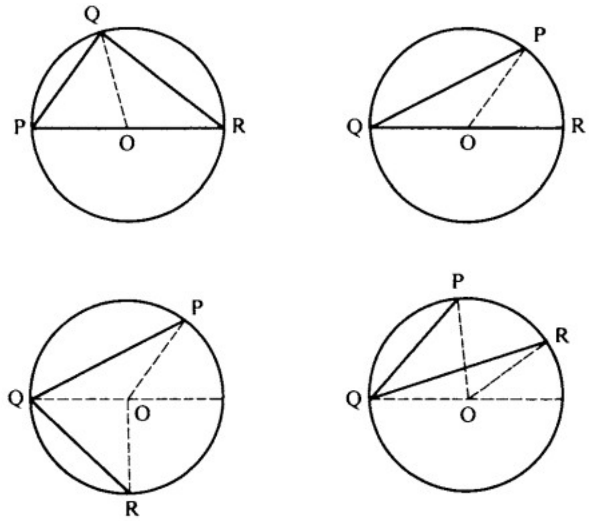

FIGURE 5.21

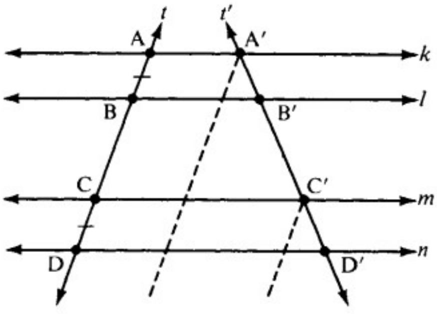

FIGURE 5.23

$x = x'$, since a real number is the least upper bound of all the rational numbers less than it (see any good text on real analysis). To show this, lay off on $\overrightarrow{BA}$ a segment BD of length $p\overline{CB}/q$, and let D′ be the parallel projection of D onto t'. From $p/q < x$, deduce B * D * A. Now apply Major Exercises 3 and 4 to show that $p/q < x'$.[10]

6. Given a segment AB of length a with respect to some unit segment OI (see Theorem 4.3). Using straightedge and compass only, show how to construct a segment of length $\sqrt{a}$. (Hint: Extend AB to a segment AC of length $a + 1$; erect a perpendicular through B and let D be one of its intersections with the circle having AC as diameter; apply the theory of similar triangles to show that $\overline{BD} = \sqrt{a}$. Review the construction in Major Exercise 1, Chapter 1.)
7. Prove that given any line l, two points A and B not on l are on the same side S of l if and only if they lie on a circle contained in S. (Hint: If A and B are on opposite sides of l, apply Major Exercise 1, Chapter 4. If they are on the same side S, let M be the midpoint and m the perpendicular bisector of AB. Any circle through A and B has its center on m. If $\overleftrightarrow{AB} \parallel l$, take any point P between M and the point where m meets l, and use the circle through A, B and P (see Exercise 12, Chapter 6). Otherwise, if A is closer to l than B, let the perpendicular from A to l meet m at O. Show that the circle centered at O with radius OA ≅ OB lies in S. Be sure to indicate where the hypothesis that *the geometry is Euclidean* is used; see Exercise P-20, Chapter 7.)

---

[10] This clever method of proof was essentially discovered by the ancient Greek mathematician Eudoxus—see E. C. Zeeman, "Research, Ancient and Modern," *Bulletin of the Institute of Mathematics and Its Applications*, 10 (1974): 272–281, Warwick University, England.

PROJECTS

1. Since there is no algebra in Euclid's *Elements*, it was quite a feat for Eudoxus to have discovered a purely geometric treatment of proportions and similar triangles. Report on this, using Heath (1956) and Moise (1990, Chapter 20) as references.
2. Eudoxus was also the founder of theoretical astronomy in antiquity (his work later refined by Ptolemy). In his model, the universe was bounded by "the celestial sphere," so that the physical interpretation of Euclid's second and third postulates was false! Even Kepler and Galileo believed in an outer limit to the world. It was René Descartes (1596–1650) who promoted the idea that we live in infinite, unbounded Euclidean space. Report on these issues, using Torretti (1978) as one reference.
3. Report on several other attempts to prove the Euclidean parallel postulate in neutral geometry, using Rosenfeld (1988) as a reference.
4. We remarked after Theorem 4.3 that the definition of π as the ratio of the circumference of any circle to its diameter could only be justified in Euclidean geometry, not neutral geometry. Report on the justification in Moise (1990), section 21.2, which uses the theory of similar triangles.

The goal of this book is to provide an introduction to both Euclidean and non-Euclidean (hyperbolic) geometry. The two geometries share many features, but they have fundamental and radical differences. Neutral geometry is the part of the path they have in common and that is what we have been studying so far, but we have now come to the fork in the path. That fork comes when you try to answer this question:

> Given a line ℓ and a point P that is not on ℓ, how many lines pass through P and are parallel to ℓ?

Using just the axioms of neutral geometry, we can prove that there is always at least one such parallel. We can also prove that if there is more than one parallel, then there must be infinitely many. But that is the extent of what the neutral axioms can say. The neutral axioms are not enough to determine whether there is one parallel or many. A single axiom is what separates Euclidean and non-Euclidean geometry: the final axiom of Euclidean geometry calls for exactly one parallel, the final axiom of non-Euclidean geometry calls for more than one parallel.

The next several chapters are devoted to Euclidean geometry. Euclidean geometry is very old, and so there is a lot of it. We only cover the fundamentals in this book, but there are many excellent books that do much more, such as *Geometry Revisited* [CG67] by Coxeter and Greitzer.

Part II

Euclidean Geometry

The goal of this book is to provide an introduction to both Euclidean and non-Euclidean (hyperbolic) geometry. The two geometries share many features, but they have fundamental and radical differences. Neutral geometry is the part of the path they have in common and that is what we have been studying so far, but we have now come to the fork in the path. That fork comes when you try to answer this question:

> Given a line ℓ and a point P that is not on ℓ, how many lines pass through P and are parallel to ℓ?

Using just the axioms of neutral geometry, we can prove that there is always at least one such parallel. We can also prove that if there is more than one parallel, then there must be infinitely many. But that is the extent of what the neutral axioms can say. The neutral axioms are not enough to determine whether there is one parallel or many. A single axiom is what separates Euclidean and non-Euclidean geometry: the final axiom of Euclidean geometry calls for exactly one parallel, the final axiom of non-Euclidean geometry calls for more than one parallel.

The next several chapters are devoted to Euclidean geometry. Euclidean geometry is very old, and so there is a lot of it. We only cover the fundamentals in this book, but there are many excellent books that do much more, such as *Geometry Revisited* [CG67] by Coxeter and Greitzer.

11

The Axiom on Parallels

Euclidean geometry is distinguished from neutral geometry by one axiom, one that describes the nature of parallel lines. There are many formulations of the parallel axiom for Euclidean geometry, but the one that gets right to the heart of the matter is *Playfair's axiom*, named after the Scottish mathematician John Playfair.

> *(Playfair's axiom) Let ℓ be a line, and let P be a point that is not on ℓ. Then there is exactly one line through P that is parallel to ℓ.*

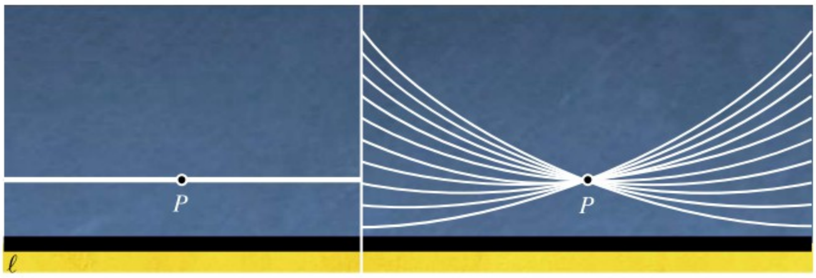

Figure 1. On the left, Euclidean geometry: a single line through P parallel to ℓ. On the right, more than one line through P parallel to ℓ.

In this chapter, we look at a small collection of theorems that are almost immediate consequences of Playfair's axiom, and as such are at the very core of Euclidean geometry. The first of these is Euclid's fifth postulate. This is the controversial postulate in the *Elements*, but also the one that guarantees the same parallel behavior that Playfair's axiom provides. Euclid's fifth is a little unwieldy, particularly when compared to Playfair's axiom, but it is the historical impetus for much of what followed. So let's use Playfair's axiom to prove Euclid's fifth postulate.

Theorem 11.1 *(Euclid's fifth postulate) If lines ℓ_1 and ℓ_2 are crossed by a transversal t, and the sum of adjacent interior angles on one side of t measure less than 180°, then ℓ_1 and ℓ_2 intersect on that side of t.*

Proof First some labels.

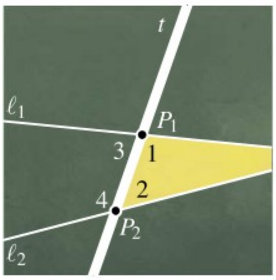

Figure 2. The labels.

Start with lines ℓ_1 and ℓ_2 crossed by transversal t. Label P_1 and P_2, the points of intersection of t with ℓ_1 and ℓ_2 respectively. On one side of t, the two adjacent interior angles should add up to less than 180°. Label the one at P_1 as $\angle 1$ and the one at P_2 at $\angle 2$. Label the supplement of $\angle 1$ as $\angle 3$ and label the supplement of $\angle 2$ as $\angle 4$.

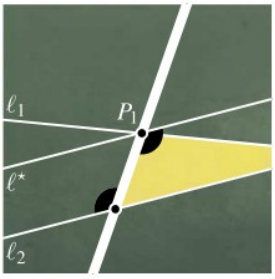

Figure 3. Constructing the unique parallel.

This theorem asserts that the lines intersect, and says where the intersection occurs. We will tackle those two statements in that order. Note that $\angle 1$ and $\angle 4$ are alternate interior angles, but they are not congruent: if they were, their supplements $\angle 2$ and $\angle 3$ would be too, and then

$$(\angle 1) + (\angle 2) = (\angle 1) + (\angle 3) = 180^\circ.$$

There is, however, another line $\ell^\star$ through P_1 that forms an angle congruent to $\angle 4$ (because of the angle construction axiom), and by the alternate interior angle theorem, $\ell^\star$ must be parallel to ℓ_2. Because of Playfair's axiom, $\ell^\star$ is the only parallel to ℓ_2 through P_1. Therefore ℓ_1 intersects ℓ_2.

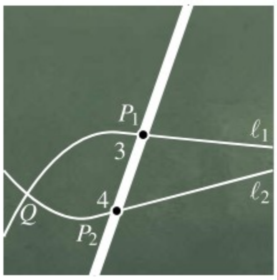

Figure 4. An impossible triangle on the wrong side of t.

The second part of the proof is to figure out on which side of t that ℓ_1 and ℓ_2 cross. Let's see what would happen if they intersected at a point Q on the wrong side of t, the side with $\angle 3$ and $\angle 4$. Then $\triangle P_1 P_2 Q$ would have two interior angles, $\angle 3$ and $\angle 4$, whose measures add up to more than 180°. This would violate the Saccheri-Legendre theorem. So ℓ_1 and ℓ_2 cannot intersect on the side of t with $\angle 3$ and $\angle 4$ and so they must intersect on the side with $\angle 1$ and $\angle 2$.

☐

One of the truly useful theorems of neutral geometry is the alternate interior angle theorem. In fact, we just used it in the last proof. You may recall from high school geometry that the converse of the theorem is often even more useful. The problem is that the converse of the alternate interior angle theorem can't be proved using just the axioms of neutral geometry. It depends on the Euclidean behavior of parallel lines.

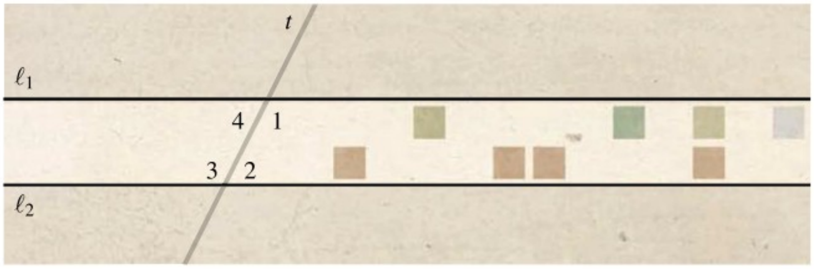

Figure 5. The converse of the alternate interior angle theorem: if $\ell_1 \parallel \ell_2$, then $\angle 1 \simeq \angle 3$ and $\angle 2 \simeq \angle 4$.

Theorem 11.2 *(Converse of the alternate interior angle theorem) If ℓ_1 and ℓ_2 are parallel, then the pairs of alternate interior angles formed by a transversal t are congruent.*

Proof Consider two parallel lines crossed by a transversal. Label adjacent interior angles: $\angle 1$ and $\angle 2$, and $\angle 3$ and $\angle 4$, so that $\angle 1$ and $\angle 4$ are supplementary and $\angle 2$ and $\angle 3$ are supplementary. That means that the pairs of alternate interior angles are $\angle 1$ and $\angle 3$, and $\angle 2$ and $\angle 4$. Now, we just have to do a little arithmetic. From the two pairs of supplementary angles:

(i): $(\angle 1) + (\angle 4) = 180^\circ$
(ii): $(\angle 2) + (\angle 3) = 180^\circ$.

Adding all four angles together,

$$(\angle 1) + (\angle 2) + (\angle 3) + (\angle 4) = 360^\circ.$$

Now we turn to Euclid's fifth postulate, or rather its contrapositive. The lines ℓ_1 and ℓ_2 are parallel, which means that they do not intersect on either side of t. Therefore Euclid's fifth says that on neither side of t may the sum of adjacent interior angles be less than 180°:

- $(\angle 1) + (\angle 2) \geq 180^\circ$
- $(\angle 3) + (\angle 4) \geq 180^\circ$.

If either sum was greater than 180°, though, the sum of all four angles would have to be more than 360°. We saw above that is not the case, so the inequalities are actually equalities:

(iii): $(\angle 1) + (\angle 2) = 180^\circ$
(iv): $(\angle 3) + (\angle 4) = 180^\circ$.

Now we have two systems of equations with four unknowns, and it is basic algebra from here. Subtract *(iv)* from *(i)* to get

$$(\angle 1) - (\angle 3) = 0 \implies (\angle 1) = (\angle 3).$$

Subtract *(i)* from *(iii)* to get

$$(\angle 2) - (\angle 4) = 0 \implies (\angle 2) = (\angle 4).$$

Therefore the alternate interior angles are congruent. □

One of the key theorems we proved in the neutral geometry section was the Saccheri-Legendre theorem: that the angle sum of a triangle is at most 180°. That is all you can say

with the axioms of neutral geometry, but in a world with Playfair's axiom and the converse of the alternate interior angle theorem, we can make a more bold statement about angle sums of triangles.

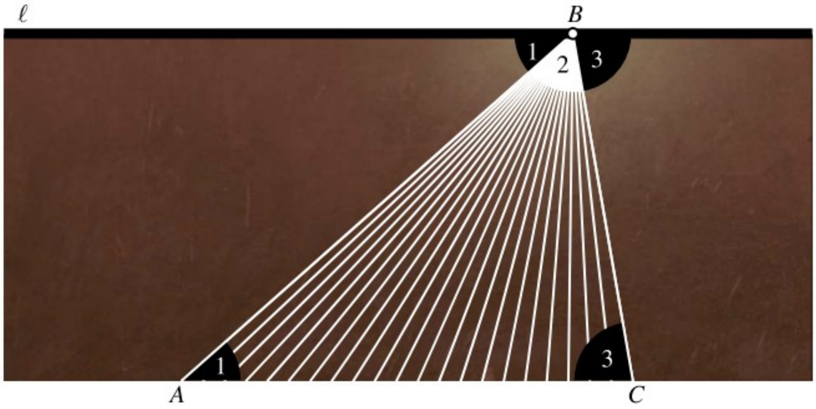

Figure 6. Use the converse of the alternate interior angle theorem to find the angle sum of a triangle.

Theorem 11.3 *The angle sum of a triangle is* 180°.

Proof Given $\triangle ABC$, by Playfair's axiom, there is a unique line ℓ through B that is parallel to $\overline{AC}$. That line and the rays $\overrightarrow{BA}$ and $\overrightarrow{BC}$ form three angles, $\angle 1$, $\angle 2$, and $\angle 3$ as shown in figure 6. By the converse of the alternate interior angle theorem, two pairs of alternate interior angles are congruent: $\angle 1 \simeq \angle A$ and $\angle 3 \simeq \angle C$. Therefore, the angle sum of $\triangle ABC$ is

$$s(\triangle ABC) = (\angle A) + (\angle B) + (\angle C) = (\angle 1) + (\angle 2) + (\angle 3) = 180^\circ. \qquad \square$$

So, the three angles in an equilateral triangle all measure 60° and the measures of the two acute angles in a right triangle must add up to 90°.

In the last chapter on quadrilaterals we talked a little bit about the uncertain status of rectangles in neutral geometry, saying that it is easy to make a convex quadrilateral with three right angles, but that once you have done that, there is no guarantee that the fourth angle will be a right angle. Here it is now in the Euclidean context:

Theorem 11.4 *Let* $\angle ABC$ *be a right angle. Let* r_A *and* r_C *be rays so that* r_A *has endpoint* A*, is on the same side of* $\overline{AB}$ *as* C*, and is perpendicular to* $\overline{AB}$*;* r_C *has endpoint* C*, is on the same side of* $\overline{BC}$ *as* A*, and is perpendicular to* $\overline{BC}$*. Then* r_A *and* r_C *intersect at a point* D*, and the angle formed at this intersection,* $\angle ADC$*, is a right angle. Therefore* $\square ABCD$ *is a rectangle.*

Proof First we need to make sure that r_A and r_C intersect. Let ℓ_A and ℓ_C be the lines containing r_A and r_C respectively. By the alternate interior angle theorem, the right angles at A and B imply that ℓ_A and $\overline{BC}$ are parallel. So $\overline{BC}$ is the one line parallel to ℓ_A through C, and that implies that ℓ_C cannot be parallel to ℓ_A: it has to intersect ℓ_A. Let's call that point of intersection D. This

theorem claims that it is the rays, not the lines, that intersect. Therefore we need to rule out the possibility that the intersection of ℓ_A and ℓ_C might happen on one (or both) of the opposite rays. Since ℓ_A is parallel to $\overline{BC}$, all the points of ℓ_A are on the same side of $\overline{BC}$ as A. None of the points of r_C^{op} is on that side of BC, so D cannot be on r_C^{op}. Likewise, all the points of ℓ_C are on the same side of $\overline{AB}$ as C. None of the points of r_A^{op} is on that side of AB, so D cannot be on r_A^{op}.

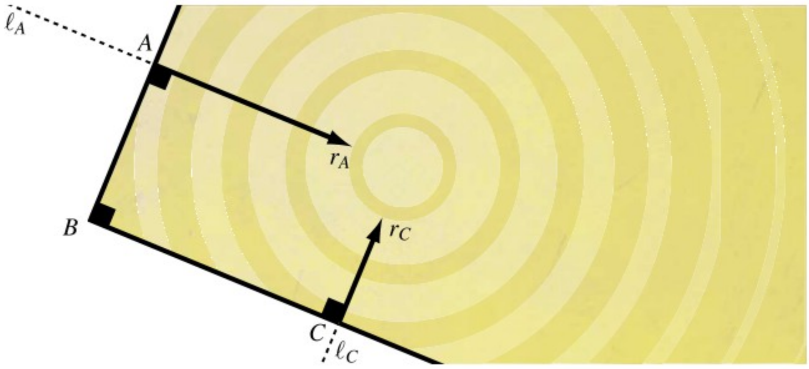

Figure 7. Constructing a rectangle.

So now $\square ABCD$ has three right angles, $\angle A$, $\angle B$, and $\angle C$. It is actually a convex quadrilateral too (verifying this is left as an exercise), so the diagonal AC divides $\square ABCD$ into two triangles $\triangle ABC$ and $\triangle ADC$ (see figure 8). Then, since the angle sum of a triangle is 180°,

$$\begin{gathered} s(\triangle ABC) + s(\triangle ADC) = 180^\circ + 180^\circ \\ (\angle CAB) + (\angle B) + (\angle ACB) + (\angle CAD) + (\angle D) + (\angle ACD) = 360^\circ \\ (\angle A) + (\angle B) + (\angle C) + (\angle D) = 360^\circ \\ 90^\circ + 90^\circ + 90^\circ + (\angle D) = 360^\circ \\ (\angle D) = 90^\circ. \end{gathered}$$

Therefore $\angle D$ is a right angle. $\square$

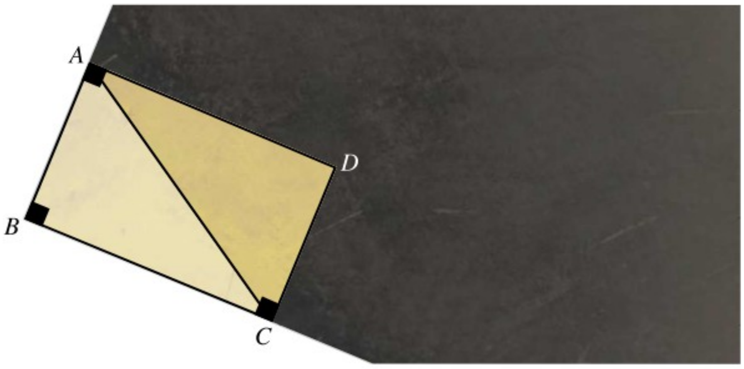

Figure 8. Verifying that the fourth angle is right.

Exercise 11.1 Fill in the gap in the proof by explaining why $\square ABCD$ must be convex.

We see then that, yes, rectangles exist in Euclidean geometry. Two essential properties of rectangles are provided in the following (easy) exercises.

Exercise 11.2 Let $\square ABCD$ be a rectangle. Prove that $\overline{AB}$ is parallel to $\overline{CD}$ and $\overline{AD}$ is parallel to $\overline{BC}$.

Exercise 11.3 Let $\square ABCD$ be a rectangle. Prove that $AB \simeq CD$ and $AD \simeq BC$ and $AC \simeq BD$.

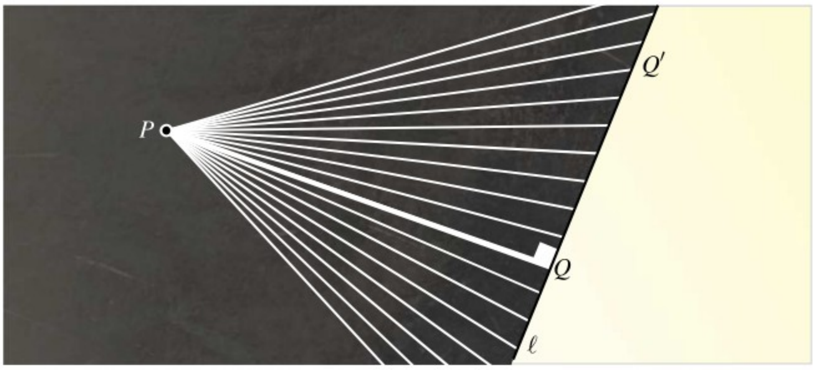

Figure 9. The distance from P to ℓ is measured along the segment from P to ℓ that is perpendicular to ℓ.

For the last result of this section, we return to parallel lines. One of the things that we will see when we study non-Euclidean geometry is that parallel lines tend to diverge from each other. That doesn't happen in Euclidean geometry. This is one of the key differences between the two geometries. Let's make this more precise. Suppose that P is a point that is not on a line ℓ. Define the distance from P to ℓ to be the minimum distance from P to a point on ℓ:

$$d(P,\ell) = \min\left\{|PQ| \,\middle|\, Q \text{ is on } \ell\right\}.$$

Exercise 11.4 Prove that the minimum actually occurs when Q is the foot of the perpendicular to ℓ through P (this can be proved using solely the axioms of neutral geometry).

For a pair of parallel lines, that distance as measured along perpendiculars does not change.

Theorem 11.5 *If ℓ and ℓ' are parallel lines, then the distance from a point on ℓ to ℓ' is constant. In other words, if P and Q are points on ℓ, then*

$$d(P,\ell') = d(Q,\ell').$$

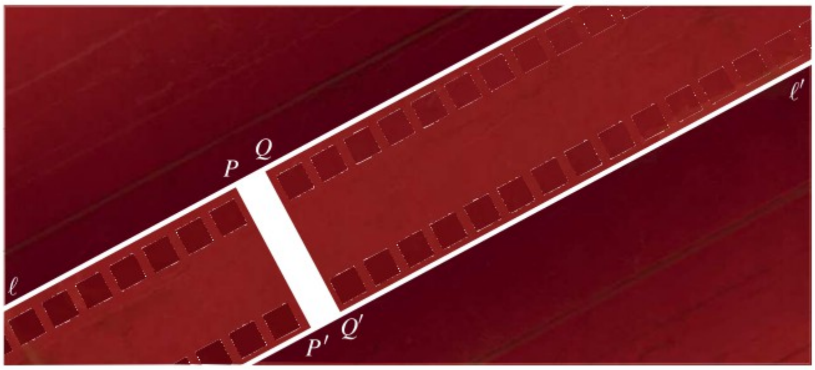

Figure 10. Perpendicular segments PP' and QQ' between parallel lines have the same length. That is, parallel lines are equidistant.

Proof Let P' and Q' be the feet of the perpendiculars on ℓ' from P and Q respectively. That way, by the previous exercise,

$$d(P, \ell') = |PP'| \text{ and } d(Q, \ell') = |QQ'|.$$

Then $\angle PP'Q'$ and $\angle QQ'P'$ are right angles. By the converse of the alternate interior angle theorem, $\angle P$ and $\angle Q$ are right angles too, so $\square PQQ'P'$ is a rectangle. According to exercise 11.2, PP' and QQ', which are opposite sides of a rectangle, are congruent. □

11.1 Exercises

11.5. Let ℓ be a line and P a point not on ℓ. Using only the results of neutral geometry, prove that there is at least one line through P that is parallel to ℓ.

11.6. Suppose that ℓ_1, ℓ_2, and ℓ_3 are three distinct lines such that ℓ_1 and ℓ_2 are parallel, and ℓ_2 and ℓ_3 are parallel. Prove that ℓ_1 and ℓ_3 are parallel.

11.7. Suppose that ℓ_1 and ℓ_2 are parallel lines, and that t is a line that intersects (but is distinct from) ℓ_1. Prove that t intersects ℓ_2.

11.8. Given three distinct parallel lines, prove that there is a labeling of them as ℓ_1, ℓ_2, and ℓ_3 so that

- no point of ℓ_1 lies between a point of ℓ_2 and a point of ℓ_3
- every point of ℓ_2 lies between a point of ℓ_1 and of ℓ_3
- no point of ℓ_3 lies between a point of ℓ_1 and a point of ℓ_2.

In this case, we can say that ℓ_2 is *between* ℓ_1 and ℓ_3.

11.9. This exercise is an extension of the previous one. Given n distinct parallel lines, prove that there is an ordering of them as $\ell_1, \ell_2, \ldots, \ell_n$ so that if $i < j < k$ then ℓ_j is between ℓ_i and ℓ_k.

11.10. Find the angle sum of a convex n-gon as a function of n.

11.11. What is the measure of an interior angle of a regular n-gon (as a function of n)?

11.12. Consider a convex quadrilateral $\square ABCD$. Prove that the two diagonals of $\square ABCD$ bisect each other if and only if $\square ABCD$ is a parallelogram.

11.13. Show that a parallelogram $\square ABCD$ is a rectangle if and only if $AC \simeq BD$.

11.14. Suppose that the diagonals of a convex quadrilateral $\square ABCD$ intersect one another at a point P and that

$$AP \simeq BP \simeq CP \simeq DP.$$

Prove that $\square ABCD$ is a rectangle.

11.15. Suppose that the diagonals of a convex quadrilateral bisect one another at right angles. Prove that the quadrilateral must be a rhombus.

11.16. Let $\triangle ABC$ be isosceles with $AB \simeq AC$, and let a be the midpoint of BC. Let b and c be points on the line through A that is parallel to BC so that $b * A * c$ and so that $bA \simeq cA \simeq Ba$. Prove that $\triangle ABC \simeq \triangle abc$.

11.17. Verify that the Cartesian model (as developed through the exercises in chapters 1–3) satisfies Playfair's axiom.

12

Parallel Projection

In the course of this chapter, we will need to use a few properties of parallelograms. It is rather common to confuse the properties of a parallelogram with its definition, so first, recall the definition of a parallelogram.

Definition 12.1 A *parallelogram* is a simple quadrilateral whose opposite sides are parallel.

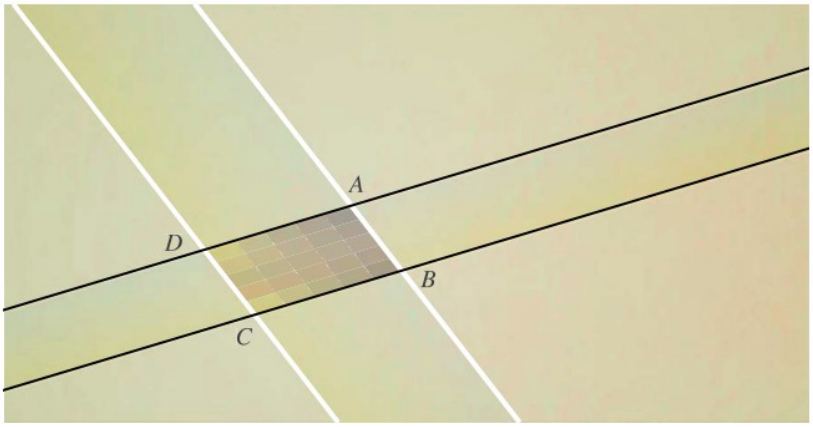

Figure 1. A parallelogram.

Now on to the properties of parallelograms that we will need for this chapter.

Exercise 12.1 Prove that in a parallelogram, the two pairs of opposite sides are congruent and the two pairs of opposite angles are congruent.

Exercise 12.2 Prove that if a convex quadrilateral has one pair of opposite sides that are both parallel and congruent, then it is a parallelogram.

Exercise 12.3 Let $\square ABB'A'$ be a simple quadrilateral. Verify that if AA' and BB' are parallel, but AB and $A'B'$ are not, then AA' and BB' cannot be congruent.

12.1 Parallel projection

The purpose of this chapter is to introduce a mechanism called *parallel projection*, a particular kind of mapping from the points on one line to the points on another. Parallel projection is the piece of machinery that you have to have in place to understand similarity, which is in turn essential for much of what we will be doing in the next chapters. The primary goal at this point is to understand how distances between points may be distorted by the parallel projection mapping. Once that is figured out, we will be able to turn our attention to the geometry of similarity.

Definition 12.2 A *parallel projection* from one line ℓ to another ℓ' is a map $\Phi : \ell \to \ell'$ that assigns to each point P on ℓ a point $\Phi(P)$ on ℓ' so that all the lines connecting a point and its image are parallel to one another.

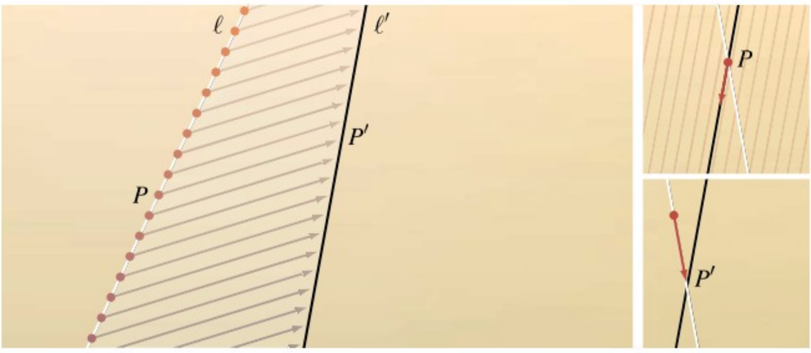

Figure 2. The path from a point P on ℓ to a point P' on ℓ' defines a parallel projection as long as neither P nor P' is the intersection of ℓ and ℓ' (as shown at right).

It is easy to construct parallel projections. Any point P on ℓ and its image $\Phi(P)$ on ℓ' completely determines the projection: for any other point Q on ℓ there is a unique line that passes through Q and is parallel to $\overleftrightarrow{P\,\Phi(P)}$. Wherever the line intersects ℓ' will have to be $\Phi(Q)$. There are only two cases where this construction will not work: if P is the intersection of ℓ and ℓ', then the lines of projection run parallel to ℓ' and so fail to provide a point of intersection; and if $\Phi(P)$ is the intersection of ℓ and ℓ', then the lines of projection actually coincide rather than being parallel.

Theorem 12.3 *A parallel projection is both one-to-one and onto.*

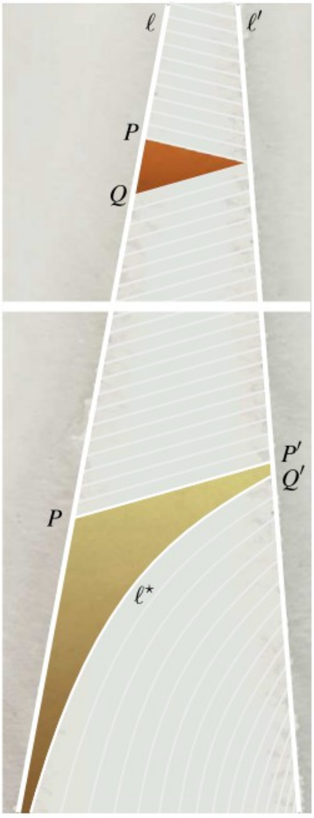

Figure 3. Using proofs by contradiction, we can show that parallel projection is both one-to-one (top) and onto (bottom).

Proof Let $\Phi : \ell \to \ell'$ be a parallel projection. First let's see why Φ is one-to-one. Suppose that it is not. That is, suppose that P and Q are two distinct points on ℓ but that $\Phi(P) = \Phi(Q)$. Then the two projecting lines $\overline{P\,\Phi(P)}$ and $\overline{Q\,\Phi(Q)}$, which ought to be parallel, actually share a point. This can't happen.

Now let's see why Φ is onto. Suppose that Q' is a point on ℓ' that is not in the image of Φ. To get a sense of how Φ is casting points from ℓ to ℓ', consider a point P on ℓ and its image $P' = \Phi(P)$ on ℓ'. By Playfair's axiom, there is a unique line $\ell^\star$ that passes through Q' and is parallel to $\overline{PP'}$. If $\ell^\star$ intersects ℓ at a point Q, then $\Phi(Q) = Q'$, contradicting the initial supposition that Q' is not in the image of Φ. If $\ell^\star$ does not intersect ℓ, then both ℓ and $\overline{PP'}$ are lines that pass through P and are parallel to $\ell^\star$, in violation of Playfair's axiom. In either case, we arrive at a contradiction. Therefore, an arbitrary point Q' of ℓ must be in the image of Φ, and so Φ is onto. $\square$

Now that we have established that parallel projection is a bijection, it helps to use a naming convention to makes things more readable. I will use a prime mark $'$ to indicate the parallel projection of a point, so $\Phi(P) = P'$, $\Phi(Q) = Q'$, and so on.

12.2 Parallel projection, order, and congruence

So far we have seen that parallel projection establishes a correspondence between the points of one line and the points of another. What about the order of the points? Can points get shuffled up in the process of a parallel projection? No.

Theorem 12.4 *Let $\Phi : \ell \to \ell'$ be a parallel projection. If A, B, and C are points on ℓ and $A * B * C$, then $A' * B' * C'$.*

Proof Because B is between A and C, A and C must be on opposite sides of $\overline{BB'}$. But, $\overline{AA'}$ does not intersect $\overline{BB'}$, so A' has to be on the same side of $\overline{BB'}$ as A; and $\overline{CC'}$ does not

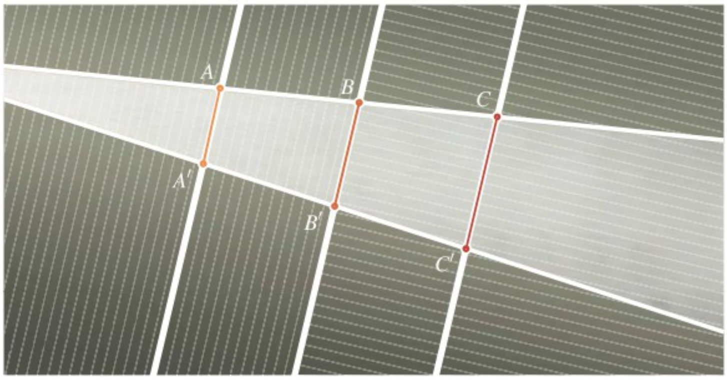

Figure 4. Parallel projection keeps points in order.

intersect $\overline{BB'}$, so C' has to be on the same side of $\overline{BB'}$ as C. Therefore A' and C' have to be on opposite sides of $\overline{BB'}$, and so the intersection of $\overline{BB'}$ and $A'C'$, which is B', must be between A' and C'. □

Now what about congruence?

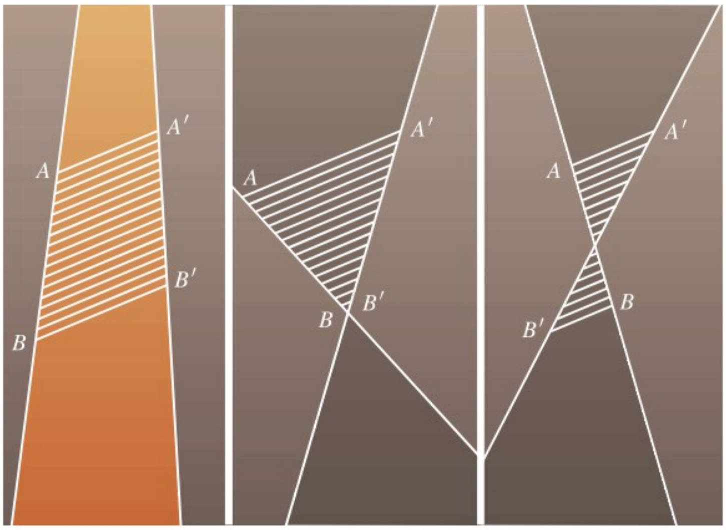

Figure 5. There are three positions for A and B relative to the image line: both on the same side, one on the image line, or one on each side. Likewise, there are three positions for a and b. There are nine cases in all.

Theorem 12.5 *Let* $\Phi : \ell \to \ell'$ *be a parallel projection. If* a, b, A, *and* B *are points on* ℓ *and if* $ab \simeq AB$, *then* $a'b' \simeq A'B'$.

Proof There are several cases, depending on the positions of ab and AB relative to ℓ'. They could lie on the same side of ℓ', they could lie on opposite sides of ℓ', one or both could straddle

ℓ', or one or both could have an endpoint on ℓ'. Each case must be handled differently. We will look at the case where both segments are on the same side of ℓ'. The others are left as exercises. There are still two cases to consider, depending on whether or not ℓ and ℓ' are parallel.

Case 1: when ℓ and ℓ' are parallel (see figure 6). This is the simpler case, but it helps illuminate the more general case. Because aa' is parallel to bb' and ab is parallel to $a'b'$, $\square aa'b'b$ is a parallelogram; AA' is parallel to BB' and AB is parallel to $A'B'$ so $\square AA'B'B$ is also a parallelogram. Because the opposite sides of a parallelogram are congruent (exercise 12.1), $a'b' \simeq ab$ and $AB \simeq A'B'$. Since $ab \simeq AB$, $a'b' \simeq A'B'$.

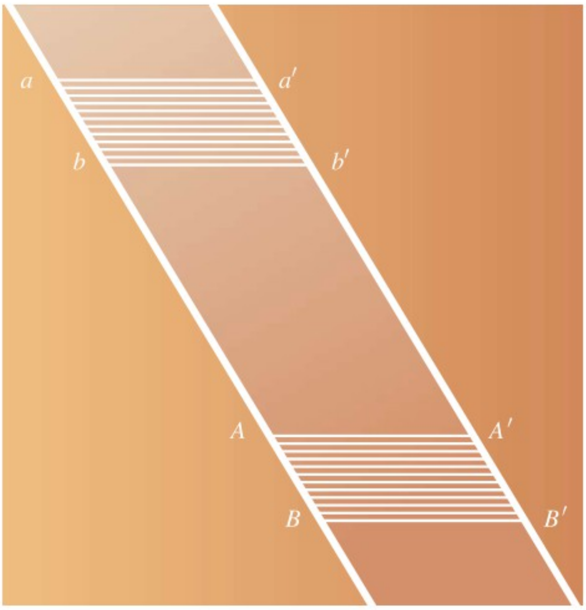

Figure 6. Case 1, when the two lines are parallel.

Case 2: when ℓ and ℓ' are not parallel (see figure 7). This is the more likely case, in which $\square aa'b'b$ and $\square AA'B'B$ will not be parallelograms. We can takes a similar approach to case 1, though, by building some parallelograms into the problem. Because ℓ and ℓ' are not parallel, the segments aa' and bb' cannot have the same length (exercise 12.3), and the segments AA' and BB' cannot have the same length. Let's assume that aa' is shorter than bb' and that AA' is shorter than BB'. If this is not the case, then it is just a matter of switching some labels to make it so. Then

- there is a point c between b and b' so that $bc \simeq aa'$, and
- there is a point C between B and B' so that $BC \simeq AA'$.

This creates four shapes of interest: the quadrilaterals $\square a'abc$ and $\square A'ABC$ that are parallelograms (exercise 12.2), and the triangles $\triangle a'b'c$ and $\triangle A'B'C$. The key here is to prove that $\triangle a'b'c \simeq \triangle A'B'C$.

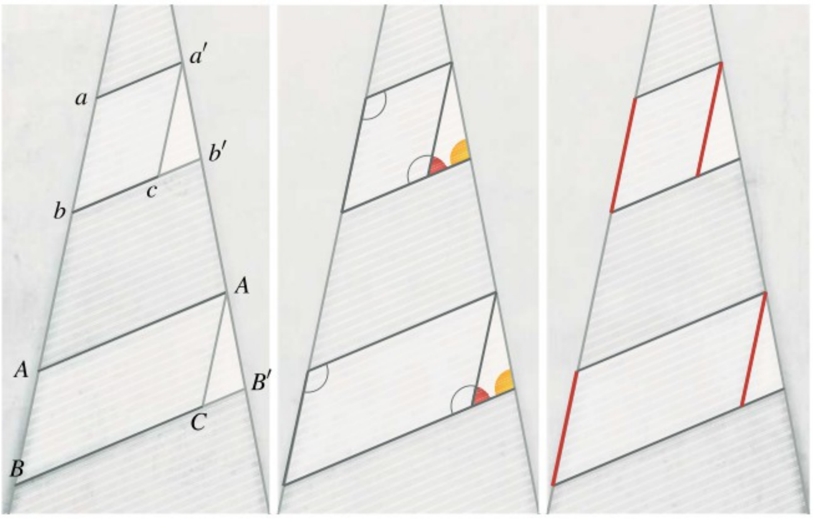

Figure 7. The non-parallel case. (l) First construct parallelograms. (c) The two angles and (r) the sides needed for AAS to show that $\triangle a'b'c' \simeq \triangle A'B'C'$.

- **A:** $\angle b' \simeq \angle B'$. The lines $\overline{cb'}$ and $\overline{CB'}$ are parallel (they are two of the projecting lines) and they are crossed by the transversal ℓ'. By the converse of the alternate interior angle theorem, $\angle a'b'c$ and $\angle A'B'C$ are congruent.
- **A:** $\angle c \simeq \angle C$. The opposite angles of the two parallelograms are congruent. Therefore $\angle a'cb \simeq \angle a'ab$ and $\angle A'AB \simeq \angle A'CB$. But $\overline{aa'}$ and $\overline{AA'}$ are parallel lines cut by the transversal ℓ, so $\angle a'ab \simeq \angle A'AB$, so $\angle a'cb \simeq \angle A'CB$, and so their supplements $\angle a'cb'$ and $\angle A'CB'$ are also congruent.
- **S:** $a'c \simeq A'C$. The opposite sides of the two parallelograms are congruent too. Therefore $a'c \simeq ab$ and $AB \simeq A'C$, and since $ab \simeq AB$, we get $a'c \simeq A'C$.

By AAS, then, $\triangle a'b'c \simeq \triangle A'B'C$. The corresponding sides $a'b'$ and $A'B'$ have to be congruent.
□

Exercise 12.4 Fill in some gaps:

(1) Prove the theorem in the case when both a and A lie on ℓ' (at the intersection of ℓ and ℓ').
(2) Prove the theorem in the case when a and A lie on opposite sides of ℓ' from b and B.

12.3 Parallel projection and distance

That brings us to the question at the very heart of parallel projection. If Φ is a parallel projection and A and B are two points on ℓ, how do the lengths $|AB|$ and $|A'B'|$ compare? In case 1 of the last proof, AB and $A'B'$ ended up being congruent, but that was because ℓ and ℓ' were parallel. In general, AB and $A'B'$ do not have to be congruent. But it turns out that in the process of parallel projecting from one line to another, all distances are scaled by a constant multiple.

Theorem 12.6 *If $\Phi : \ell \to \ell'$ is a parallel projection, then there is a constant k such that*

$$|A'B'| = k|AB|$$

for all points A and B on ℓ.

It is helpful to get a little perspective on this before the proof. First note that the previous theorem gives us a way to narrow the scope of the problem. Fix a point O on ℓ and let r be one of the two rays along ℓ with O as its endpoint. The segment construction axiom says that every segment AB on ℓ is congruent to a segment OP where P is some point on r. We have just seen that parallel projection maps congruent segments to congruent segments. So if Φ scales all segments of the form OP by a factor of k, then it must scale all the segments of ℓ by the same factor.

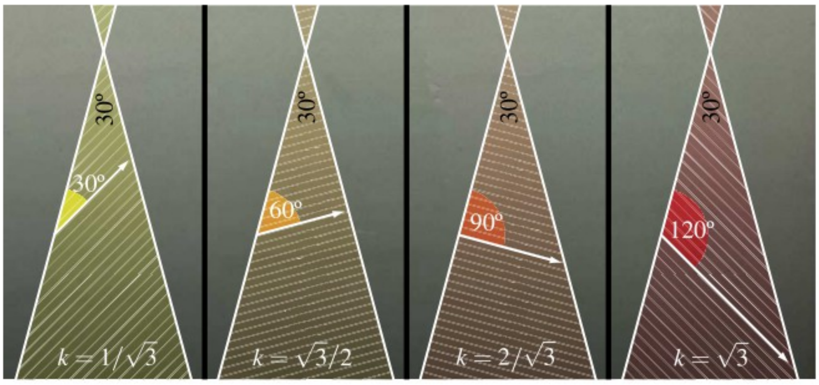

Figure 8. Some parallel projections and their scaling constants.

Second, we can extend that by considering what happens when we parallel project end-to-end congruent copies of a segment. For this, let me introduce another convenient notation convention: for the rest of this argument, let P_d denote the point on r that is a distance d from O. Now, pick a positive real value x, and let

$$k = |O'P'_x|/|OP_x|,$$

so that Φ scales the segment OP_x by a factor of k. Eventually we will have to show that Φ scales all segments by that factor, but for now let's restrict our attention to the segments OP_{nx}, where n is a positive integer. Between O and P_{nx} are P_x, P_{2x}, … $P_{(n-1)x}$ in order:

$$O * P_x * P_{2x} * \cdots * P_{(n-1)x} * P_{nx}.$$

We have seen that parallel projection preserves the order of points, so

$$O' * P'_x * P'_{2x} * \cdots * P'_{(n-1)x} * P'_{nx}.$$

Each segment $P_{ix}P_{(i+1)x}$ is congruent to OP_x and consequently each parallel projection $P'_{ix}P'_{(i+1)x}$ is congruent to $O'P'_x$. Add their lengths:

$$\begin{aligned}|O'P'_{nx}| &= |O'P'_x| + |P'_xP'_{2x}| + |P'_{2x}P'_{3x}| + \cdots + |P'_{(n-1)x}P'_{nx}| \\ &= kx + kx + kx + \cdots + kx \quad (n \text{ times}) \\ &= k \cdot nx\end{aligned}$$

and so Φ scales OP_{nx} by a factor of k.

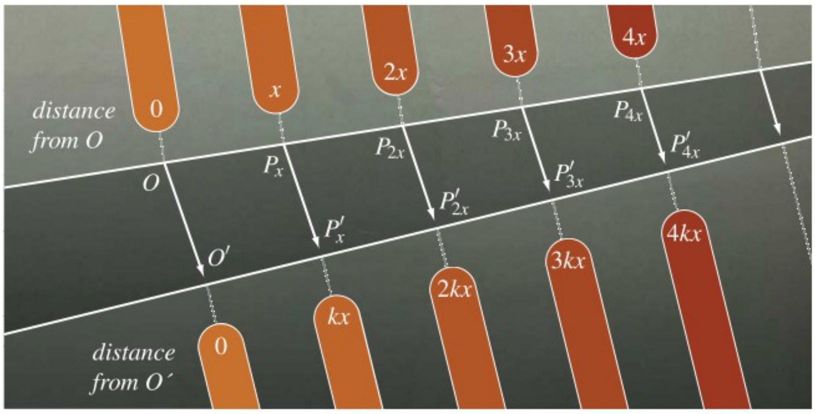

Figure 9. Scaling of segments of length kx, where k is an integer.

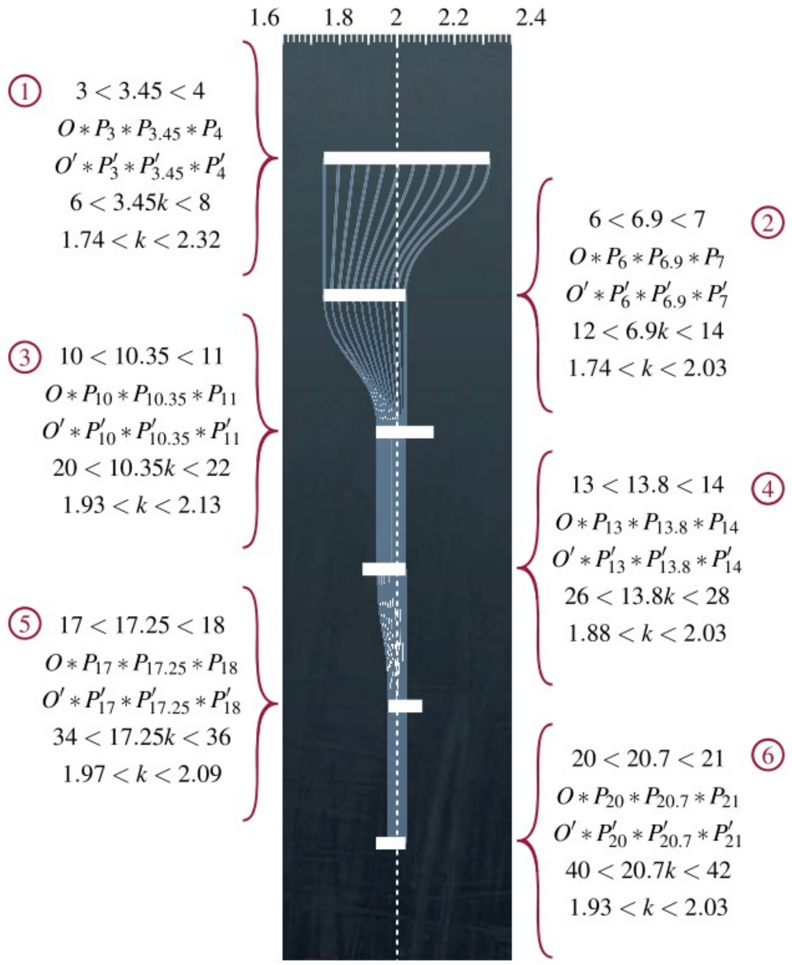
Sadly, no matter what x is, the points P_{nx} account for an inconsequential portion of the set of all points of r. However, if OP_x and OP_y were to have two different scaling factors we could use this end-to-end copying to magnify the difference between them. Third, then, consider an example that demonstrates how this works, and which shows how this ultimately prevents there being two different scaling factors. In this example, let's suppose that $|O'P'_1| = 2$, so all integer length segments on ℓ are scaled by a factor of 2. Let's take a look at what this means for $P_{3.45}$. Let k be the scaling factor for $OP_{3.45}$. Figure 10 shows how the first few end-to-end copies of $OP_{3.45}$ begin to limit the possible values of k.

Fourth, note that the floor function, $f(x) = \lfloor x \rfloor$, assigns to each real number x the largest integer that is less than or equal to it. The ceiling function, $f(x) = \lceil x \rceil$, assigns to each real number x the smallest integer that is greater than or equal to it.

It is finally time to prove that parallel projection scales distance.

Proof Let $k = |O'P'_1|$ so that k is the scaling factor for the segment of length 1 (and consequently for all integer length segments). Now take a point P_x on ℓ and let k' be the scaling factor for the segment OP_x. We want to show that $k' = k$ and we can do that by following the same strategy as in the example above, by capturing k' in an increasingly narrow band around k by looking at the parallel projection of P_{nx} as n increases. Start by working back and forth between



① $3 < 3.45 < 4$
$O * P_3 * P_{3.45} * P_4$
$O' * P'_3 * P'_{3.45} * P'_4$
$6 < 3.45k < 8$
$1.74 < k < 2.32$

② $6 < 6.9 < 7$
$O * P_6 * P_{6.9} * P_7$
$O' * P'_6 * P'_{6.9} * P'_7$
$12 < 6.9k < 14$
$1.74 < k < 2.03$

③ $10 < 10.35 < 11$
$O * P_{10} * P_{10.35} * P_{11}$
$O' * P'_{10} * P'_{10.35} * P'_{11}$
$20 < 10.35k < 22$
$1.93 < k < 2.13$

④ $13 < 13.8 < 14$
$O * P_{13} * P_{13.8} * P_{14}$
$O' * P'_{13} * P'_{13.8} * P'_{14}$
$26 < 13.8k < 28$
$1.88 < k < 2.03$

⑤ $17 < 17.25 < 18$
$O * P_{17} * P_{17.25} * P_{18}$
$O' * P'_{17} * P'_{17.25} * P'_{18}$
$34 < 17.25k < 36$
$1.97 < k < 2.09$

⑥ $20 < 20.7 < 21$
$O * P_{20} * P_{20.7} * P_{21}$
$O' * P'_{20} * P'_{20.7} * P'_{21}$
$40 < 20.7k < 42$
$1.93 < k < 2.03$

Figure 10. An example. Projecting end-to-end congruent copies of a segment of length 3.45 by a parallel projection that scales all integer length segments by a factor of two.

inequalities of real numbers and orders of points:

$$\begin{gathered}\lfloor nx \rfloor \leq nx \leq \lceil nx \rceil \\ O * P_{\lfloor nx \rfloor} * P_{nx} * P_{\lceil nx \rceil} \\ O' * P'_{\lfloor nx \rfloor} * P'_{nx} * P'_{\lceil nx \rceil} \\ k\lfloor nx \rfloor \leq k'nx \leq k\lceil nx \rceil.\end{gathered}$$

(The notation here is a bit casual—if nx is an integer, then $\lfloor nx \rfloor = nx$, so $P_{\lfloor nx \rfloor}$ is not actually between O and P_{nx}. This does not cause any problems for the proof.) Because $(nx - 1) \leq \lfloor nx \rfloor$

and $\lceil nx \rceil \leq (nx+1)$ we can move to a less precise but more manageable set of inequalities:

$$k(nx-1) \leq k'nx \leq k(nx+1).$$

Divide by nx to get

$$k\left(\frac{nx-1}{nx}\right) \leq k' \leq k\left(\frac{nx+1}{nx}\right).$$

As n increases, the ratios $(nx-1)/(nx)$ and $(nx+1)/(nx)$ both approach 1. In the limit as n goes to infinity, they are 1. Since the inequalities have to be true for all n, the only possible value for k' , then, is k. □

12.4 Exercises

12.5. Suppose that Φ is a parallel projection from ℓ to ℓ'. If ℓ and ℓ' intersect at P, prove that $\Phi(P) = P$.

12.6. Prove that if ℓ and ℓ' are parallel, then the scaling factor of a parallel projection between them must be one, but that if ℓ and ℓ' are not parallel, then there is a parallel projection with every possible scaling factor k where $0 < k < \infty$.

12.7. Let $\Phi : \ell \to \ell'$ be a parallel projection. Show that the inverse map $\Phi^{-1} : \ell' \to \ell$ is also a parallel projection.

12.8. Let $\Phi_1 : \ell \to \ell'$ and $\Phi_2 : \ell' \to \ell''$ be parallel projections. Is the composition $\Phi_2 \circ \Phi_1 : \ell \to \ell''$ necessarily a parallel projection?

12.9. In chapter 6, we constructed a distance function, and one of the keys to the construction was locating the points on a ray that were a distance of $m/2^n$ from its endpoint. In Euclidean geometry, there is a construction that locates all the points on a ray that are any rational distance m/n from its endpoint. Take two non-opposite rays r and r' with a common endpoint O. Along r, lay out m congruent copies of a segment of length 1, ending at the point P_m. Along r', lay out n congruent copies of a segment of length 1, ending at the point Q_n. Mark the point Q_1 on r' that is a distance 1 from O. Verify that the line that passes through Q_1 and is parallel to P_mQ_n intersects r a distance of m/n from O.

Chapter 3

Calculating the Value of π?

Up to now we have described π and mentioned ways in which attempts have been made to calculate its value. They varied from highly intelligent (say, ingenious) guesses by mathematicians, to attempts at performing calculations that were later proved impossible (i.e., squaring the circle), to carefully planned constructions that would yield the value of π if carried out far enough and carefully enough. Some methods of calculating the value of π, strangely enough, relied on probability, or in one case on mysterious insights. Here we will provide you with a variety of methods for calculating the value of π. We chose those that should be easily understood by the general reader. Where a concept is used that may be a bit off the beaten path, or simply unfamiliar to some, we provide some background information. We will be presenting the classical attempts, rather than those used in the more recent computer-driven methods. We begin with one of the most famous classical methods, by one of the most gifted mathematicians in the history of mathematics, Archimedes.

Archimedes' Method for Finding the Value of π

Perhaps the easiest way to begin to calculate the value of π was developed by Archimedes. It is a method that can appeal to one's intuition. He noticed that as the number of sides of a regular polygon increases, while keeping the radius or the apothem[1] constant, the limiting value of the perimeter is the circumference of a circle. That is, suppose we take the first few regular polygons (an equilateral triangle, a square, a regular pentagon, and a regular hexagon) and inscribe them in the same-size circle. As the number of sides of the regular polygon increases, the perimeter of the polygon gets closer and closer to the circumference (i.e., perimeter) of the circle. Remember that the circumscribed circle must contain each of the vertices of the polygon. Here is what it can look like.

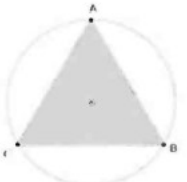

Fig. 3-1a

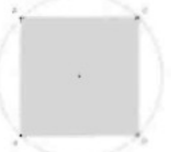

Fig. 3-1b

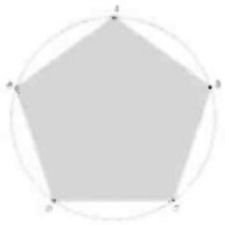

Fig. 3-1c

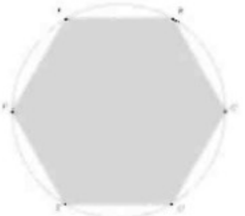

Fig. 3-1d

---

[1] The apothem is the segment from the center of a regular polygon to the midpoint of one of its sides. It is perpendicular to the side.

This may be easier to see when the regular polygon's sides increase further so that it becomes a dodecagon (which has twelve sides). We can actually calculate the increasing perimeters and see them gradually approach the circumference of the circle.

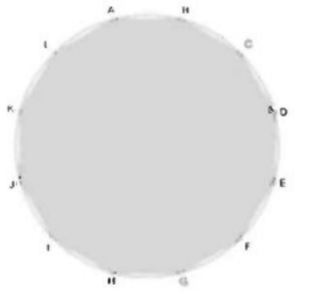

Fig. 3-2

Let's take the hexagon as our example of a "general polygon." From this we will then generalize to polygons of many more (or fewer) sides. We begin with a regular hexagon inscribed in a circle of radius $\frac{1}{2}$. The measure of $\angle AOB$ is one-sixth of a complete revolution of 360°, or 60°. Since $\overline{OK} \perp \overline{AB}$ at K, $BK = AK = a$.

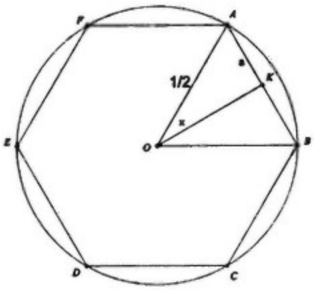

Fig. 3-3

We seek to find the perimeter of the hexagon, when we know the length of the radius $\left(\frac{1}{2}\right)$ and the measure of

$$\angle AOK = \frac{1}{2}(60°) = 30°$$

Using the trigonometric function sine,[2] we get

$$\angle AOK = \sin 30° = \frac{a}{\frac{1}{2}} = 2a$$

Since $\sin 30° = \frac{1}{2}$, then $2a = \frac{1}{2}$, and $a = \frac{1}{4}$. The perimeter of the hexagon is then 12 times a, which equals 3.

Let's generalize this for any regular polygon of n sides.

$$\angle x = \frac{1}{2} \bullet \frac{360°}{n} = \frac{180°}{n}$$

Therefore, for the general regular polygon of n sides

$$\sin \frac{180°}{n} = 2a$$

The perimeter of the n-sided regular polygon is then n times $2a$, which makes this perimeter equal to

$$n \sin \frac{180°}{n}$$

We can then take various values of n and compute the perimeter of the regular polygon whose circumscribed circle has a radius of $\frac{1}{2}$.

---

[2] The sine function is defined for a right triangle as the ratio of the side opposite the angle in question and the hypotenuse (the side opposite the right angle).

We shall work out the first few examples here and then provide the results of others in a table.

When $n = 3$:

$$3\sin\frac{180^\circ}{3} = 3\sin 60^\circ \approx 3(0.86602540378443864676372317075294)$$
$$= 2.5980762113533159402911695122588$$

When $n = 4$:

$$4\sin\frac{180^\circ}{4} = 4\sin 45^\circ \approx 4(0.70710678118654752440084436210485)$$
$$= 2.8284271247461900976033774484194$$

When $n = 5$:

$$5\sin\frac{180^\circ}{5} = 5\sin 36^\circ \approx 5(0.58778525229247312916870595463907)$$
$$= 2.9389262614623656458435297731954$$

When $n = 6$:

$$6\sin\frac{180^\circ}{6} = 6\sin 30^\circ = 6(0.50000000000000000000000000000000)$$
$$= 3.00000000000000000000000000000000$$

We just calculated the first four entries in the table below and here provide you with the remaining ones.

180	3.1414331587110323074954161329369…
250	3.1415099708381519785686472871987…
500	3.1415719827794756248676550789799…
1,000	3.1415874858795633519332270354959…
10,000	3.141592601912665692979346479289…

Now compare this 10,000-sided regular polygon (our last entry) to the value of π that we already know. Remember it is inscribed in the circle with radius $\frac{1}{2}$. This 10,000-sided polygon is optically quite indistinguishable from the circle (obviously, without magnification enhancements). The circumference of the circumscribed circle of radius $\frac{1}{2}$ is $2\pi r = 2\pi\left(\frac{1}{2}\right) = \pi$.

Look at the known value of π for comparison.

π ≈ 3.1415926535 8979323846 2643383279 5028841971 6939937510 5820974944…

Up to the seventh decimal place, the approximation with a 10,000-sided regular polygon perimeter is correct. If we were to calculate the perimeter of a regular polygon of 100,000 sides, we would get an even closer approximation. The perimeter of a regular polygon of 100,000 sides is 3.14159265307302196048314802075 31…, which approximates π correct to nine decimal places.

Archimedes (obviously) did not have the luxury of using electronic (or even mechanical) calculating devices to assist him in his calculations.[3] He also did not have the facility brought about by the place value system (such as our decimal system), nor did he have the use of trigonometry available to him. Yet he still used a 96-sided regular polygon. He saw the circle as the limiting figure of an inscribed circle as well as the circumcircle we just used above. By taking the average of the perimeters of each pair of circles of n-sided regular polygons, he would "sandwich in" the perimeter of the circle, which in the case of a circle with radius of $\frac{1}{2}$ is π.

---

[3] The mechanical calculator was invented by four mathematicians over a rather wide stretch of time. Wilhelm Schickardt (1592–1635), a German mathematician, built the first digital calculator in 1623. Blaise Pascaal (1623–1662) built the first mechanical calculating machine in 1642 for his father, who was a tax collector. The machine, called Pascaline, was commercially sold after 1645. Gottfried Wilhelm Leibniz (1646–1716) developed a mechanical calculator in 1673 that failed during a demonstration in London but nonetheless, because of the spectacular concept involved, was accepted in the Royal Society. The English mathematician Charles Babbage (1792–1871), despite devoting a greater part of his professional life to its development, never reached a completed product.

Let us now repeat the above exercise with the polygon circumscribed about the circle, or, put another way, where the circle of radius $\frac{1}{2}$ is inscribed in the polygon (i.e., the circle must be tangent to each side of the polygon). As before, we will consider regular polygons with successively greater numbers of sides, each with our given circle inscribed.

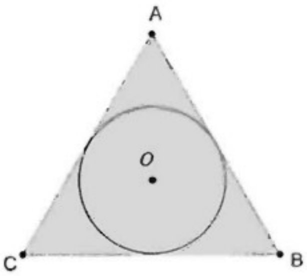

Fig. 3-4a

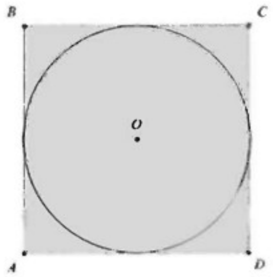

Fig. 3-4b

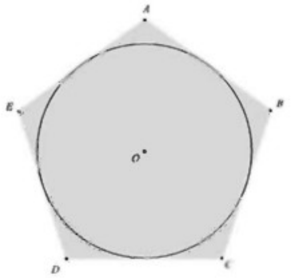

Fig. 3-5

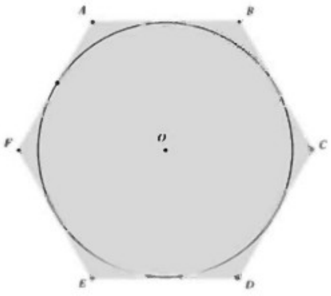

Fig. 3-6

Notice how gradually the perimeter of the polygon appears to get closer and closer to the circumference of the circle.

He began his work in 1812 and worked for decades on the project. In the end, the lack of precision tools prevented him from achieving his "analytical engine" in 1833. His work was first realized in the form of a working machine in 1944 when the IBM Corporation and Harvard University collaborated to produce the Automatic Sequence Controlled Calculator.

This time we will consider a regular pentagon circumscribed about our circle of radius $\frac{1}{2}$ as our first polygon to study. Then we will generalize our procedure and extend it to many others.

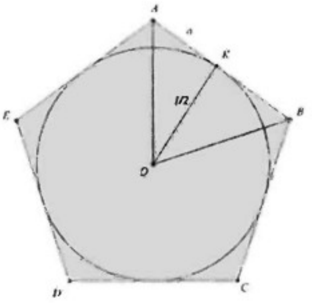

Fig. 3-7

Our objective is to find the perimeter of the pentagon with a side of $2a$. We know that

$$\tan \angle AOK = \frac{a}{OK}{}^{4} \text{ and } m\,\angle AOB = 72^\circ$$

so that

$$m\angle AOK = 36^\circ \text{, while } OK = \frac{1}{2}$$

Therefore,

$$a = \frac{1}{2}\tan 36^\circ \approx \frac{1}{2}(0.72654252800536088589546675748062)$$
$$= 0.36327126400268044294773337874031$$

---

[4] The tangent function is defined for a right triangle as the ratio of the side opposite the angle being considered to the side adjacent to this angle.

Thus the perimeter of the pentagon is 10 times a, or about 3.6327126400268044294773337874031 (this is found by taking 5 times $2a$, or about 3.6327), not yet a very close approximation of π. The circumference of the circle is $2\pi r = 2\pi\left(\frac{1}{2}\right) = \pi$.

In the general case of a regular polygon of n sides

$$m\angle AOK = \frac{1}{2}\bullet\frac{360^\circ}{n} = \frac{180^\circ}{n}$$

From the example of the pentagon, $\tan\angle AOK = \frac{a}{OK}$. It follows that

$$a = OK\tan\angle AOK = \frac{1}{2}\ \bullet \tan\ \frac{180^\circ}{n}$$

The perimeter of the polygon is then

$$n\bullet 2a = n\bullet 2\bullet\frac{1}{2}\bullet\tan\frac{180^\circ}{n} = n\tan\frac{180^\circ}{n}$$

As before, we will calculate the perimeters of the various polygons, this time, though, circumscribed about our circle with radius $\frac{1}{2}$.

We already have the calculated perimeter for the pentagon, so we will do the calculation for the hexagon now.

When $n = 6$:

$$n\bullet\tan\frac{180^\circ}{n} = 6\bullet\tan\frac{180^\circ}{6}\bullet\tan 30^\circ = 6\bullet\frac{\sqrt{3}}{3} \approx 3.4641$$

For more than four decimal places we get the following:

n	**Perimeter of circumscribed polygon of *n* sides**
3	5.1961524227066318805823390245176…

Again you will notice how the more sides the polygon has, the closer its perimeter gets to the circumference of the circle—which we now know is π.

Archimedes, as we said before, saw the inscribed and the circumscribed polygons "sandwiching in" the circle, as seen below by the inscribed and circumscribed dodecagons ($n = 12$).

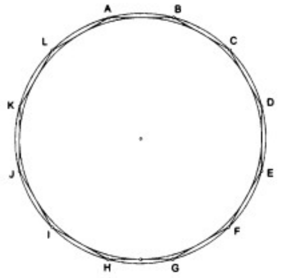

Fig. 3-8

He essentially suggested taking the average of the two perimeters for each type of polygon to get a better approximation of π.

The average of the two perimeters (the right-hand column) is closest to the value of π for each type of polygon. When Archimedes did these calculations, he didn't take as many examples as we did here. He began with two regular hexagons, then doubled the number of sides, using two dodecagons (12-sided polygons), then used two 24-gons,[5] then two 48-gons, and then two 96-gons.

Although his calculations were probably not as accurate as ours are, and we do not have a record of how he did his calculations, he did conclude from the 96-gon that the ratio of the circumference of a circle to its diameter—which is π—is greater than $3\frac{10}{71}$ and less than $3\frac{1}{7}$. We can write this symbolically as

$$3\frac{10}{71} < \pi < 3\frac{1}{7}$$

For comparison to the above, this is

$$3.1408450704225352112676056338028\ldots < \pi < 3.1428571428571428571428571428571\ldots$$

We have come a long way since Archimedes' ingenious methods. As we noted earlier, we can now calculate π to many more places than ever thought possible; however, this "primitive" method gives much intuitive insight into what this ratio that π represents really is.

A Reverse Method to Archimedes by Cusanus

Archimedes had used inscribed and circumscribed regular polygons within and about a given circle, each time increasing the number of sides. The argument was that as the number of sides of the polygons increased, the circumference of the circle, "sandwiched" between the two polygons, was the limiting value of the polygon.

---

[5] 24-gon is a short way of referring to a 24-sided polygon.

An analogous method developed by Nicholas of Cusa (1401–1464) has us "sandwiching" in regular polygons with increasing numbers of sides by inscribed and circumscribed circles. Nicholas of Cusa[6] took his name from his hometown of Cues (today Kues) on the Mosel River in Germany. By today's assessments, he is considered one of the pioneering German thinkers in the transition from the Middle Ages to modern times, yet he was not too well known as a mathematician. He was better known for his substantial career in the church. He became a cardinal in 1488 and was bishop of Brixen (northern Italy) and a governor (or vicar general) of Rome. As a mathematician, he made ill-fated attempts to square the circle[7] and to trisect the general angle,[8] both of which we now know are impossible. As with many mathematicians fascinated with one of the three "famous problems of antiquity," namely, squaring the circle, Cusanus's attempts led him to a fine approximation of π. Let's take a look at what Cusanus achieved in these attempts. We will demonstrate this here, but in more modern terms.

In 1450 Cusanus nested a given regular polygon with the fixed perimeter 2 with inscribed and circumscribed circles. He used a sequence of the regular n-gons ($n = 4, 8, 16, 32, \ldots$).

---

[6] Sometimes referred to by his Latin name, Cusanus.

[7] One of the three famous problems of antiquity—no longer a problem today—is how to "square a circle." That means how to construct (with only an unmarked straightedge and a pair of compasses) the side length of a square equal in area to a given circle. Today, we know this to be impossible.

[8] Another of the three famous problems of antiquity—no longer a problem today—is how to "trisect an angle." That means how to construct (with only an unmarked straightedge and a pair of compasses) angle trisectors of a general angle—not any specific number of degrees, for it would be possible for some special angles, such as a right angle Today, we know this general angle trisection to be impossible

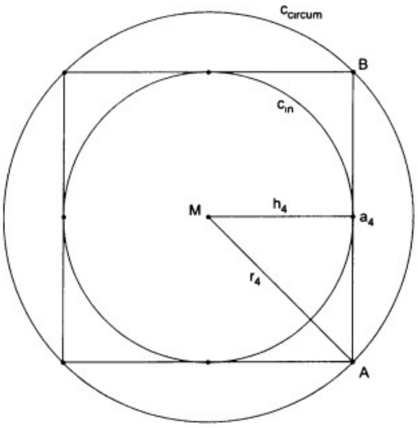

Fig. 3-9

Let's begin as Cusanus did by starting with a square (which may, of course, be referred to as a regular 4-gon). We will call the perimeter of the square p_4. Since each side of the square is $a_4 = \frac{1}{2}$, then $p_4 = 4 \bullet a_4 = 2$.

Consider the inscribed circle with circumference C_{in} and the circumscribed circle with circumference C_{circum} of the square pictured above. The radius of the inscribed circle is

$$h_4 = \frac{a_4}{2} = \frac{1}{4} = 0.25$$

The radius of the circumscribed circle is

$$r_4 = \sqrt{h_4^2 + \left(\frac{a_4}{2}\right)^2} = \frac{\sqrt{2}}{4} \approx 0.3535533905$$

We can plainly see that the perimeter of the square is somewhere between the circumferences of the two circles, so we can compare the perimeter, p_4, and the two circumferences, C_{in} and C_{circum}, to get

$$C_{\text{in}} < p_4 < C_{\text{circum}} \quad \text{or} \quad 2\pi\, h_4 < 2 < 2\pi\, r_4$$

Dividing all terms by 2 gives us

$$\pi\, h_4 < 1 < \pi\, r_4$$

Then dividing all terms by π we get

$$h_4 < \frac{1}{\pi} < r_4$$

Taking the reciprocal values of each of the terms reverses the inequality, so we get

$$\frac{1}{r_4} < \pi < \frac{1}{h_4}$$

Since $r_4 = \frac{\sqrt{2}}{4}$, it follows that $\frac{1}{r_4} = \frac{4}{\sqrt{2}} \approx 2.82842713$ and $\frac{1}{h_4} = 4$. Therefore $2.82842713 < \pi < 4$, a rather rough approximation for the value of π. But wait, as we increase the number of sides of the regular polygon, the estimates should get better.

The next approximation was done by doubling the number of sides of the regular polygon we just used to get a regular octagon. Cusanus considered a regular 8-gon with h_8 as the radius of the inscribed circle with circumference C_{in} and r_8 as the radius of the circumscribed circle with circumference C_{circum}.

Since each side is $a_8 = \frac{1}{4}$, the perimeter, p_8, of the regular 8-gon is $p_8 = 8 \cdot a_8 = 2$.

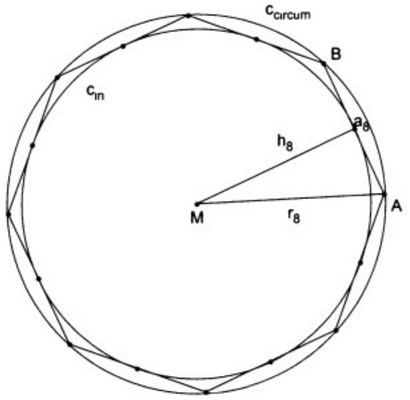

Fig. 3-10

$m\angle AMB = 45°$, therefore, $m\angle AMC = 22.5°$

$$\tan \angle AMC = \tan 22.5° = \sqrt{2} - 1 = \frac{\frac{a_8}{2}}{h_8} = \frac{a_8}{2h_8}$$ [9]

This can then be transformed into the following equation:

$$h_8 = \frac{a_8}{2\tan \angle AMC} = \frac{\frac{1}{4}}{2\bullet\left(\sqrt{2}-1\right)} = \frac{1}{8\left(\sqrt{2}-1\right)} = \frac{\sqrt{2}+1}{8} \approx 0.3017766952$$ [10]

With the Pythagorean theorem, $r_8^2 = h_8^2 + \left(\frac{a_8}{2}\right)^2$, we get

$$r_8 = \sqrt{\frac{\sqrt{2}}{32} + \frac{1}{16}} \approx 0.3266407412$$

For the perimeter, p_8, and circumferences, C_{in} and C_{circum}, we get

$$C_{\text{in}} < p_8 < C_{\text{circum}} \quad \text{or} \qquad 2\pi\, h_8 < 2 < 2\pi\, r_8$$

Dividing both sides by 2, it follows that $\pi h_8 < 1 < \pi r_8$, which, when dividing each term by π, yields $h_8 < \frac{1}{\pi} < r_8$.

---

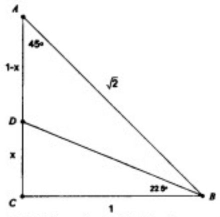
[9] Tan $22.5° = \sqrt{2} - 1$ can be obtained by applying a theorem from the high school course to an isosceles right triangle with one of its base angles bisected to get 22.5°

The theorem states that the angle bisector of a triangle divides the side to which it is drawn proportionally to the two adjacent sides Hence,

$$\frac{\sqrt{2}}{1} = \frac{1-x}{x}\text{, then } x\sqrt{2} = 1 - x\text{, and } x = \frac{1}{\sqrt{2}+1}$$

Rationalizing the denominator gives us

$$x = \frac{1}{\sqrt{2}+1} \bullet \frac{\sqrt{2}-1}{\sqrt{2}-1} = \sqrt{2} - 1$$



[10] This was obtained by rationalizing the denominator, that is, by multiplying by 1 in the form of $\frac{\sqrt{2}+1}{\sqrt{2}+1}$

Again, taking the reciprocal of each term reverses the inequality to give us

$$\frac{1}{r_8} < \pi < \frac{1}{h_8}$$

That means for the reciprocal values

$$\frac{1}{r_8} = \sqrt{32 - 16\sqrt{2}}$$

$$= 4\sqrt{2 - \sqrt{2}} \approx 3.061467458$$

and $\frac{1}{h_8} = 8\,(\sqrt{2} - 1) \approx 3.313708498$

We finally have a more accurate value range for π:

$$3.061467458 < \pi < 3.313708498$$

We will now take a giant leap to the general case, where we will try to sandwich in the value of π. This may be a bit complicated for the reader no longer familiar with some of the intricacies of high school mathematics, yet it is the conclusion of this generalization that is of greater importance than the process.

For the general case, h_n is the radius of the inscribed circle with circumference C_{in}, and r_n is the radius of the circumscribed circle with circumference C_{circum} of a regular n-gon ($n = 4, 8, 16, 32, \ldots$). We have established above that

$$\frac{1}{r_n} < \pi < \frac{1}{h_n}$$

In this way one can generalize nested intervals for π, if one iteratively[11] determines the radii of the inscribed and circumscribed circles with increasing numbers of sides of the regular n-

---

[11] Iteration is a computational procedure in which the desired result is approached through a repeated cycle of operations, each of which more closely approximates the desired result

gon (with the perimeter 2).

How did Cusanus get his iteration method? To explain this, we look again at a regular n-gon ($n = 4, 8, 16, 32, \ldots$):

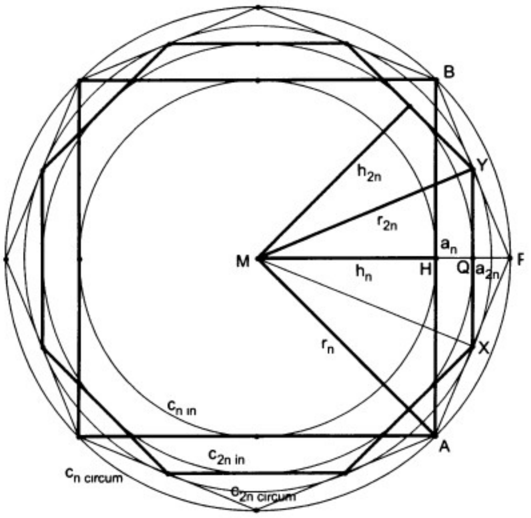


Fig. 3-11

We assume $AB = a_n$, $MA = MB = r_n$, and $MH = h_n$. After doubling the number of sides of the polygon, we get the regular $2n$-gon. Here P is the midpoint of the arc $\widehat{AB}$, and X and Y are the midpoints of the sides $\overline{AP}$ and $\overline{BP}$ in the triangle ΔABP. Therefore, $XY = \frac{AB}{2}$. $\overline{XY}$ is the side of the regular $2n$-gon with the perimeter 2 and the center M. It follows that $MP = MA = r_n$, $MX = MY = r_{2n}$, and $MQ = h_{2n}$ (compare the cases where $n = 4$ and $2n = 8$ in the above figure).

Because Q is the midpoint of the segment $\overline{PH}$, we have $h_{2n} = \frac{r_n + h_n}{2}$.

In the right triangle ΔMPX it follows that $MX^2 = MQ \bullet MP$.[12] This may be written as $r_{2n}^2 = r_n \bullet h_{2n}$, which then leads to

$$r_{2n} = \sqrt{r_n \bullet h_{2n}}$$

To generate the values for the rest of the n-gons (where n = 16, 32, 64, etc.), we can use the general case. We use the following general terms:

$$h_4 = \frac{1}{4}; r_4 = \frac{\sqrt{2}}{4} \qquad \text{(start values)}$$

$$h_{2n} = \frac{r_n + h_n}{2}; r_{2n} = \sqrt{r_n \bullet h_{2n}} \qquad \text{(iteration terms)}$$

These yield the following table of values:

n	h_n	r_n	$\frac{1}{r_n}$	$\frac{1}{h_n}$
4	0 25	0 3535533905	2 828427124	4
8	0 3017766952	0 3266407412	3 061467458	3 313708498
16	0 3142087182	0 3203644309	3 121445152	3 182597878
32	0 3172865746	0 3188217886	3 136548490	3 151724907
64	0 3180541816	0 3184377538	3 140331156	3 144118385
128	0 3182459677	0 3183418463	3 141277250	3 142223629
256	0 3182939070	0 3183178758	3 141513801	3 141750369
512	0 3183058914	0 3183118835	3 141572940	3 141632080
1024	0 3183088874	0 3183103855	3 141587725	3 141602510
2048	0.3183096365	0 3183100110	3 141591421	3 141595117
4096	0 3183098237	0 3183099173	3 141592345	3 141593269
8192	0 3183098705	0 3183098939	3 141592576	3 141592807
16384	0 3183098822	0 3183098881	3 141592634	3 141592692
32768	0 3183098852	0 3183098866	3 141592648	3 141592663

We have achieved seven decimal places accuracy for the value of π: 3.1415926. Here for puposes of comparison is the value of π correct to thirty-one decimal places:

π = 3.1415926535897932384626433832795...

---

[12] This comes from similar triangles MXP and MQX, or by applying the familiar mean proportional theorems.

While the method of Archimedes relies on the trigonometric functions sine and tangent, the method of Cusanus depends only on elementary theorems like the Pythagorean theorem, similarity, and the basic definition of the trigonometric functions. Furthermore, the arithmetic and geometric means are used for the iteration:

$$A(x,y)=\frac{x+y}{2}=\frac{r_n+h_n}{2}=h_{2n}$$
$$G(x,y)=\sqrt{x\bullet y}=\sqrt{r_n\bullet h_{2n}}=r_{2n}$$

Calculation of the Value of π by Counting Squares

It is always challenging to determine the actual value of π. There isn't any arithmetically comfortable method for calculating the value of π. On the one hand, we only need an elementary knowledge of mathematics for the following methods, but, on the other hand, these approximations of the value of π are not as exact as the calculations done by Archimedes or Cusanus. We offer here a few relatively simple methods for calculating the value of π.

To determine the area of a circle, we can cover it with a lattice of squares (each with a side of length 1), and we will count the number of squares (*a*) in the interior of the circle. We then will count the number of squares (*b*) that are intersected by the circle's circumference.

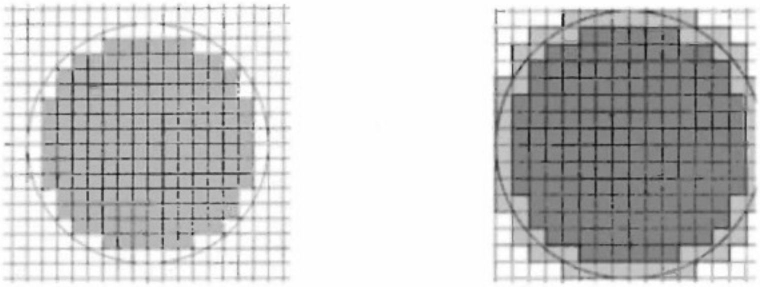
We will *assume*[13] that one-half of the area of these intersected squares lies in the interior of the circle, and the other half of the area of these intersected squares lies outside the circle.

---

[13] It is this assumption that will limit our accuracy of the approximation of π.

So we have $a + \frac{b}{2}$ as an approximate value for the area of the circle. Let's consider this with the following example.

Example 1:
Circle with the radius $r = 8$



$a = 14 \cdot 6 + 12 \cdot 4 + 10 \cdot 2 + 6 \cdot 2 = 164$ $b = 60$

Fig. 3-12

By the known method (using the formula for the area of a circle) we get

$Area_{\text{circle}} = \pi \cdot r^2 \approx 3.14 \cdot 8^2 = 200.96$

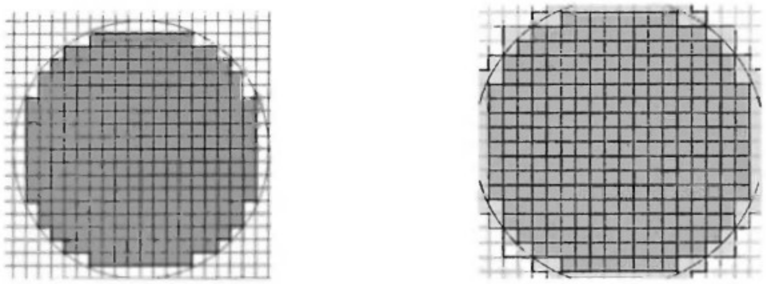
Now using the counting method, we get the following result, which compares favorably with the traditional method above.

Approximate value: $Area_{\text{circle}} \approx a + \frac{b}{2} = 164 + 30 = 194$, which is close to the "actual" 201 found by the formula.

This approximation leads to π as follows: The approximate area of the circle is 194. This should then be equal to $8^2 \pi = 64\pi$, so that $64\pi \approx 194$. This gives a value for $\pi = \frac{194}{64} \approx 3.03125$.

The approximation of π becomes better when a larger number of squares is used, say, when $r = 10$:

Example 2:
Circle with the radius $r = 10$



$a = 18 \cdot 8 + 16 \cdot 4 + 14 \cdot 2 + 12 \cdot 2 + 8 \cdot 2 = 276$ $b = 68$

Fig. 3-13

$Area_{\text{circle}} = \pi \cdot r^2 \approx 3.14 \cdot 10^2 = 314$

Approximate value: $Area_{\text{circle}} \approx a + \frac{b}{2} = 276 + 34 = 310$, which is now closer to the "actual" value, 314, as determined by the formula above. Again, $Area_{\text{circle}} = 310 = 10^2\pi = 100\pi$. Thus, $\pi \approx \frac{310}{100} = 3.1$, which compares favorably to the previous approximation.

Instead of the whole circle, it suffices to look at a quadrant, count the respective squares, and then quadruple it.

Calculating the Value of π by Counting Lattice Points

The method used by the German mathematician Carl Friedrich Gauss (1777–1855) is relatively simpler. Instead of counting the number of squares, he determined the area of a circle by counting the number of lattice points of the square lattice in the interior of the circle. Lattice points are points with integer coordinates. We can locate all the lattice points of the circle with radius r with $x^2 + y^2 \leq r^2$ (the Pythagorean theorem).

If $f(r)$ represents the number of lattice points that lie in the circular area with the radius r, then we get (with the help of Gauss's idea) an approximation for π:

$$\pi \approx \frac{f(r)}{r^2}$$

This should bring back thoughts (especially if you were to multiply both side of this "almost-equation" by r^2) of the now-famous formula for the area of a circle, $Area = \pi r^2$. Here we have $\pi r^2 \approx f(r)$.

There is a formula for finding $f(r)$, but this formula is complicated. Instead, we will give some examples. Consider the following.

Example:

$$f(r) = 317,\ r^2 = 100, \text{ therefore, } \frac{f(r)}{r^2} = 3.17 \approx \pi$$

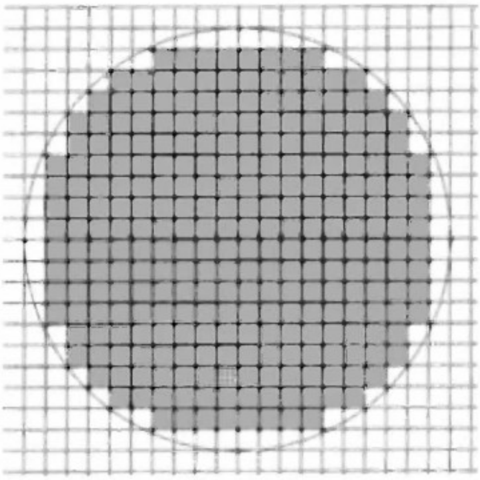


Fig. 3-14

Instead of the whole circle, it suffices to look at a quadrant and to count the respective lattice points again. (Be careful to count the origin only once.)

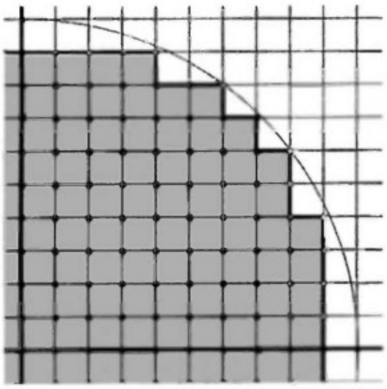

Fig. 3-15

Further values:

r	5	10	20	30	100	200	300	... 100,000
$f(r)$	81	317	1,257	2,821	31,417	125,629	282,697	31,415,925,457
$\frac{f(r)}{r^2}$	3.24	3.17	3.1425	3.134	3.1417	3.140725	3.14107	3.1415925457

It appears that this sequence heads for the actual value of π, 3.1415926....

For $r = 20$, we already get the correct second place after the decimal point. Strangely enough, for $r = 30$ the value of π gets less accurate, but then eventually gets closer to the true value of π.

Using Physical Properties to Calculate the Value of π

A physicist might determine the value of π by using what may be considered a simpler method than was involved with the tedious task of counting squares or lattice points.

He would weigh (as exactly as possible) one circle with a radius of 10 cm, which he would cut out of an evenly thick piece of cardboard. Then he would compare its weight (or its mass) with that of a square (of 10 cm length side) cut out of the same material.

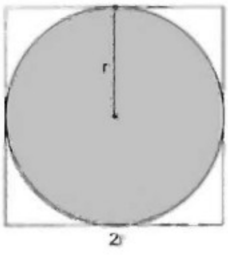

Fig. 3-16

We now compare the area of the circle, radius r, to the area of the square, side $2r$, by considering their weights.[14]

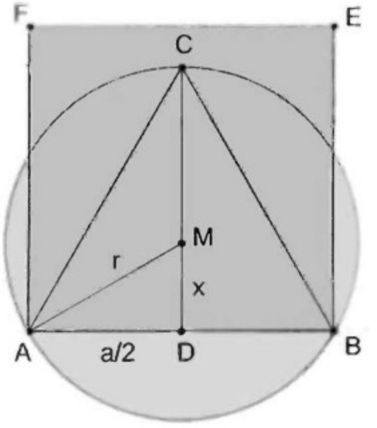
$\frac{m_{circle}}{m_{square}} = \frac{(2r)^2}{\pi r^2} = \frac{4r^2}{\pi r^2} = \frac{4}{\pi} \approx 1.273239$.[15] Therefore, $\pi \approx 3.141594$.

In the eighteenth century, the French agronomist Franzose Olivier de Serres "proved," by using a scale, that a circle weighs as much as a square whose side has the length of that of an equilateral triangle inscribed in the circle—this assumes that both figures are cut out of the same material. When you follow the discussion below, you will see that this implies that $\pi = 3$!

---

[14] Technically speaking, we actually have a cylinder and a rectangular solid, if one were to consider the width of the cardboard as the height of these objects.

[15] Actually a constant value



in ΔADM: $m\angle DAM = \frac{1}{2}(60°) = 30°$

$\sin\angle DAM = \frac{x}{r} = \frac{1}{2}$; therefore, $x = \frac{r}{2}$

$\left(\frac{a}{2}\right)^2 = r^2 - x^2 = \frac{3}{4}r^2$; therefore, $\frac{a}{2} = \frac{\sqrt{3}}{2}$

Area of the square $= a^2 = \left(r\sqrt{3}\right)^2 = \mathbf{3}\, r^2$

Area of the circle $= \boldsymbol{\pi}\, r^2$

We can then conclude that $\pi = 3$.

Fig. 3-17

The Monte-Carlo Method to Determine the Value of π

The Monte-Carlo method[16] is a procedure that makes use of probability, calculus, and statistics to form a summary to establish facts with a large number of tests for a random experiment. The Buffon's needle problem (see chapter 1, pages 38–39) is considered one of the Monte-Carlo methods.

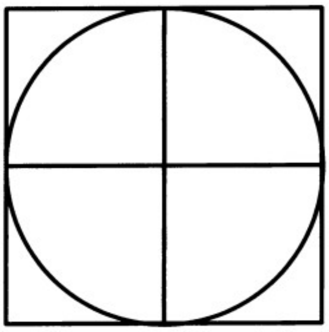
Another such procedure can be simulated by means of raindrops that fall on a predefined square, or similarly by using a number of random dart throws. This "dartboard algorithm," which can be used in a school setting, shall serve as an example here.

To do this, a chance rain is simulated and the hits counted within and outside the inscribed circle (with radius of length 1) on a square with side length 2. Using dart throws, instead of raindrops, may be a better procedure. With the following considerations, one then reaches a possibility to determine the value of π.

---

[16] The name is taken from the gambling paradise

The relationship between the hits in the circle and the complete number of throws yields an approximation for π:



square
side: $2r = 2$
area: $A_{SQ} = (2r)^2 = 4$

circle
radius: $r = 1$
area: $A_C = \pi \bullet r^2 = \pi$

Fig. 3-18

$$\frac{A_C}{A_{SQ}} = \frac{\pi \bullet r^2}{4r^2} = \frac{\pi}{4}$$

$$\frac{\pi}{4} = \text{probability (circle hits)} = \frac{\text{number of circle hits}}{\text{number of throws}}$$

The method yields a good approximation for π only after a very large number of throws. The randomizer (the dart thrower or water dropper) must produce really coincidental numbers and may not be subject to any regularities, that is, the person may not influence where the darts or water droplets fall.

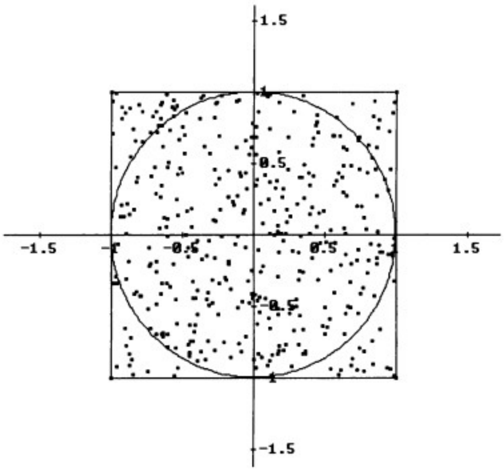


Fig. 3-19

For the first quadrant we get, for example, in the case of ten throws, that the first and the fourth throws don't satisfy the condition $x^2 + y^2 \leq 1$. Therefore, since two points are outside the target region, only eight points are drawn:

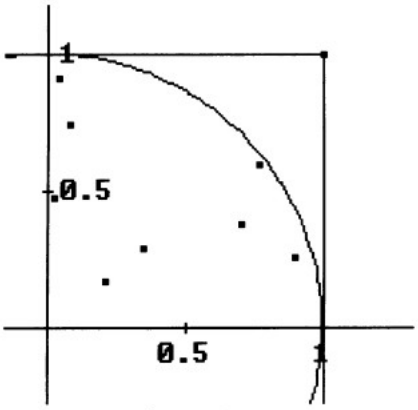

Fig. 3-20

For the calculation of the ratios of the areas, a Monte-Carlo integration is now used. One may proceed as follows:

- With a random numbers generator, an x and a y value between 0 and $2r$ are "thrown."
- The Pythagorean theorem is used to check if the thrown point $P(x, y)$ lies within or outside the circle.
- The hits in the circle are counted.
- The procedure is repeated—the more often repeated the more accurate the expected value of π will be.

Calculating π from a Series of Numbers

Earlier we considered the following formula for π, which was developed by the famous German mathematician Gottfried Wilhelm Leibniz (1646–1716), who, together with Isaac Newton, is credited with developing the modern calculus:

$$\frac{\pi}{4} = 1 - \frac{1}{3} + \frac{1}{5} - \frac{1}{7} + \frac{1}{9} - \frac{1}{11} + \cdots$$

Leibniz, who is also considered one of the great philosophers of the Western world, commented on the unusual connection between the number π and the pattern of alternately adding and subtracting odd unit fractions with the words "Numero deus impare gaudet" (God is happy with the odd number).

We mentioned then that it approaches the value of π rather slowly, since it will take one hundred thousand terms to get to a five-place accuracy of π, and for six-place accuracy we will need to carry this series out for one million terms.

Let's take a look at how this series "behaves." We multiply both sides by 4:

$$\pi = 4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}+\frac{1}{13}-\frac{1}{15}\pm\ldots\right) = 4\bullet\sum_{i=1}^{\infty}\frac{(-1)^{i+1}}{2i-1}$$ [17]

n	**Partial Sum**	**Exact Value**	**Approximate Value**
1	$4\bullet 1$	4	4
2	$4\bullet\left(1-\frac{1}{3}\right)$	$\frac{8}{3}$	2.666666666
3	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}\right)$	$\frac{52}{15}$	**3**.466666666
4	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}\right)$	$\frac{304}{105}$	2.895238095
5	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}\right)$	$\frac{1{,}052}{315}$	**3**.339682539
6	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}\right)$	$\frac{10{,}312}{3{,}465}$	2.976046176
7	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}+\frac{1}{13}\right)$	$\frac{147{,}916}{45{,}045}$	**3**.283738483
8	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}+\frac{1}{13}-\frac{1}{15}\right)$	$\frac{135{,}904}{45{,}045}$	**3**.017071817
9	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}+\frac{1}{13}-\frac{1}{15}+\frac{1}{17}\right)$	$\frac{2{,}490{,}548}{765{,}765}$	**3**.252365934
10	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}+\frac{1}{9}-\frac{1}{11}+\frac{1}{13}-\frac{1}{15}+\frac{1}{17}-\frac{1}{19}\right)$	$\frac{44{,}257{,}352}{14{,}549{,}535}$	**3**.041839618
100	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}\pm\quad-\frac{1}{199}\right)$	numerator and denominator have 88 places (see below)	**3.1**31592903
1,000	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}\pm\quad-\frac{1}{1{,}999}\right)$	–	**3.1**31592902
10,000	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}\pm\quad-\frac{1}{19{,}999}\right)$	–	**3.141**492653
100,000	$4\bullet\left(1-\frac{1}{3}+\frac{1}{5}-\frac{1}{7}\pm\quad-\frac{1}{199{,}999}\right)$	–	**3.1415**82653

From the chart above, when $n = 100$ (exact value):

$$\frac{8252079759413970386664454687621174435983101115012912631997769614579677862845786070667088}{2635106162757236442495826303084698495556581115509040892412867358728390766099042109898375}$$

---

[17] This expression is merely a mathematical shorthand way of writing the series.

The approximation value "jumps" back and forth around the actual value of π, since the terms are adding or subtracting alternately; it is, therefore, alternately bigger or smaller than π.

We compare the approximate value for $n = 100{,}000$ (the last entry in the chart) with the correct value of π = **3.1415**9265358979323 84..., and we have indeed (only) four correct places. Then as we increase the value of n, the approximation for π becomes increasingly more accurate (i.e., closer to the true value of π).

$n = 1{,}000{,}000$: approximation value = **3.141591**653
$n = 10{,}000{,}000$: approximation value = **3.141592**553
$n = 100{,}000{,}000$: approximation value = **3.1415926**43

A Better Series Calculation for the Value of π

There are other series that converge[18] to the value of π faster than the Leibniz series.

Earlier we mentioned the following formula for deriving the value of π, which was discovered by the famous Swiss mathematician Leonhard Euler:

$$\frac{\pi^2}{6} = 1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \frac{1}{5^2} + \cdots$$

or (after multiplication by a 6 and square root extraction):

$$\pi = \sqrt{6 \bullet \left(1 + \frac{1}{2^2} + \frac{1}{3^2} + \frac{1}{4^2} + \frac{1}{5^2} + \cdots\right)} = \sqrt{6 \bullet \sum_{i=1}^{\infty} \frac{1}{i^2}}$$

This formula is sensationally fast in comparison to that of Leibniz. In the case of the Leibniz series, the computer needed more than two and a half hours for $n = 10^8$; the Euler series[19] delivers the accompanying approximation value for $n = 10^8$ in virtually zero seconds of computer time!

---

[18] To "converge," in this sense, means to approach a particular value as a limit

The approximate values of π are about the same quality as before. For $n = 10^8$ we get eight-place accuracy: π ≈ **3.1415926**44. Let's take a look at some partial sums:

n	Partial Sum	Exact Value	Approximate Value
1	$\sqrt{6\cdot\frac{1}{1^2}}$	$\sqrt{6}$	2.449489742

---

[19] Euler also found the sums of the reciprocals of the fourth and sixth powers (by the way, to date no one has been able to do this for third powers!).

For purposes of comparison, here is the value of π:

$\pi = 3.14159265358979323 84...$

The Genius's Method for Finding the Value of π

The extraordinarily brilliant Indian mathematician Srinivasa Ramanujan (1887–1920) made contributions to the generation of the value of π but left little evidence on how he arrived at his results. Born in 1887 in the small south Indian town of Erode, Ramanujan spent his youth fascinated with mathematics to the detriment of other subjects. As the fledgling Indian Mathematical Society was being founded, it provided a forum for Ramanujan to exhibit his mathematical prowess. For example, in 1911 he posed problems based on his earlier work and found no solvers among the readership. One such example was to evaluate

$$\sqrt{1+2\sqrt{1+3\sqrt{1+4\sqrt{1+\cdots}}}},$$

which appeared harmlessly simple, but yet found no successful solvers. The trick was found in his notebook of theorems that he established. Here, he simply applied the following theorem, which said that if you could represent a number as $(x + n + a)$, the above expression could be represented as

$$x+n+a=\sqrt{ax+(n+a)^2+x\sqrt{a(x+n)+(n+a)^2+(x+n)\sqrt{\cdots}}}$$

So if $3 = x + n + a$, where, say, $x = 2$, $n = 1$, and $a = 0$, then the value of this nest of radicals is simply equal to 3. This is nearly impossible to do without knowledge of Ramanujan's theorem.

With this new exposure, he wrote to three of the top mathematicians in England, E. W. Hobson, H. F. Baker, and G. H. Hardy.[20] Of these three Cambridge professors, only Godfrey Harold Hardy (1877–1947) responded and ultimately invited Ramanujan to England. Hardy thought that the statements contained in the letter had to be correct. For, if they were wrong, nobody would have had such a wild imagination to make them up.

Despite a clash of cultures, the two got along very well and mutually assisted each other. This was the beginning of Ramanujan's popularity outside India. It should be remembered that, even though wearing shoes and using eating utensils were new to this Indian, he came from a long heritage of mathematical culture. The Indians were using our numeration system (including the zero) for over a thousand years before it was introduced in Europe with the publication of Fibonacci's book, *Liber abaci,* in 1202.

---

[20] The letter to Hardy, dated "Madras, 16th January 1913" and which enticed Hardy to respond, was the following

Dear Sir,

I beg to introduce myself to you as a clerk in the Accounts Department of the Port Trust Office at Madras on a salary of only £ 20 per annum. I am now about 23 years of age. I have no University education but I have undergone the ordinary school course. After leaving school I have been employing the spare time at my disposal to work at mathematics. I have not trodden through the conventional regular course which is followed in a University course, but I am striking out a new path for myself. I have made a special investigation of divergent series in general and the results I get are termed by the local mathematicians as "startling.". . .

I would request you to go through the enclosed papers. Being poor, if you are convinced that there is anything of value I would like to have my theorems published. I have not given the actual investigations nor the expressions that I get but I have indicated the lines on which I proceed. Being inexperienced I would very highly value any advice you give me. Requesting to be excused for the trouble I give you.

I remain,
Dear Sir,
Yours truly,
S. Ramanujan.

(As reprnted in Robert Kanigel, *The Man Who Knew Infinity: A Life of the Genius Ramanujan* [New York: Charles Scribner's Sons, 1991], pp. 159–60.)

In our context, Ramanujan came up with some amazing results in the determination of the value of π. He empirically (his word) obtained the approximate value of π with the following expression:

$$\left(9^2+\frac{19^2}{22}\right)^{\frac{1}{4}}=\left(81+\frac{361}{22}\right)^{\frac{1}{4}}=\left(\frac{2{,}143}{22}\right)^{\frac{1}{4}}$$

$$=\left(97.4\overline{09}\right)^{\frac{1}{4}}$$

$$\approx 3.14159265258264612520603717964402237155 7\ldots$$

He further stated that the value he used for π for purposes of calculation was

$$\frac{355}{113}\left(1-\frac{.0003}{3{,}533}\right)=3.1415926535897943\ldots,$$

which he went on to say "is greater than π by about 10^{-15}" and "is obtained by simply taking the reciprocal of

$$1-\left(\frac{113\pi}{355}\right)=11{,}776{,}666.6185424743744652803554 3.\ldots\text{"}^{21}$$

The more ambitious reader can find the justification for this work in appendix B.

Srinivasa Ramanujan gave us other uncanny approximations of π. Even today we are mystified by how he arrived at the various results. Although we are becoming more able to understand his derivations, we still cannot fully appreciate the complexity of the way his unique mind functioned. The following are some of his findings on the value of π.

---

[21] Srinivasa Ramanujan, "Modular Equations and Approximations to π," *Quarterly Journal of Mathematics* 45 (1914): 350–72. Reprinted in *S. Ramanujan: Collected Papers*, ed. G. H. Hardy, P. V Seshuaigar, and B. M. Wilson (New York: Chelsea, 1962), pp. 22–39.

In chapter 2 we have already mentioned the following formula:

$$\frac{1}{\pi}=\frac{\sqrt{8}}{9{,}801}\sum_{n=0}^{\infty}\frac{(4n)!(1{,}103+26{,}390n)}{(n!)^4\,396^{4n}}$$

Another formula is

$$\frac{1}{\pi}=\sum_{n=0}^{\infty}\binom{2n}{n}^3\frac{42n+5}{2^{12n+4}}$$

The following are some approximations of π that are due to Ramanujan:

$\frac{355}{113}\approx 3.141592920$ was originally discovered by Adriaen Métius (1571-1635),[22] and later Ramanujan gave a geometric construction for this term.

$\frac{9}{5}+\sqrt{\frac{9}{5}}\approx 3.141640786$

$\frac{19\sqrt{7}}{16}\approx 3.141829681$

Some series discovered by Ramanujan follow. However, the important point is that evaluating such series to huge numbers of digits requires developing specific algorithms.

$$\frac{1}{\pi}=\frac{2\sqrt{2}}{9{,}801}\sum_{k=0}^{\infty}\frac{(4k)!}{(k!)^4\,4^{4k}}\frac{(1{,}103+26{,}390k)}{99^{4k}} \qquad [\text{Ramanujan}]$$

$$\frac{1}{\pi}=12\sum_{k=0}^{\infty}(-1)^k\frac{(6k)!}{(3k)!(k!)^3}\frac{(13{,}591{,}409+545{,}140{,}134k)}{640{,}320^{3k+3/2}} \qquad [\text{Chudnovsky}]$$

---

[22] He and his father, Adriaen Anthoniszoon (c. 1600), took the approximation $3\frac{15}{106}<\pi<3\frac{17}{120}$, added the numerators (15 + 17 = 32) and the denominators (106 + 120 = 226), took the means (16 and 113), and gave $\pi=3\frac{16}{113}=\frac{355}{113}=3.1415929$, a very close approximation. (D. E. Smith, *History of Mathematics*, vol. 2 [New York: Dover, 1958])

Here are some more of the wondrous discoveries by the genius Ramanujan that you may wish to ponder.

$$\frac{2}{\pi}=1-5\left(\frac{1}{2}\right)^3+9\left(\frac{1\bullet 3}{2\bullet 4}\right)^3-13\left(\frac{1\bullet 3\bullet 5}{2\bullet 4\bullet 6}\right)^3+\ldots$$

$$\frac{4}{\pi}=1+\left(\frac{1}{2}\right)^2+\left(\frac{1}{2\bullet 4}\right)^2+\left(\frac{1\bullet 3}{2\bullet 4\bullet 6}\right)^2+\left(\frac{1\bullet 3\bullet 5}{2\bullet 4\bullet 6\bullet 8}\right)^2+\ldots \qquad [\text{Forsyth}]$$

$$\frac{1}{\pi}=\frac{1}{72}\sum_{k=0}^{\infty}(-1)^k\frac{(4k)!}{(k!)^4\,4^{4k}}\frac{(23+260k)}{18^{2k}}$$

$$\frac{1}{\pi}=\frac{1}{3{,}528}\sum_{k=0}^{\infty}(-1)^k\frac{(4k)!}{(k!)^4\,4^{4k}}\frac{(1{,}123+21{,}460k)}{882^{2k}}$$

$$\frac{1}{\pi}=12\sum_{k=0}^{\infty}(-1)^k\frac{(6k)!}{(3k)!(k!)^3}\frac{(A+Bk)}{C^{3k+3/2}} \qquad [\text{Borwein}]$$

In the last formula

$$A = 1{,}657{,}145{,}277{,}365 + 212{,}175{,}710{,}912\ \sqrt{61}$$

$$B = 107{,}578{,}229{,}802{,}750 = 13{,}773{,}980{,}892{,}672\ \sqrt{61}$$

$$C = 5{,}280\ (236{,}674 + 30{,}303)\ \sqrt{61}$$

and each additional term in the series adds about thirty-one digits.

We have seen numerous ways that the value of π was calculated. Some were primitive, while others were quite sophisticated. Most remarkably are those that would have appeared to have evolved from spectacular guesses. Today's methods all involve the computer, and how accurate the future calculations of the value of π will be is going to be merely limited by man's creativity and the computer's ability.

In modern physics the color of light is determined by the frequency of oscillation of an electromagnetic wave, and the pitch of a musical note is determined by the frequency of oscillation of a vibrating string, membrane, or air column in a musical instrument. But the timbre of a musical instrument is determined by combining numerous oscillations of different frequencies, each with its own characteristic amplitude. Thus the recognizable differences of *concert tone A* on a flute, a piano, or a violin reflects in each case the summation of many different frequencies of relatively small amplitude added to the lowest frequency, which determines the perceived pitch.

In all the examples listed above, complex oscillations are analyzed as sums of many simple oscillations. This subject is known as *harmonic analysis*; it is known also as *Fourier analysis* after Joseph Fourier, who successively applied it to analyze the flow of heat through a metal rod in 1822. There are many distinguished books about Fourier series, though most presume knowledge of the Lebesgue integral. The author recommends especially the book by Dym and McKean [6]. It provides a useful summary of the needed properties of the Lebesgue integral in the beginning.

6.1 THE VIBRATING STRING AND TRIGONOMETRIC SERIES

We will begin with an important example from physics,[15] which explains why one might wish to express all functions from a broad class as the sums of infinite series of sine waves and cosine waves.

■ EXAMPLE 6.1

Suppose a piece of music wire (such as a violin, guitar, or piano string) is stretched taut and fastened down at the endpoints of the interval $[0,1]$ on the x-axis. Now either a finger or an implement is used to stretch the string away from the axis, into some initial plane curve described by a displacement function $f(x)$. At time $t = 0$ the string is released, and, depending on the manner in which the plucking or hammering of the string was done, the string has an initial velocity at each point $x \in [0,1]$ given by $g(x)$. This leads to the following partial differential equation governing the function $u(x,t)$, which is the displacement of the string at coordinate x and at time t.

$$\frac{\partial^2 u}{\partial t^2} = a^2 \frac{\partial^2 u}{\partial x^2}. \tag{6.1}$$

Here a is a constant reflecting the tension to which the string is tightened and the density of the steel in the string. Since our purpose here is to motivate a mathematical problem and not to keep track of the effect of physical constants on the solution, *we will take* $a = 1$ *henceforth*.

The boundary conditions on the string and the initial conditions on the displacement and velocity at time $t = 0$ are given as follows.

---

[15] Neither first-year physics nor differential equations (ordinary or partial) is required for this course. The Example is presented for physical motivation and historical perspective.

$$\begin{cases} u(0,t) &= 0, \\ u(1,t) &= 0, \\ u(x,0) &= f(x), \\ \frac{\partial u}{\partial t}(x,0) &= g(x). \end{cases} \tag{6.2}$$

What is needed is a technique that may be enable us to construct a function $u(x, t)$ which satisfies Equation (6.1) and conditions (6.2). A classic method of solution is to seek solutions having the special simplified form

$$u(x,t) = F(x)G(t),$$

where F and G must be determined. (This method is called *separation of variables*.) Substitution into Equation (6.1) yields

$$\frac{F''(x)}{F(x)} = \frac{G''(t)}{G(t)},$$

which proves that both sides must be equal to the same constant since the left side is independent of t and the right side is independent of x. If that constant were a *nonnegative* number λ^2, then we would have

$$F''(x) = \lambda^2 F(x), \tag{6.3}$$

which has the general solution

$$F(x) = c_1 e^{\lambda x} + c_2 e^{-\lambda x}.$$

But then there would be no solution for $F(x)$ other than the identically zero solution given the boundary conditions (6.2). (See Exercise 6.5.)

Thus we take the constant to be a *negative* number $-\lambda^2$, which yields the general solution

$$F_n(x) = c \sin 2n\pi x \tag{6.4}$$

for some integer $n \in \mathbb{Z}$ and an arbitrary constant c. Similar work for the function G yields a sequence of corresponding solutions

$$u_n(t) = (A_n \cos 2n\pi t + B_n \sin 2n\pi t) \sin 2\pi n x.$$

We observe that Equation (6.1) will be satisfied by any function of the form

$$u(x,t) = \sum_{n=0}^{\infty} (A_n \cos nt + B_n \sin nt) \sin nx, \tag{6.5}$$

provided that all questions of convergence of the series itself and its twice derived series can be managed.

The goal of this example is to satisfy both the *boundary* conditions and the *initial* conditions in (6.2). In order to achieve this, we will need to be able to express both f and g as sums of infinite *trigonometric series*:

$$f(x) = \sum_{n=1}^{\infty} A_n \sin 2n\pi x$$

and

$$g(x) = \sum_{n=1}^{\infty} 2n\pi B_n \cos 2n\pi x.$$

Trigonometric Series

Thus the problem of describing the motion of a vibrating string leads us to the importance of determining which functions f and g can be expressed as *convergent* infinite series of sine and cosine functions of various periods. And we will need a method of computation of the necessary coefficients of such expansions.

As a problem of pure mathematics, we ask for which functions f defined on $[0, 1]$ it is possible to expand

$$f(x) = \sum_{n=0}^{\infty} a_n \cos 2n\pi x + b_n \sin 2n\pi x \tag{6.6}$$

in a suitably convergent manner. (We have included the index $n = 0$ in the summation in order to allow for nonzero constant functions.) Also, we need to ask whether given such a function f we can find the coefficients a_n and b_n.

Theorem 6.1.1 If *the series in Equation (6.6) converges* uniformly *on* $[0, 1]$ *to some function* f, *then* $f \in \mathcal{C}[0, 1]$,

$$\begin{cases} a_n = & 2\int_0^1 f(x) \cos 2n\pi x \, dx, \\ b_n = & 2\int_0^1 f(x) \sin 2n\pi x \, dx \end{cases} \tag{6.7}$$

for each $n > 0$, *and* $a_0 = \int_0^1 f(x)\, dx$. *Moreover,* if *the series*

$$\sum_{n=0}^{\infty} (-2n\pi a_n \sin 2n\pi x + 2n\pi b_n \cos 2n\pi x)$$

converges uniformly *on* $[0, 1]$, *then* f *is differentiable and*

$$f'(x) = \sum_{n=0}^{\infty} -2n\pi a_n \sin 2n\pi x + 2n\pi b_n \cos 2n\pi x. \tag{6.8}$$

Proof: Since each summand on the right side of Equation (6.6) is a continuous function on $[0, 1]$, the uniform convergence of this series guarantees the continuity of

CHAPTER 8

EUCLIDEAN SPACE

8.1 EUCLIDEAN SPACE AS A COMPLETE NORMED VECTOR SPACE

Throughout pure and applied mathematics, it is necessary to consider functions of more than one variable. If a function depends on n real variables, $x_1, x_2, \ldots, x_n$, it is possible to combine these n real variables into one *vector variable*

$$\mathbf{x} = (x_1, x_2, \ldots, x_n).$$

In this notation, $\mathbf{x}$ is not a real number, but rather an n-tuple of real numbers. In addition, it is often necessary to consider functions that have vector values instead of real values. Up to this point, our course has focused on real-valued functions of one real variable. In this chapter we will begin the rigorous study of vector-valued functions of vector variables.

In the study of real-valued functions of a single real variable, we saw the advantages of considering normed vector spaces of more than one dimension. For example, the reader has seen that the vector space $C[a, b]$ has infinitely many dimensions (Exercise 2.57). In the present chapter, we will focus on finite-dimensional vector spaces equipped with what is called the *Euclidean* norm. However, we begin with a more general context.

Advanced Calculus: An Introduction to Linear Analysis. By Leonard F. Richardson

Copyright © 2008 John Wiley & Sons, Inc.

Definition 8.1.1 *In any (real) vector space V (Tabel 2.1, p. 59), we call a function*

$$\langle\cdot,\cdot\rangle : V \times V \to \mathbb{R}$$

a scalar product *if and only if it has the following three properties.*

i. $\langle a\mathbf{x} + \mathbf{y}, \mathbf{z}\rangle = a\langle \mathbf{x}, \mathbf{z}\rangle + \langle \mathbf{y}, \mathbf{z}\rangle$ *for all* $a \in \mathbb{R}$ *and for all* $\mathbf{x}$ *and* $\mathbf{y}$ *in* V.

ii. $\langle \mathbf{x}, \mathbf{y}\rangle = \langle \mathbf{y}, \mathbf{x}\rangle$ *for all* $\mathbf{x}$ *and* $\mathbf{y}$ *in* V.

iii. $\langle \mathbf{x}, \mathbf{x}\rangle \geq 0$ *for all* $\mathbf{x} \in V$ *and* $\langle \mathbf{x}, \mathbf{x}\rangle = 0 \Leftrightarrow \mathbf{x} = \mathbf{0} \in V$.

■ EXAMPLE 8.1

In the vector space $\mathbb{R}^n$, define the *Euclidean* scalar product by

$$\langle \mathbf{x}, \mathbf{y}\rangle = \sum_{i=1}^{n} x_i y_i. \tag{8.1}$$

The reader should verify that this product satisfies all three conditions to be called a scalar product.

Theorem 8.1.1 *In any (real) vector space V equipped with a scalar product as defined in Definition 8.1.1, we define*

$$\|\mathbf{x}\| = \sqrt{\langle \mathbf{x}, \mathbf{x}\rangle} \tag{8.2}$$

for all $\mathbf{x} \in V$. *The function* $\|\cdot\|$ *as defined in Equation (8.2)* is *a* norm, *as in Definition 2.4.4, and the* Cauchy–Schwarz *Inequality is satisfied:*

$$|\langle \mathbf{x}, \mathbf{y}\rangle| \leq \|\mathbf{x}\|\|\mathbf{y}\|.$$

Proof: To prove the Cauchy–Schwarz inequality, we fix $\mathbf{x}$ and $\mathbf{y}$, and we proceed as follows. For all $t \in \mathbb{R}$, define a polynomial

$$p(t) = \langle t\mathbf{x} + \mathbf{y}, t\mathbf{x} + \mathbf{y}\rangle.$$

Observe that $p(t) \geq 0$ for all t. By linearity of $\langle\cdot,\cdot\rangle$ in each variable we see that

$$p(t) = \|\mathbf{x}\|^2 t^2 + 2\langle \mathbf{x}, \mathbf{y}\rangle t + \|\mathbf{y}\|^2 = at^2 + bt + c,$$

where $a = \|\mathbf{x}\|^2$, $b = 2\langle \mathbf{x}, \mathbf{y}\rangle$, and $c = \|\mathbf{y}\|^2$. But the quadratic polynomial $p(t) \geq 0$ for all $t \in \mathbb{R}$ if and only if

$$b^2 - 4ac \leq 0,$$

which is equivalent to $b^2 \leq 4ac$. Hence

$$|\langle \mathbf{x}, \mathbf{y}\rangle|^2 \leq \|\mathbf{x}\|^2\|\mathbf{y}\|^2.$$

The first two conditions of Definition 2.4.4 are easily verified for $\|\cdot\|$. The third condition, the triangle inequality, is left for Exercise 8.1. ∎

Definition 8.1.2 *If a vector space V is equipped with a norm $\|\cdot\|$, we define the* open ball *of radius $r \geq 0$ about $\mathbf{p} \in V$ by*

$$B_r(\mathbf{p}) = \left\{\mathbf{v} \in V \,\middle|\, \|\mathbf{v} - \mathbf{p}\| < r\right\}.$$

Similarly, we define the closed ball *of radius $r \geq 0$ about $\mathbf{p} \in V$ by*

$$\bar{B}_r(\mathbf{p}) = \left\{\mathbf{v} \in V \,\middle|\, \|\mathbf{v} - \mathbf{p}\| \leq r\right\}.$$

The *bar* above the symbol B_r indicates that the set $\bar{B}_r$ is the *closed* ball, meaning that it includes the spherical boundary surface.

■ EXAMPLE 8.2

In the familiar Cartesian plane of Euclidean geometry, with the norm of a vector being its geometrical length, we have

$$\langle \mathbf{x}, \mathbf{y} \rangle = x_1 y_1 + x_2 y_2 = \|\mathbf{x}\|\|\mathbf{y}\| \cos\theta,$$

where θ is the angle between $\mathbf{x}$ and $\mathbf{y}$. Thus the Cauchy–Schwarz inequality in the plane follows from the fact that $|\cos\theta| \leq 1$ for all θ. (The Cauchy–Schwarz inequality follows alternatively from the argument given in Theorem 8.1.1.) In the plane of Euclidean geometry, $B_1(\mathbf{0})$ is the region strictly inside the circle of radius 1 centered at the origin. The reader should check that $B_0(\mathbf{p}) = \emptyset$, the empty set, for all points $\mathbf{p}$.

Definition 8.1.3 *If $\mathbf{x} = (x_1, x_2, \ldots, x_n)$ and $\mathbf{y} = (y_1, y_2, \ldots, y_n)$ are in $\mathbb{R}^n$, the set of all n-tuples of real numbers, we define the* Euclidean scalar product *of $\mathbf{x}$ and $\mathbf{y}$ as in Equation (8.1) and the* Euclidean norm *of $\mathbf{x}$ as in Equation (8.2). The* Euclidean space $\mathbb{E}^n$ *of n dimensions is defined to be the vector space $\mathbb{R}^n$ equipped with the Euclidean scalar product and the Euclidean norm.*

The reader should have checked that the Euclidean scalar product as defined above does satisfy the three properties required to be a scalar product, and that the Euclidean norm is in fact a norm.

We remark that it is very common when dealing with $\mathbb{E}^n$ to call it $\mathbb{R}^n$ informally. This means that we should suppose that the Euclidean inner product and norm are in use unless stated explicitly to the contrary. (See Exercise 8.4.)

Theorem 8.1.2 *The Euclidean normed vector space $\mathbb{E}^n$ has the following two properties.*

i. The Euclidean space $\mathbb{E}^n$ is complete in the sense of Definition 2.5.3.

ii. For a sequence of vectors $\mathbf{x}^{(j)}$ in $\mathbb{E}^n$, the sequence

$$\mathbf{x}^{(j)} \to \mathbf{x} \in \mathbb{E}^n \Leftrightarrow x_k^{(j)} \to x_k$$

as $j \to \infty$, *for each* $k = 1, 2, \ldots, n$.

Remark 8.1.1 The second part of the theorem tells us that convergence of a sequence in $\mathbb{E}^n$ is equivalent to convergence in each separate coordinate sequence.

Proof: The reader will recall that the vectors $\mathbf{x} \in \mathbb{R}^n$, which are the vectors of $\mathbb{E}^n$, comprise a vector space using the familiar operations under which

$$c\mathbf{x} = (cx_1, \ldots, cx_n)$$

and

$$\mathbf{x} + \mathbf{y} = (x_1 + y_1, \ldots, x_n + y_n).$$

We begin by proving claim (i). To see that every convergent sequence in any normed vector space is Cauchy in the sense of Definition 2.5.3, see Exercise 8.8. We will prove that every Cauchy sequence $\mathbf{x}^{(k)}$ in V converges. By hypothesis, For each $\epsilon > 0$ there exists K such that j and $k \geq K$ implies $\left\|\mathbf{x}^{(j)} - \mathbf{x}^{(k)}\right\| < \epsilon$. However, for each $l = 1, \ldots, n$, we have

$$\left|x_l^{(j)} - x_l^{(k)}\right| \leq \sqrt{\sum_{m=1}^{n} \left(x_m^{(j)} - x_m^{(k)}\right)^2} = \left\|\mathbf{x}^{(j)} - \mathbf{x}^{(k)}\right\|.$$

Thus the sequence $x_l^{(j)}$ is Cauchy in $\mathbb{R}$, and so it has a limit: $x_l^{(j)} \to x_l$ as $j \to \infty$, for each $l = 1, \ldots, n$. Now we denote $\mathbf{x} = (x_1, \ldots, x_n)$. Then we conclude that

$$\left\|\mathbf{x}^{(j)} - \mathbf{x}\right\| = \sqrt{\sum_{l=1}^{n} \left(x_l^{(j)} - x_l\right)^2} \to 0$$

as $j \to \infty$, by the theorems governing limits of sequences. Hence the original Cauchy sequence does converge in the sense of the norm of $\mathbb{E}^n$. Note that we have also proven that if each sequence of coordinates converges, then the sequence of vectors in $\mathbb{E}^n$ converges as well. We leave the second claim to Exercise 8.9.

■ EXAMPLE 8.3

Here are two examples of convergence and *divergence*, which means *failure of convergence*, for sequences of vectors.

i. Let $\mathbf{x}^{(j)} = \left(\frac{j^2+1}{2j^2-3}, j \sin\left(\frac{1}{j}\right)\right)$. Then $x^{(j)} \to \left(\frac{1}{2}, 1\right) \in \mathbb{E}^2$ as $j \to \infty$, because of the convergence of the sequence in each coordinate separately.

ii. In $\mathbb{E}^2$, the sequence $x^{(j)} = \left(\frac{1}{j}, j\right)$ diverges as $j \to \infty$.

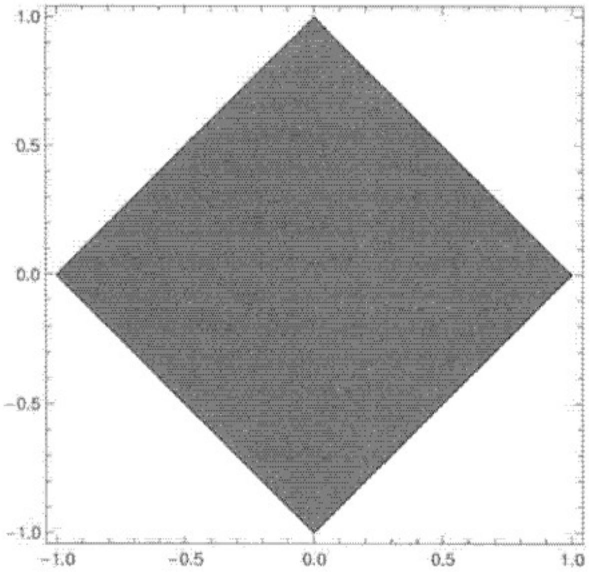

Figure 8.1 The unit ball $B_1(\mathbf{0})$ in the taxicab norm.

■ **EXAMPLE 8.4**

Here is an example of a *non-Euclidean* norm that can be placed on the vector space $\mathbb{R}^2$. Define the *taxicab* norm on $\mathbb{R}^2$ by

$$\|\mathbf{x}\|_t = |x_1| + |x_2|.$$

In Exercise 8.4 the reader will show that the taxicab norm satisfies the requirements of Definition 2.4.4 to be a norm. To understand the name *taxicab norm* consider a city in which all roads run parallel to the x-axis or the y-axis. The length of an honest taxicab ride would be determined using the taxicab norm. Fig. 8.1 shows the unit ball around the origin in the taxicab norm.

EXERCISES

8.1 † Complete the proof of Theorem 8.1.1 by proving the triangle inequality:

$$\|\mathbf{x} + \mathbf{y}\| \leq \|\mathbf{x}\| + \|\mathbf{y}\|$$

for all $\mathbf{x}$ and $\mathbf{y}$ in V. That is, prove that the norm defined in terms of a given scalar product does satisfy the triangle inequality. (Hint: Apply the Cauchy–Schwarz Inequality.)

8.2 In $\mathbb{E}^n$, $\|\mathbf{x} - \mathbf{y}\|$ is interpreted geometrically as being the distance between $\mathbf{x}$ and $\mathbf{y}$. Prove the *geometrical version* of the triangle inequality in $\mathbb{E}^n$:

$$\|\mathbf{x} - \mathbf{z}\| \leq \|\mathbf{x} - \mathbf{y}\| + \|\mathbf{y} - \mathbf{z}\|$$

for all $\mathbf{x}, \mathbf{y}$, and $\mathbf{z}$ in $\mathbb{E}^n$. Interpret this inequality in terms of a geometrical triangle in $\mathbb{E}^n$.

8.3 Two vectors $\mathbf{x}$ and $\mathbf{y}$ in $\mathbb{E}^n$ are called *orthogonal* if and only if

$$\langle \mathbf{x}, \mathbf{y} \rangle = 0.$$

We will prove the Pythagorean Theorem in $\mathbb{E}^n$.

a) Prove: The vectors $\mathbf{x}$ and $\mathbf{y}$ are orthogonal if and only if

$$\|\mathbf{x}\|^2 + \|\mathbf{y}\|^2 = \|\mathbf{x} + \mathbf{y}\|^2.$$

b) Interpret part (a) as a theorem about triangles in $\mathbb{E}^n$ with a vertex at the origin.

c) Let $\mathbf{x}, \mathbf{y}$, and $\mathbf{z}$ be in $\mathbb{E}^n$. Prove that the triangle with vertices at $\mathbf{x}, \mathbf{y}$ and $\mathbf{z}$ is a right triangle with right angle at $\mathbf{x}$ if and only if

$$\|\mathbf{x} - \mathbf{y}\|^2 + \|\mathbf{x} - \mathbf{z}\|^2 = \|\mathbf{y} - \mathbf{z}\|^2.$$

8.4 † Define the *taxicab norm* as in Example 8.4. Show that $\| \cdot \|_t$ satisfies the requirements of Definition 2.4.4 to be a norm.

8.5 Find necessary and sufficient conditions on the real numbers a_1 and a_2 to assure that

$$\langle \mathbf{x}, \mathbf{y} \rangle_{\mathbf{a}} = a_1 x_1 y_1 + a_2 x_2 y_2$$

satisfies Definition 8.1.1 and is thus a bona fide scalar product on the two-dimensional vector space $\mathbb{R}^2$. Then sketch the unit ball around the origin in $\mathbb{R}^2$ using the norm $\| \cdot \|_{\mathbf{a}}$ that is determined by this scalar product.

8.6 In $\mathbb{E}^1$, what is the open ball $B_1(\mathbf{0})$? Answer the same question in $\mathbb{E}^3$.

8.7 Find the $\lim_{j \to \infty} \mathbf{x}^{(j)}$ in $\mathbb{E}^2$, or state that it does not exist.

a) $\mathbf{x}^{(j)} = \left(\frac{1}{j}, \left(1 + \frac{1}{j}\right)^j \right)$.

b) $\mathbf{x}^{(j)} = \left(\frac{1}{j}, \frac{e^j}{j^{100}} \right)$.

8.8 † Prove that every convergent sequence $\mathbf{x}^{(k)}$ in a normed vector space V must be Cauchy, as claimed in Theorem 8.1.2.

8.9 † Show that $\mathbf{x}^{(j)} \to \mathbf{x}$ in the sense of the norm of $\mathbb{E}^n$ if and only if the sequence $x_l^{(j)} \to x_l$ for each $l = 1, \ldots, n$, completing the proof of Theorem 8.1.2.

8.10 Suppose $t_k \to t \in \mathbb{R}$ and $\mathbf{x}^{(k)} \to \mathbf{x} \in \mathbb{E}^n$ as $k \to \infty$. Prove: $t_k \mathbf{x}^{(k)} \to t\mathbf{x}$ as $k \to \infty$.

8.11 A sequence $\mathbf{x}^{(j)}$ in $\mathbb{E}^n$ is called *bounded* if there exists a number $M > 0$ such that $\|\mathbf{x}^{(j)}\| \leq M$ for all $j \in \mathbb{N}$.

a) Prove that every convergent sequence in $\mathbb{E}^n$ is bounded.

b) Give an example of a bounded sequence in $\mathbb{E}^2$ that is not convergent.

c) † *(The Bolzano–Weierstrass Theorem)* Prove that every bounded sequence in $\mathbb{E}^n$ has a convergent subsequence. (Hint: One approach is to give a proof by induction on the dimension n. Or one can work informally as follows, applying the Bolzano–Weierstrass Theorem for $\mathbb{R}$ a total of n times. Here is a notational suggestion: If one wishes to denote a subsequence of a subsequence, use two *strictly increasing* functions ϕ_1 and ϕ_2 mapping $\mathbb{N}$ into itself, and $\mathbf{x}^{(\phi_1 \circ \phi_2(j))}$ can be used as in Definition 1.5.1 to denote the jth term of a subsequence of a subsequence of a sequence $\mathbf{x}^j$.)

8.12 Prove: A sequence $\mathbf{x}_n \to \mathbf{L} \in \mathbb{E}^k$ if and only if *every* subsequence $\mathbf{x}_{n_i}$ possesses a sub-subsequence $\mathbf{x}_{n_{i_j}}$ that converges to $\mathbf{L}$ as $j \to \infty$. (Hint: To prove the *only if* part, suppose false and write out the logical negation of convergence of $\mathbf{x}_n$ to $\mathbf{L}$.)

8.13 *Prove or give a counterexample*: A sequence $\mathbf{x}_n \in \mathbb{E}^k$ converges if and only if *every* subsequence $\mathbf{x}_{n_i}$ possesses a sub-subsequence $\mathbf{x}_{n_{i_j}}$ that converges as $j \to \infty$.

8.14

a) Suppose a vector space V is equipped with an inner product $\langle \cdot, \cdot \rangle$, and suppose we define a corresponding norm by $\|\mathbf{x}\|^2 = \langle \mathbf{x}, \mathbf{x} \rangle$. Prove the *Parallelogram Law:*

$$\|\mathbf{x}+\mathbf{y}\|^2 + \|\mathbf{x}-\mathbf{y}\|^2 = 2\|\mathbf{x}\|^2 + 2\|\mathbf{y}\|^2.$$

b) Prove that the taxicab norm defined in Exercise 8.4 does not correspond as in part (a) above to any inner product on $\mathbb{R}^2$.

c) Under the hypotheses of part (a) above, prove the identity

$$\langle \mathbf{x}, \mathbf{y} \rangle = \frac{1}{4}\left(\|\mathbf{x}+\mathbf{y}\|^2 - \|\mathbf{x}-\mathbf{y}\|^2\right).$$

d) *(For this part, you might be able to negotiate extra credit from your teacher.)* Suppose only that V has a norm. Define what is *hoped* to be a scalar product on V by the formula in the preceding part. Prove that this defines a legitimate scalar product on V provided the norm satisfies the Parallelogram Law of part. (Hints: Positivity and symmetry are easy to verify. To show additivity of the product in the first variable, express $4\langle \mathbf{x}+\mathbf{y}, \mathbf{z} \rangle$ in terms of the identity given in the previous part. Then add and subtract $\|\mathbf{x}-\mathbf{y}+\mathbf{z}\|^2$ to show that

$$4\langle \mathbf{x}+\mathbf{y}, \mathbf{z} \rangle = 2(\|\mathbf{x}+\mathbf{z}\|^2 + \|\mathbf{y}\|^2 - \|\mathbf{x}\|^2 - \|\mathbf{y}-\mathbf{z}\|^2).$$

Then let $\mathbf{x}$ and $\mathbf{y}$ change roles and add the results. When this is done, show that $\langle \alpha\mathbf{x}, \mathbf{y} \rangle = \alpha\langle \mathbf{x}, \mathbf{y} \rangle$ for all $\alpha \in \mathbb{N}$. Extend this to $\alpha \in \mathbb{Q}$. Then justify that the inner product is a continuous function of $\mathbf{x}$ and extend to all $\alpha \in \mathbb{R}$.)

8.15 Prove that Euclidean space is *self-dual.* That is, prove that $T : \mathbb{E}^n \to \mathbb{R}$ is a bounded linear functional if and only if there exists $\mathbf{y} \in \mathbb{E}^n$ such that $T(\mathbf{x}) = \langle \mathbf{x}, \mathbf{y} \rangle$ for each $\mathbf{x} \in \mathbb{E}^n$.

8.2 OPEN SETS AND CLOSED SETS

In the calculus of one variable, it is possible to accomplish much with functions defined on an interval. Intervals are quite simple sets to consider as domains on which functions may be defined. Many useful theorems concerning the continuity, differentiability, or integrability of functions can be proven based on whether a domain is a closed or an open interval, or a finite or an infinite interval. In two or more variables, however, the domain of definition of a function can be much more complicated than an interval. For example, the real-valued function

$$f(x, y) = \frac{1}{x\sqrt{1 - 2x^2 - 3y^2}}$$

is defined on the domain that is the region lying *inside* but *not on* an ellipse, *excluding* those points inside the ellipse that are on the y-axis. It is easy to construct more intricate examples than this. Hence a rigorous study of the calculus of functions defined on a Euclidean space $\mathbb{E}^n$ necessitates a careful study of those *topological* properties of sets in $\mathbb{E}^n$ that are needed to prove important theorems regarding continuity, differentiability, and integrability of such functions. Most of the definitions and theorems work for all vector spaces V equipped with a norm, so we state them in this context.

Definition 8.2.1 *In a normed vector space V a subset $S \subseteq V$ is called an* open set *if and only if for each $\mathbf{x} \in S$ there exists a number $r > 0$ corresponding to $\mathbf{x}$ such that the open ball $B_r(\mathbf{x}) \subseteq S$.*

Expressed informally, a set S is said to be open if each point $\mathbf{p}$ of S has at least some small open ball, or *buffer zone* around itself that remains entirely inside S. The radius of the buffer zone may need to be smaller for some points of S than for others.

■ EXAMPLE 8.5

The first example is the open ball $B_r(\mathbf{x})$, which we claim is an open set. (The language *open ball* would be a poor choice if the claim just made were false, but a name alone does not establish that a definition is satisfied.)

Proof: To show that the definition of openness is satisfied, we must show that if $\mathbf{y} \in B_r(\mathbf{x})$ then there exists $d > 0$ such that $B_d(\mathbf{y}) \subseteq B_r(\mathbf{x})$. We claim that $d = r - \|\mathbf{y} - \mathbf{x}\| > 0$ works. In fact, if $\mathbf{z} \in B_d(\mathbf{y})$, then

$$\begin{aligned} \|\mathbf{z} - \mathbf{x}\| &\le \|\mathbf{z} - \mathbf{y}\| + \|\mathbf{y} - \mathbf{x}\| \\ &< d + \|\mathbf{y} - \mathbf{x}\| = r, \end{aligned}$$

proving that $\mathbf{z} \in B_r(\mathbf{x})$ as claimed. ■

Theorem 8.2.1 *Suppose A is an arbitrary set. Suppose for each $a \in A$ there is an* open *set $O_a \subseteq V$* indexed *by a. Then $\mathcal{O} = \bigcup_{a\in A} O_a$ is an open set.*

Remark 8.2.1 In this theorem, the *index set* A may be finite or infinite, countable or uncountable.

Proof: In words, this theorem says that the union of a family of open sets must always be open. Let $\mathbf{x} \in \mathcal{O}$. We must show there exists $r > 0$ such that $B_r(\mathbf{x}) \subseteq \mathcal{O}$. But there exists $a \in A$ such that $\mathbf{x} \in O_a$. Since O_a is open, there exists $r > 0$ such that $B_r(\mathbf{x}) \subseteq O_a \subseteq \mathcal{O}$. ■

It is natural at this point to ask whether the intersection of an arbitrary family of open sets must be open. This is false, as shown in Exercise 8.21.

Theorem 8.2.2 *If $O_1, \ldots, O_k$ is a family of finitely many open sets, then $\mathcal{O} = \bigcap_{j=1}^{k} O_j$ is open.*

Proof: In words, this says the intersection of finitely many open sets must be open. For each $\mathbf{x} \in \mathcal{O}$, $\mathbf{x} \in O_j$ for each j. Hence there exists for each j a number $r_j > 0$ such that $B_{r_j}(\mathbf{x}) \subseteq O_j$. Let $r = \inf\{r_1, \ldots, r_k\}$, so that $r > 0$. Then $B_r(\mathbf{x}) \subseteq \mathcal{O}$. ■

Definition 8.2.2 *In a normed vector space V, a set $S \subseteq V$ is called a* closed set *if and only if its complement $S^c = V \setminus S$ is open.*

We will use the following definition to prove an alternative and equivalent form of the concept of *closed* set.

Definition 8.2.3 *A point* $\mathbf{p}$ *is called a* cluster point *of a subset S of a normed vector space V if and only if there exists a sequence of vectors $\mathbf{x}^{(j)} \in S \setminus \{\mathbf{p}\}$ such that $\mathbf{x}^{(j)} \to \mathbf{p}$ as $j \to \infty$. If $\mathbf{p} \in S$ but $\mathbf{p}$ is* not *a cluster point of S, then $\mathbf{p}$ is called an* isolated point *of S.*

Note that a cluster point of S may or may not be an element of the set S. An isolated point of S must, however, be an element of S.

Theorem 8.2.3 *A subset S of a normed vector space V is closed if and only if every cluster point $\mathbf{p}$ of S is an element of S.*

Proof: Suppose first that S is closed. Let $\mathbf{p}$ be any cluster point of S. We need to prove that $\mathbf{p} \in S$. By hypothesis, there is a sequence $\mathbf{x}^{(j)} \in S \setminus \{\mathbf{p}\}$ such that $\mathbf{x}^{(j)} \to \mathbf{p}$ as $j \to \infty$. Thus, for every open ball $B_r(\mathbf{p})$ there exists $J \in \mathbb{N}$ such that $j \geq J \implies \mathbf{x}^{(j)} \in B_r(\mathbf{p})$. Thus $\mathbf{p} \notin S^c = V \setminus S$ since the latter set is open. Hence $\mathbf{p} \in S$.

Next, we suppose every cluster point of S is in S. We need to prove that the complement of S is open. Let $\mathbf{x} \in S^c = V \setminus S$. We claim there exists $r > 0$ such that $B_r(\mathbf{x}) \subseteq S^c = V \setminus S$. Suppose this claim were false. Then for each $j \in \mathbb{N}$

there exists $\mathbf{x}^{(j)} \in S \setminus \{\mathbf{x}\}$ such that $\mathbf{x}^{(j)} \in B_{\frac{1}{j}}(\mathbf{x})$. But then $\mathbf{x}^{(j)} \to \mathbf{x}$. Thus $\mathbf{x}$ is a cluster point of S, which forces $\mathbf{x} \in S$. This is a contradiction, which proves the claim. ∎

■ EXAMPLE 8.6

Every closed ball $\bar{B}_r(\mathbf{x})$ is a closed set.

Proof: We will show that the complement of the closed ball is open. If $\mathbf{y} \in V \setminus \bar{B}_r(\mathbf{x})$, let $\delta = \|\mathbf{y} - \mathbf{x}\| - r$. We claim that $B_\delta(\mathbf{y})$ is contained in the complement of the closed ball. So let $\mathbf{z} \in B_\delta(\mathbf{y})$. Then

$$\|\mathbf{z} - \mathbf{x}\| + \|\mathbf{z} - \mathbf{y}\| \geq \|\mathbf{x} - \mathbf{y}\|$$

by the triangle inequality, so

$$\begin{aligned} \|\mathbf{z} - \mathbf{x}\| &\geq \|\mathbf{x} - \mathbf{y}\| - \|\mathbf{z} - \mathbf{y}\| \\ &> \|\mathbf{x} - \mathbf{y}\| - \delta = r. \end{aligned}$$

Thus $\mathbf{z}$ lies outside the closed ball, as required. ∎

■ EXAMPLE 8.7

It follows from the preceding example that for each $\mathbf{p} \in \mathbb{E}^n$, the singleton set $\{\mathbf{p}\} = \bar{B}_0(\mathbf{p})$ is a closed set. The reader should show that this singleton set $\{\mathbf{p}\}$ is not an open set. Note that this does *not* follow from some linguistic relationship between the words *open* and *closed* in every day parlance. Instead, it is necessary to show that if $r > 0$ then $B_r(\mathbf{p})$ is not a subset of $\{\mathbf{p}\}$.

Theorem 8.2.4 *Suppose A is an arbitrary set. (A may be finite or infinite, countable or uncountable.) Suppose for each $a \in A$ there is a* closed *set $F_a \subseteq \mathbb{E}^n$ indexed by a. Then $\mathcal{F} = \bigcap_{a \in A} F_a$ is a closed set.*

Proof: It suffices to observe the

$$\mathcal{F} = \left(\bigcup_{a \in A} F_a^c \right)^c .$$

Since each set F_a^c is open being the complement of the closed set F_a, the union is open and its complement, $\mathcal{F}$, is closed. ∎

EXERCISES

8.16 Prove that Theorem 8.2.2 implies that the *empty set* $\emptyset$ is open in any normed vector space V, and that the whole space V is closed.

8.17 For each of the following sets, state whether it is open, closed, both, or neither.

- **a)** $A = \{\mathbf{x} \in \mathbb{E}^2 \,|\, x_1 \neq 0\}$.
- **b)** $B = \{\mathbf{x} \in \mathbb{E}^2 \,|\, x_1 = 0\}$.
- **c)** $C = \{\mathbf{x} \in \mathbb{E}^2 \,|\, x_1 \geq 0 \text{ and } x_2 > 0\}$.
- **d)** $E = \{\mathbf{x} \in \mathbb{E}^2 \,|\, x_1 + x_2 > 0\}$.
- **e)** $F = \{\mathbf{x} \in \mathbb{E}^2 \,|\, x_1 + x_2 \leq 0\}$.
- **f)** $D = A \cup B$.
- **g)** $G = \{\mathbf{x} \in \mathbb{E}^2 \,|\, 1 < x_1^2 + x_2^2 < 4\}$.

8.18 Prove that a point $\mathbf{p}$ is a cluster point of a set $D \subseteq \mathbb{E}^n$ if and only if for each $\delta > 0$ there exists $\mathbf{x} \in D$ such that $0 < \|\mathbf{x} - \mathbf{p}\| < \delta$.

8.19 Prove that if $\mathbf{p}$ is an isolated point of D, once $\delta > 0$ is sufficiently small the set $\{\mathbf{x} \in D \mid 0 < \|\mathbf{x} - \mathbf{p}\| < \delta\} = \emptyset$, the empty set.

8.20 Let $\mathcal{O}$ denote an *arbitrary open* subset of $\mathbb{E}^n$. Prove that $\mathcal{O}$ is the union of a (possibly infinite) family of open *balls*.

8.21 † Let $\mathbf{p} \in \mathbb{E}^n$. Show that the singleton set $\{\mathbf{p}\}$ can be written as the intersection of an infinite sequence of open balls, thereby showing that intersections of open sets need not be open. (Hint: Define a sequence $r_n > 0$ for which $\inf\{r_n \mid n \in \mathbb{N}\} = 0$.)

8.22 Prove or give a counterexample: No set $S \subseteq \mathbb{E}^n$ can be *both* open and closed.

8.23 Prove or give a counterexample: Every set $S \subseteq \mathbb{E}^n$ must be either open or closed.

8.24 Prove that if $F_1, \ldots, F_k$ is a family of finitely many closed sets, then $\mathcal{F} = \bigcup_{j=1}^k F_j$ is closed.

8.25 Use Example 8.7 to prove that every set $S \subseteq \mathbb{E}^n$ is the union of a family of closed sets.

8.26 † If $S \subset \mathbb{E}^n$, define the *interior* of S, denoted by S^o, to be

$$S^o = \{\mathbf{x} \in S \mid \exists\, r > 0 \text{ such that } B_r(\mathbf{x}) \subseteq S\}.$$

Prove that $S \subseteq \mathbb{E}^n$ is an open set if and only if $S = S^o$.

8.27 Prove that $\left(\bar{B}_r(\mathbf{x})\right)^o = B_r(\mathbf{x})$ in the space $\mathbb{E}^n$.

8.28 Define the *closure* $\bar{S}$ of $S \subseteq \mathbb{E}^n$ to be the intersection of all closed sets that contain S. Prove that $\bar{S}$ is a closed set and that $\bar{S} = S \cup C$, where C is the set of all cluster points of S.

8.29 Prove: The closed ball $\bar{B}_r(\mathbf{x})$, defined in Definition 8.1.2, is actually the closure of the open ball $B_r(\mathbf{x})$, provided $r > 0$.

8.30 Define the *boundary* of $S \subseteq \mathbb{E}^n$, denoted by ∂S, to be $\partial S = \bar{S} \setminus S^o$. Find the boundary of $B_r(\mathbf{x})$ in $\mathbb{E}^n$.

8.31 Define a set $S \subseteq \mathbb{E}^n$ to be dense in $\mathbb{E}^n$ if and only if $\bar{S} = \mathbb{E}^n$. Denote by $\mathbb{Q}^n$ the subset of $\mathbb{E}^n$ consisting of vectors with exclusively rational coordinates. Prove that $\mathbb{Q}^n$ is dense in $\mathbb{E}^n$.

8.32 Prove or give a counterexample: Every open set in $\mathbb{E}^n$ can be expressed as the union of either a finite or a countable family of open balls.

8.33 Find $(\mathbb{Q}^n)^o$ and $\partial\mathbb{Q}^n$. Justify your answers. (Hint: It will help to consider the density of the set of irrational numbers in the set $\mathbb{R}$.)

8.3 COMPACT SETS

In Chapters 1 through 3, we saw that closed, finite intervals $[a, b]$ have very useful properties as domains of continuous functions. Such intervals were very important for establishing an Extreme Value Theorem (Theorem 2.4.2) and a uniform continuity theorem (Theorem 2.3.2), for example. In this section we seek to describe the class of subsets of $\mathbb{E}^n$ that have similar properties as domains for functions of vector variables. We take our cue from the Heine–Borel Theorem (Theorem 1.7.2) for functions defined on intervals $[a, b]$.

Definition 8.3.1 *If $E \subseteq \mathbb{E}^n$, we call a family*

$$\mathcal{O} = \{O_a \mid a \in A\}$$

of open sets O_a an open cover *of E if and only if*

$$E \subseteq \bigcup_{a \in A} O_a.$$

If there exists a finite *subset F of the* index *set A such that*

$$E \subseteq \bigcup_{a \in F} O_a,$$

then we call $\mathcal{O}_F = \{O_a \mid a \in F\}$ a finite subcover *of E. We call the set E* compact *if and only if* every *open cover of E has a finite subcover. A set E is called* bounded *if and only if* $\sup \left\{ \|\mathbf{x}\| \,\middle|\, \mathbf{x} \in E \right\} < \infty$.

The reader should take care not to confuse the concept of an open cover with the *union* of its elements.

■ **EXAMPLE 8.8**

Let

$$S = \{(m, n) \mid m \in \mathbb{Z},\ n \in \mathbb{Z}\} = \mathbb{Z}^2 = \mathbb{Z} \times \mathbb{Z}.$$

We claim that the subset S of $\mathbb{E}^2$ is not compact. For a proof, we observe that

$$S \subset \bigcup_{(m,n) \in S} B_1((m, n)).$$

However, the open cover $\{B_1((m,n)) \mid m \in \mathbb{Z},\ n \in \mathbb{Z}\}$ of S has no finite subcover. Do you see why not?

■ EXAMPLE 8.9

The set $B_1(\mathbf{0})$ is not a compact subset of $\mathbb{E}^2$. For a proof, show that

$$\mathcal{O} = \{B_r(\mathbf{0}) \mid 0 < r < 1\}$$

is an open cover of $B_1(\mathbf{0})$, yet there is no finite subcover. The reader should show why this is true.

The following theorem provides a powerful generalization of the phenomena exhibited by the two preceding examples.

Theorem 8.3.1 (Heine–Borel Theorem for $\mathbb{E}^n$) *A set $E \subseteq \mathbb{E}^n$ is compact if and only if E is* both *closed and bounded.*

Proof: We leave the proof that every compact set must be both bounded and closed to Exercises 8.38 and 8.39, respectively. Here we suppose that E is both closed and bounded, and we will prove that E is necessarily compact. We suppose that this were *false*, and deduce a contradiction.

Thus we assume there exists an open cover $\mathcal{O} = \{O_a \mid a \in A\}$ of E for which there exists *no* finite subcover. Since E is bounded, there exists $R > 0$ such that $E \subseteq B_R(\mathbf{0})$, which is, in turn, contained in the *hyper*cube $[-R, R]^{\times n}$, an n-fold Cartesian product of the interval $[-R, R]$. It will be convenient in this proof to denote the hypercube by a pair of diagonally opposite corner-vectors $\mathbf{a}_1 = (-R, -R, \dots, -R)$ and $\mathbf{b}_1 = (R, R, \dots, R)$. Thus we will denote the cube

$$[-R, R]^{\times n} = [\mathbf{a}_1, \mathbf{b}_1].$$

Next we subdivide the cube $[\mathbf{a}_1, \mathbf{b}_1]$ into 2^n congruent subcubes as follows. Simply bisect the interval $[-R, R]$ on each of the n coordinate axes, and form all 2^n possible Cartesian products of a half-interval from each of the axes. Each such subcube can be denoted $[\mathbf{a}, \mathbf{b}]$, where the coordinates of $\mathbf{a} = (a_1, a_2, \dots, a_n)$ denote the left-hand endpoints of the n chosen subintervals on the axes, and with a similar convention is employed for $\mathbf{b}$ using right-hand endpoints. Observe that for each such subcube $[\mathbf{a}, \mathbf{b}] \subset [\mathbf{a}_1, \mathbf{b}_1]$, the set $E \cap [\mathbf{a}, \mathbf{b}]$ is covered by $\mathcal{O}$. Among the 2^n subcubes formed, there must exist at least one subcube $[\mathbf{a}_2, \mathbf{b}_2]$ having the property that $E \cap [\mathbf{a}_2, \mathbf{b}_2]$ has no finite subcover from $\mathcal{O}$. (Otherwise, there would exist a finite subcover for E itself.) Now we repeat the process by subdividing $[\mathbf{a}_2, \mathbf{b}_2]$ into 2^n subcubes and we select a subcube $[\mathbf{a}_3, \mathbf{b}_3]$ in the same manner as before. In this way, we obtain a decreasing nest

$$[\mathbf{a}_1, \mathbf{b}_1] \supset [\mathbf{a}_2, \mathbf{b}_2] \supset \dots \supset [\mathbf{a}_k, \mathbf{b}_k] \supset \dots$$

of subcubes having the property that for each $k \in \mathbb{N}$ the set $E_k = E \cap [\mathbf{a}_k, \mathbf{b}_k]$ is covered by $\mathcal{O}$ but has no finite subcover.

Select a point $\mathbf{p}_k \in E_k$ for each $k \in \mathbb{N}$. If j and $k \geq N$ then $\mathbf{p}_j$ and $\mathbf{p}_k \in E_N$. Hence

$$\|\mathbf{p}_j - \mathbf{p}_k\| \leq \frac{R\sqrt{n}}{2^{N-2}} \to 0$$

as $N \to \infty$. Thus the sequence $\mathbf{p}_k$ is a Cauchy sequence, and $\mathbf{p}_k \to \mathbf{p} \in E_N$ for each $N \in \mathbb{N}$. (Here we use the fact that E_N is a closed set.) Since $\mathbf{p} \in E$, there exists $a \in A$ such that $\mathbf{p} \in O_a$. Since O_a is open, there exists $r > 0$ such that $B_r(\mathbf{p}) \subseteq O_a$. Now select $N \in \mathbb{N}$ such that $k \geq N$ implies

$$\frac{R\sqrt{n}}{2^{k-2}} < r,$$

so that $\mathbf{p} \in E_N \subset B_r(\mathbf{p}) \subseteq O_a$. Thus we have covered E_N with a *single* set O_a from $\mathcal{O}$, contradicting the claim that E_N has no finite subcover from $\mathcal{O}$. ■

EXERCISES

8.34 If E is a compact subset of $\mathbb{E}^n$, prove (*without using the Heine–Borel Theorem*) that every closed subset of E is compact.

8.35 Use *only* the definition of compactness to show that every finite subset of $\mathbb{E}^n$ is compact.

8.36

- **a)** Let $S = \{\mathbf{x}^{(j)} \mid j \in \mathbb{N}\} \subset \mathbb{E}^n$ be any *convergent* sequence. Show that S is a compact set if and only if $\lim_{j\to\infty} \mathbf{x}^{(j)} \in S$.
- **b)** Let $S = \{\mathbf{x}_n = (1 + \frac{n}{2^n}, \frac{n}{2^n}) \mid n = 0, 1, 2, 3, \ldots\} \subset \mathbb{E}^2$. True or False: S is compact.

8.37 Let $S = \{\mathbf{x}^{(j)} \mid j \in \mathbb{N}\} \subset \mathbb{E}^n$ be *any* sequence. Prove or give a counterexample: The set S is a compact set if and only if the sequence $\mathbf{x}^{(j)}$ is convergent to an element of S.

8.38 † Prove part of the Heine–Borel theorem by showing that if $E \subseteq \mathbb{E}^n$ is *compact*, then E is *bounded*. (Hint: Show how to cover E with suitable open balls centered at $\mathbf{0}$.)

8.39 † Prove part of the Heine–Borel theorem by showing that if $E \subseteq \mathbb{E}^n$ is *compact*, then E is *closed*. (Hint: Suppose that $\mathbf{p}$ is any point not in E. Show how to cover E with the complements of suitable closed balls centered at $\mathbf{p}$. Conclude that E^c is *open*.)

8.40 † Let f be a real-valued function defined on a closed finite interval $[a, b]$ in $\mathbb{E}^1$. Define the *graph* $G_f = \{(x_1, x_2) \in \mathbb{E}^2 \mid x_2 = f(x_1), x_1 \in [a, b]\}$.

- **a)** Prove: If $f \in \mathcal{C}[a, b]$, then G_f is a compact subset of $\mathbb{E}^2$. (Hint: Use the Heine–Borel Theorem.)

b) Let

$$g(x_1) = \begin{cases} \sin \frac{\pi}{x_1} & \text{if } x_1 \in (0,1], \\ 0 & \text{if } x_1 = 0. \end{cases}$$

Is the graph G_g a compact subset of $\mathbb{E}^2$? Prove your conclusion.

8.41 Let $E_1 \supseteq E_2 \supseteq \dots \supseteq E_k \supseteq \dots$ be a decreasing nest of *nonempty closed* subsets of $\mathbb{E}^n$.

a) Give an example to show it is possible for $\bigcap_{k=1}^{\infty} E_k$ to be empty.

b) If E_1 is compact, show that $\bigcap_{k=1}^{\infty} E_k \neq \emptyset$. (Hint: Select a point $\mathbf{x}_k \in E_k$ for each $k \in \mathbb{N}$. Apply Exercise 8.11.c.)

8.42 For each of the following subsets of $\mathbb{E}^n$, determine whether or not it is compact and justify your conclusion.

a) $B_r(\mathbf{x})$, with $r > 0$.

b) $\bar{B}_r(\mathbf{x})$, with $r > 0$.

c) $S^{n-1} = \bar{B}_r(\mathbf{x}) \setminus B_r(\mathbf{x})$, with $r > 0$.

8.43 Let $K \subset \mathbb{E}^n$ be compact. Suppose f and g are in $\mathcal{C}(K)$ and suppose that $f(\mathbf{x}) = 0$ for each $\mathbf{x} \in K$ such that $g(\mathbf{x}) = 0$. Prove: If $\epsilon > 0$, there exists $M \geq 0$ such that

$$|f(\mathbf{x})| < M|g(\mathbf{x})| + \epsilon$$

for all $\mathbf{x} \in K$. (Hint: Use the Heine–Borel Theorem. For interesting applications of this exercise in approximation theory, see [13].)

8.4 CONNECTED SETS

In order to generalize the Intermediate Value Theorem (Theorem 2.3.1) to functions defined on Euclidean space, it will be necessary to identify a class of subsets of $\mathbb{E}^n$ with properties sufficiently similar to those of intervals. Let us begin by writing a formal definition of the concept of *interval*.

Definition 8.4.1 *An* interval *is any subset I of $\mathbb{R}$ such that for all a and b in I with $a \leq b$ the set $\{x \in \mathbb{R} \mid a \leq x \leq b\} \subseteq I$.*

This concept includes all open, closed, half-open and half-closed, finite or infinite intervals. (See Exercise 8.44.) The difficulty in generalizing this concept is that there is no natural *linear ordering*, or notion of *inequality* in $\mathbb{E}^n$ when $n > 1$. The concept we seek is that of being a *connected* set. In order to define this concept it is convenient to begin with its opposite: a set is called *disconnected*, in the sense that it can be *separated* into two parts, or components.

Definition 8.4.2 *We say that a set $E \subseteq V$, a normed vector space, is* disconnected *if there exists a pair of* disjoint open *subsets A and B of V for which $E \subseteq A \cup B$ and such that both*

$$E_1 = E \cap A \neq \emptyset \text{ and } E_2 = E \cap B \neq \emptyset.$$

In this case, we say that A and B separate *E. If E is* not *disconnected, then E is called* connected.

■ EXAMPLE 8.10

Let $E = \mathbb{Q}$, the set of all rational numbers. We claim that E is a *disconnected* subset of $\mathbb{E}^1$. In fact, let

$$A = \left\{x \in \mathbb{E}^1 \,\middle|\, x < \sqrt{2}\right\} \text{ and } B = \left\{x \in \mathbb{E}^1 \,\middle|\, x > \sqrt{2}\right\}.$$

Then A and B are disjoint open sets that separate E. The key to this construction is that there exists $\sqrt{2} \in \mathbb{E}^1 \setminus \mathbb{Q}$.

In Exercise 8.45 the reader will prove that a subset of $\mathbb{E}^1$ is connected if and only if it is an interval. The set $\mathbb{Q}$, which is shown above to be disconnected, is not an interval. We show below that the concept of a set E being disconnected can be expressed without reference to open sets A and B as in the definition. This will give us a more visually intuitive concept of the meaning of connectivity.

Theorem 8.4.1 *A set $E \subseteq V$, a normed vector space, is disconnected if and only if we can decompose E as $E = E_1 \cup E_2$, both sets nonempty, where $E_1 \cap E_2 = \emptyset$ and where neither E_1 nor E_2 contains any cluster points of the other set.*

Proof: First we suppose that E is separated. Thus A and B exist as in the definition. If $\mathbf{e} \in E_1$, then there exists $r > 0$ such that $B_r(\mathbf{e}) \subseteq A$. Since E_2 is disjoint from A, $\mathbf{e}$ is not a cluster point of E_2. Similarly, E_2 has no cluster point of E_1.

Next we suppose that $E = E_1 \cup E_2$, a disjoint union, where neither E_1 nor E_2 has any cluster point of the other, and each set is nonempty. Let $\mathbf{e} \in E$. Since $\mathbf{e}$ is in one of the two sets E_1 or E_2 without being a cluster point of the other, there exists $r_{\mathbf{e}} > 0$ such that $B_{r_{\mathbf{e}}}(\mathbf{e})$ is disjoint from the set to which $\mathbf{e}$ does not belong. Let

$$A = \bigcup_{\mathbf{e} \in E_1} B_{\frac{r_{\mathbf{e}}}{2}}(\mathbf{e}).$$

Similarly, we let

$$B = \bigcup_{\mathbf{e} \in E_2} B_{\frac{r_{\mathbf{e}}}{2}}(\mathbf{e}).$$

It follows that A and B are open sets and that $A \cap E = E_1$ and $B \cap E = E_2$. We need prove only that $A \cap B = \emptyset$. Suppose this claim were false. Then there exists $\mathbf{p} \in A \cap B$. Hence there exist $\mathbf{e}_1 \in E_1$ and $\mathbf{e}_2 \in E_2$ such that $\|\mathbf{e}_1 - \mathbf{p}\| < \frac{r_{\mathbf{e}1}}{2}$ and $\|\mathbf{e}_2 - \mathbf{p}\| < \frac{r_{\mathbf{e}2}}{2}$. By the triangle inequality for norms, it follows that

$$\|\mathbf{e}_1 - \mathbf{e}_2\| < \frac{r_{\mathbf{e}_1} + r_{\mathbf{e}_2}}{2} \leq \max\{r_{\mathbf{e}_1}, r_{\mathbf{e}_2}\}.$$

This is a contradiction. ■

Theorem 8.4.2 *Let f be any continuous real-valued function defined on an interval I. Let G_f denote the graph of f as defined in Exercise 8.40. We claim that G_f is a connected subset of $\mathbb{E}^2$.*

Proof: We suppose the claim were false, and we will deduce a contradiction. If G_f were disconnected, then $G_f = E_1 \cup E_2$, a disjoint union of two nonempty sets, neither one containing any cluster point of the other. So there exist $(x_i, f(x_i)) \in E_i$, for $i = 1, 2$. Suppose without loss of generality that $x_1 < x_2$. (We know $x_1 \neq x_2$, since G_f is the graph of a function.) Define

$$c = \sup \left\{ t \in [x_1, x_2] \,\middle|\, (q, f(q)) \in E_1, \forall q \in [x_1, t] \right\}.$$

Thus $x_1 \leq c \leq x_2$. If $(c, f(c)) \in E_1$ then $c < x_2$. Hence for $n \in \mathbb{N}$ there exists

$$c_n \in \left(c, c + \frac{1}{n} \right) \cap [x_1, x_2]$$

for which $(c_n, f(c_n)) \in E_2$. This would imply that $(c_n, f(c_n)) \to (c, f(c))$, by continuity of f. Hence $(c, f(c))$ is a cluster point of E_2, which is a contradiction. On the other hand, if $(c, f(c)) \in E_2$, then $c > x_1$, $(c, f(c))$ is a cluster point of E_1. This yields a similar contradiction. ■

Corollary 8.4.1 *The Euclidean space $\mathbb{E}^n$ is connected, for each $n \in \mathbb{N}$.*

Proof: Suppose the corollary were false. Then $\mathbb{E}^n = E_1 \cup E_2$, a disjoint union of two sets, neither of which contains any of the other's cluster points. Let $\mathbf{p} \in E_1$ and $\mathbf{q} \in E_2$. Let

$$\phi(t) = \mathbf{p} + t(\mathbf{q} - \mathbf{p})$$

for each $t \in [0, 1]$. Then $\phi(0) \in E_1$ and $\phi(1) \in E_2$. Define

$$c = \sup \left\{ t \in [0, 1] \,\middle|\, (q, \phi(q)) \in E_1, \forall q \in [0, t] \right\}.$$

Now complete the proof just as in Theorem 8.4.2. ■

Theorem 8.4.3 *Suppose E and F are* nondisjoint *connected subsets of a normed vector space V. Then $G = E \cup F$ is connected.*

Proof: Suppose false. Then there exist nonempty disjoint open sets A and B such that $A \cap G \neq \emptyset \neq B \cap G$. Since E cannot be separated, E is contained entirely in one open set or the other. Without loss of generality, suppose $E \subseteq A$. Similarly, F is contained entirely in one of the open sets. Since $B \cap G \neq \emptyset$, $F \subseteq B$. But this is impossible since $E \cap F \neq \emptyset$ and $A \cap B = \emptyset$. ■

EXERCISES

8.44 † Prove that if $I \subseteq \mathbb{R}$ is an interval, as defined in Definition 8.4.1, then I must have one of the following forms: $[a, b], (a, b), [a, b)$ or $(a, b]$. In this notation $-\infty \leq a \leq b \leq \infty$, but closed endpoints must be finite. (Hint: Consider $\sup(I)$ and $\inf(I)$.)

8.45 †

a) Prove that every connected subset $S \subseteq \mathbb{E}^1$ is an interval.

b) Prove that every interval I is a connected subset of $\mathbb{E}^1$. In particular, this includes the claim that the real line $\mathbb{E}^1$ is itself a connected set. (Hint: Consider Theorem 8.4.2 and the function $f(x) \equiv 0$. Explain how connectedness in E^2 implies connectedness in E^1.)

8.46 Prove that the union of the x_1-axis and the x_2-axis in $\mathbb{E}^2$ is a connected set.

8.47 Prove that $S^1 = \{\mathbf{x} \in \mathbb{E}^2 \mid \|\mathbf{x}\| = 1\}$ is a connected set.

8.48 Suppose $E \subseteq \mathbb{E}^2$ such that for all $\mathbf{x} \in E$, $x_2 = 0$. Suppose E is a connected subset of $\mathbb{E}^1$, which we identify with the x_1-axis of $\mathbb{E}^2$. Prove that E is also connected as a subset of $\mathbb{E}^2$.

8.49 Let $E = \{\mathbf{x} \in \mathbb{E}^2 \mid x_1x_2 > 0\}$. Is E connected? Prove your conclusion.

8.50 Let $E = \{\mathbf{x} \in \mathbb{E}^2 \mid x_1x_2 \geq 0\}$. Is E connected? Prove your conclusion.

8.51 Let $E = \{\mathbf{x} \in \mathbb{E}^2 \mid x_1^2 = 1\}$. Is E connected? Prove your conclusion.

8.52 In E^2, let $E = \{\mathbf{x} \mid x_1 = 0\} \cup \{\mathbf{x} \mid x_1x_2 = 1, x_1 > 0\}$. Is E connected? Prove your conclusion.

8.53 Let

$$g(x) = \begin{cases} x \sin \frac{\pi}{x} & \text{if } x > 0, \\ 0 & \text{if } x = 0. \end{cases}$$

Prove that the graph of g is a connected subset of $\mathbb{E}^2$.

8.54 Let

$$f(x) = \begin{cases} \sin \frac{\pi}{x} & \text{if } x > 0, \\ 0 & \text{if } x = 0. \end{cases}$$

Prove that the graph of f is a connected subset of $\mathbb{E}^2$. (Hint: Try writing $G_f \subseteq A \cup B$ with A and B open and disjoint. Prove that G_f must be contained entirely within one of the two open sets.)

8.55 Let $E \subseteq \mathbb{E}^n$ be any connected set and let $\mathbf{p}$ be a cluster point of E. *Prove or disprove*: $E \cup \{\mathbf{p}\}$ is connected.

8.56 Let $E \subseteq \mathbb{E}^n$ be any connected set and let $\bar{E}$ be the *closure* of E. *Prove or disprove*: $\bar{E}$ is connected.

8.57 Let $f(x) = e^{-x^2}$ for all $x \in \mathbb{R}$. Denote the graph of f by G_f and the x-axis in $\mathbb{E}^2$ by G_0. *Prove or disprove*: $S = G_f \cup G_0$ is a connected subset of $\mathbb{E}^2$. (Hint: Apply Theorem 8.4.1.)

8.58 Prove or give a counterexample: Every open set $\mathcal{O} \subseteq \mathbb{E}^n$ can be expressed as the union of a finite or countable family of *disjoint* open balls. (Hint: See Exercise 8.32.)

8.5 TEST YOURSELF

EXERCISES

8.59 Let $\mathbf{x} = (5, -2, 3) \in \mathbb{E}^3$. Give an example of a non-$\mathbf{0}$ vector $\mathbf{y} \in \mathbb{E}^3$ for which $\|\mathbf{x}\|^2 + \|\mathbf{y}\|^2 = \|\mathbf{x} + \mathbf{y}\|^2$.

8.60 Let $S \subseteq \mathbb{E}^n$ be a set of vectors for which each sequence

$$\left\{\mathbf{x}^{(k)} \mid k \in \mathbb{N}\right\} \subseteq S$$

has a convergent *sub*sequence. True or False: S must be bounded.

8.61 The *taxicab* norm in $\mathbb{R}^2$ is defined by $\|\mathbf{x}\|_t = |x_1| + |x_2|$. Draw a sketch of the unit ball $B_1(\mathbf{0})$ in $\mathbb{R}^2$ using the taxicab norm. Label your axes.

8.62 Give an example of a set $D \subseteq \mathbb{E}^2$ and a point $\mathbf{p}$ which is an *isolated* point of D.

8.63 Give an example of a set $S \subseteq \mathbb{E}^2$ for which S is dense $\mathbb{E}^2$ but has empty interior.

8.64 True or False: The interior of the closure of an *open* set $S \subseteq \mathbb{E}^n$ need *not* be S itself.

8.65 Let $f(x) = \sin \frac{\pi}{x}$ for all $x \neq 0$. True or False: The graph G_f is compact.

8.66 Let $E_1 \supseteq E_2 \supseteq \ldots \supseteq E_k \supseteq \ldots$ be a decreasing nest of closed subsets of $\mathbb{E}^n$. True or False: $\bigcap_{k=1}^{\infty} E_k$ must be non-$\emptyset$.

8.67 Let $S = \left\{\mathbf{x}_n = \left(1 + \frac{n}{2^n}, \frac{n}{2^n}\right) \mid n = 0, 1, 2, 3, \ldots\right\} \subset \mathbb{E}^2$. True or False: S is compact.

8.68 Let

$$g(x) = \begin{cases} x^2 \cos \frac{1}{x} & \text{if } x \neq 0, \\ 0 & \text{if } x = 0. \end{cases}$$

True or False: The graph G_g is connected.

8.69 For each one of the following two sets, decide whether it is *connected* or *not connected*.

- **a)** $S = \left\{\mathbf{x} \in \mathbb{E}^2 \mid |x_2| = |x_1|\right\}$.
- **b)** $T = \left\{\mathbf{x} \in \mathbb{E}^2 \mid |x_2| < |x_1|\right\}$.

8.70 True or False: If $S \neq \emptyset$ is open in $\mathbb{E}^n$, then $S = \cup_{a \in A} B_a$, a union of nonempty *disjoint* open balls of finite radius.

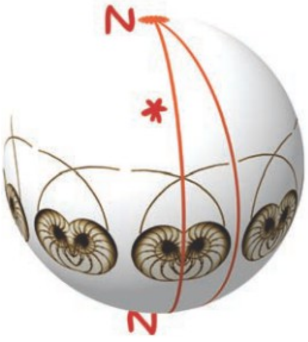
The Five "Reflecting Red" Types

The all-red signatures for sphere patterns must have the form `*AB...N` since we can no longer afford two $*$'s. The ones for which *ch* is positive are in perfect correspondence with the true blue types, since $ch(*\texttt{AB...N})$ is exactly half of $ch(\mathbf{AB...N})$, as we see from the following:

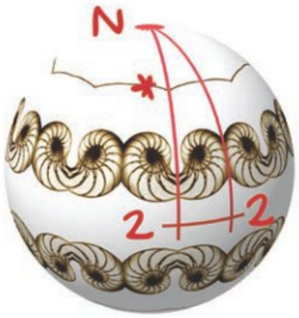
$$ch(*\texttt{AB...N}) = {}^{\$}2 - 1 - \left(\frac{A-1}{2A} + \cdots + \frac{N-1}{2N}\right),$$

$$ch(\mathbf{AB...N}) = {}^{\$}2 - \left(\frac{A-1}{A} + \cdots + \frac{N-1}{N}\right).$$

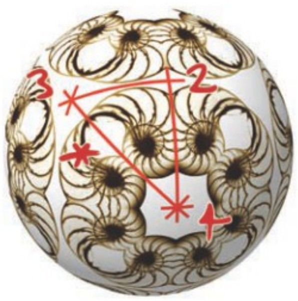
But remember the proviso: `*MN` exists only if $M = N$.



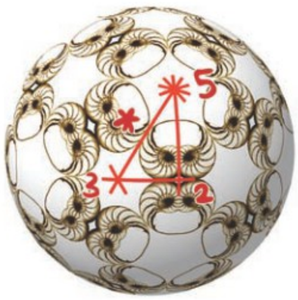
Signature *NN



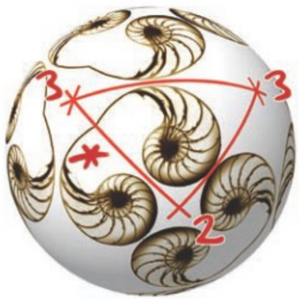
Signature *22N



Signature *432



Signature *532



Signature *332

The Four Hybrid Types

As in the plane case, these must all be obtainable by promotion from the red reflective cases. Here are all the possibilities:

$$\begin{tikzcd} {*532} & {*432} & {*332} \arrow[d] & {*22N} \arrow[d] & {*NN} \arrow[d] \\ & & 3{*}2 & 2{*}N & N{*} \arrow[d] \\ & & & & N\times \end{tikzcd}$$

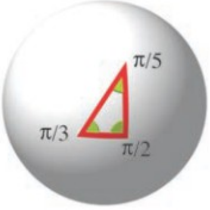
The Existence Problem: Proving the Proviso

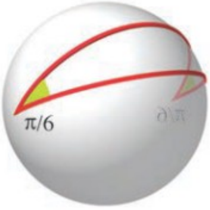
All 17 possibilities that we enumerated for plane patterns actually arose. In the spherical case, the corresponding statement is not quite true; the types **MN** and *MN only exist if $M = N$. The other cases cause no problem.

For example, *442 was generated by reflections in a triangle of angles $\frac{\pi}{4}$, $\frac{\pi}{4}$, $\frac{\pi}{2}$, and a plane pattern with this type of symmetry exists because such a triangle exists in the Euclidean plane. Similarly, *532 is generated by reflections in a triangle of angles $\frac{\pi}{5}$, $\frac{\pi}{3}$, $\frac{\pi}{2}$, and a spherical pattern with this symmetry exists because there is a spherical triangle with these angles.[1]



A triangle on the sphere with angles $\frac{\pi}{5}$, $\frac{\pi}{3}$, and $\frac{\pi}{2}$.

Now for the proviso! The type *MN, when it exists, is generated by the reflections in the sides of a two-sided polygon with angles $\frac{\pi}{M}$ and $\frac{\pi}{N}$. This *does* exist when $M = N$; it's the lune bounded by two great semicircles at angle $\frac{\pi}{N}$ (at right), but does not when $M \neq N$. (For the same reason *M, which equals *M1, fails to exist for $M > 1$.)



A two-sided spherical polygon with two angles of $\frac{\pi}{6}$ radians.

A hypothetical pattern of type **MN** with $M \neq N$ would contain just two types of gyration point. But then, by superposing it with its image under a reflection fixing a gyration point of each type, we should obtain one of type *MN, which is impossible. Therefore, **MN** also fails to exist if $M \neq N$, and **M** fails to exist if $M \neq 1$.

Group Theory and All the Spherical Symmetry Types

Group theory is not discussed in detail here, at least not until much later in this book; there are many texts available that teach group theory better than we are able to in the space available here. In brief, the symmetries of a pattern form a group; suppose A and B are symmetries of a pattern, described by some motion of the pattern that takes a fundamental region to a copy of itself. Then, the "product" symmetry AB is what you get when the motion associated with A is followed by the motion associated with B. You may wish

---

[1] In the plane, the sum of the angles of a triangle is always π radians $= 180^\circ$. On a sphere, the sum can be larger. For example, a triangle on the globe with one vertex on the North Pole and two vertices on the equator has two angles of $\frac{\pi}{2}$ radians at the equator. The sum of the angles of that triangle will be π plus the angle at the pole.

$2 \times G$	direct product of G with a group of order 2.	

Table 4.2. Legend for Table 4.1.

to confirm for yourself that in the examples we have seen so far this composition is associative (i.e., that (AB)C = A(BC) for all choices of A, B, and C) and that in the relation AB = C, any two of A, B, and C uniquely determine the third.

The size or *order* of a group is the number of elements in it—here it is the number of symmetries. Two different geometrical groups have the same abstract structure if their elements multiply in the same way.

All the Spherical Types

Table 4.1 lists the types of spherical repeating patterns and their equivalences as groups. The table is complete for patterns with up to 24 symmetries, after which we restrict to multiples of 3. The last column gives the number of distinct geometrical groups, followed in parentheses by the number of different abstract structures (as separated by the lines). Each row of Table 4.1 lists all the groups of a given size; groups with different abstract structures are separated by the curved and straight lines. Codes for these structures are given below the table and are explained in Table 4.2: the polyhedral groups are isomorphic to the alternating and symmetric groups A_4, S_4, or A_5 according as n is 3, 4, or 5.

Where Are We?

We have shown in this chapter that the spherical form of the Magic Theorem implies that the spherical symmetry types fall into seven infinite families plus seven individual types. The groups of symmetries of these patterns are listed by increasing number of symmetries in Table 4.1. As before, the proof of the Magic Theorem that leads to this conclusion is postponed to Chapter 6.

Dirac Sea: the vacuum as a sea of negative energy

The British physicist Paul Dirac brought a new understanding of the vacuum as an infinite energy, as we conceive it now.

He predicted the existence of anti-matter back in 1928, with his famous Dirac Equation, that was the first bridge between quantum physics and relativity theory.

Dirac Sea: the vacuum as a sea of negative energy

The British physicist Paul Dirac brought a new understanding of the vacuum as an infinite energy, as we conceive it now.

He predicted the existence of anti-matter back in 1928, with his famous Dirac Equation, that was the first bridge between quantum physics and relativity theory.

A very small rotation with
$\theta \sim 0$ can be written:

(1.30)

25 01 2020

$$\tilde{x} \simeq x + \theta y + O(\theta^2)$$
$$\tilde{y} \simeq y - \theta x + O(\theta^2)$$

In this infinitesimal limit, the rotation matrix $R(\theta')$ can be written in terms of a matrix r

$$R(\theta) \simeq I + \theta r + \dots,$$
$$r = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix} \qquad (1.31)$$

Obs: Using of rotations preserve the Euclidean metric with Gyrocommutative Gyrogroups,
I will be able to develop a new glimpse.

Curvature of Plane Curves.png

Osculating → Osculate

Verb:

(of a curve or surface) touch (another curve or surface) so as to have a common tangent at the point of contact.

Should the students be asked to sketch the osculating circle to a given curve at a given point, and then notice that as the point of contact changes, the radius of the circle is inversely proportional to the measure of curvature?

If seven points on a twisted cubic be joined, two and two, by twenty-one lines, then any seven planes that contain these 21 lines will osculate a second cubic curve.

Chapter 8

The Curvature of Space

Curvature and Intrinsic Geometry of a Surface in the Works of Euler

By the *curvature* of a curve at a point we mean the limit of the ratio of the angle $\Delta\alpha$ between the tangents at the endpoints of an arc to the length Δs of that arc as the latter contracts to the point; that is, the limit

$$k = \frac{d\alpha}{ds} = \lim_{\Delta s \to 0} \frac{\Delta\alpha}{\Delta s}. \tag{8.1}$$

k is also the reciprocal of the *radius of curvature* at the point in question, that is, the radius of the osculating circle at that point. (The osculating circle at a point P of a curve is defined as the limit of circles determined by three points on the curve as they tend to P.) The concepts of the curvature of a curve and of the osculating (literally "kissing," from the Latin *osculans*) circle were already known to Leibniz.[1] Leibniz also suggested the possibility of characterizing the curvature of a surface by means of an osculating sphere.[2]

Euler characterized the curvature of a surface in his *Investigations of the curvature of surfaces* (Recherches sur la courbure des surfaces. Berlin, 1767) *[176, vol. 28, pp. 1–22]*. Euler called a normal section of a surface $z = f(x, y)$ perpendicular to the xOy plane a *principal section*. By varying the angle φ between a normal section and the principal section Euler found that at each point of the surface there is a maximal radius of curvature f and a minimal radius of curvature g, that their planes are perpendicular to one another, and

---

[1] Leibniz first considered osculation of curves—in particular, osculation of curves and circles—in his *New reflections on the nature of the angles of tangency and osculation and their use in mathematical practice to replace complex figures with simpler ones* (Meditatio nova de natura Anguli contactus et osculi, horumque usu in practica Mathesi ad figuras faciliores succedaneas difficilioribus substituendas. Leipzig 1686) *[312, v. 7, pp. 326–329]*.

[2] In a letter to Johann Bernoulli, dated July 29, 1698.

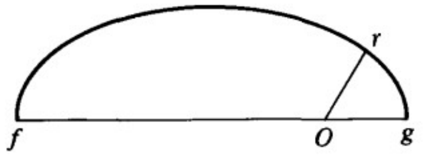

Figure 101

that the connection between an arbitrary radius of curvature $r = r(\varphi)$ and the radii of curvature f and g is given by

$$r = \frac{2fg}{f + g - (f - g)\cos 2\varphi}.$$

Euler writes:

> For a simple derivation of this formula we join the maximal and minimal osculating radii by putting $Of = f$ and $Og = g$ and describe on fg a semi-ellipse with one focus at O (Figure 101). Then for the section MN one must take the angle fOr, doubled with respect to the angle EZM, and the line Oz will be equal to the osculating radius for the section MN. Thus drawing conclusions about the curvature of surfaces, at first glance a matter of great complexity, reduces for each element to the determination of two osculating radii one of which is maximal and the other minimal for that element; these two things entirely determine the nature of the curvature, and we obtain the curvature of all possible sections perpendicular to the given element *[176, vol. 28, p. 21]*.

In 1837 Charles Dupin (1784 1873) *[157, p. 109]* modified Euler's formula to read

$$\frac{1}{r} = \frac{1}{f}\cos^2 \varphi + \frac{1}{g}\sin^2 \varphi.$$

In this paper *On solids whose surfaces can be developed onto a plane* (De solidis quarum superficiem in planum explicare licet. Petersburg, 1772) *[176, vol. 28, pp. 161–186]* Euler introduced the concept of a *developable surface*, that is, a surface that can be applied to a plane without folding or tearing, and proved the fundamental theorem that such a surface is a cylinder, or a cone, or a surface formed by the tangents to a space curve. His point of departure was that on such a surface an infinitesimal triangle must be congruent to the corresponding triangle in the plane to which the surface is applied. Further, he introduced on the surface curvilinear coordinates t, u equal to the rectangular coordinates of the corresponding points of the plane and, denoting the partial derivatives $\partial x/\partial t$, $\partial y/\partial t$, $\partial z/\partial t$ by l, m, n, and $\partial x/\partial u$, $\partial y/\partial u$, $\partial z/\partial u$ by λ, μ, ν, set down the developability conditions in the form $l^2 + m^2 + n^2 = 1, \lambda^2 + \mu^2 + \nu^2 = 1, l\lambda + m\mu + n\nu = 0$, that is, as the requirements of unicity and perpendicularity of the partial derivatives with respect to t and u of the radius vector of a point of the surface. An equivalent form of this condition is that the square of an arc element of a curve on a developable surface equals the sum of the squares of the differentials of the coordinates,

$$ds^2 = dt^2 + du^2,$$

that is, the arc element of a developable surface coincides with the arc element of a plane.

In a note published only in 1862 *[176, vol. 29, pp. 437–440]* Euler also established the general conditions of applicability of a surface to other surfaces. These results of Euler pertain to the so-called *intrinsic geometry of a surface*, that is, the study of properties of a surface that are unchanged when the surface is bent.

Euler's work on *geodesics* also pertains to the intrinsic geometry of surfaces. A *geodesic* is the shortest of all curves on a surface joining two of its points (in the plane the geodesics are straight lines and on a sphere they are great circles).[3]

The problem of finding geodesics on a surface was first posed in 1697 by Johann Bernoulli (1667–1748). Shortly after that, Johann Bernoulli wrote a letter to l'Hospital to the effect that he had found the general differential equation of geodesics. This result was published only in 1742 *[50, p. 364]*. Jacob Bernoulli (1654–1705) showed in 1698 that when cylindrical and conical surfaces are applied to planes, their geodesics go over into straight lines.

Euler was the first to publish the differential equation of geodesics. He did this in the paper *On the shortest curve on an arbitrary surface joining two arbitrary points* (De linea brevissima in superficie quacumque duo quaelibet puncta jungente. Petersburg, 1732) *[176, v. 25, pp. 1–12]*. Euler's equation was

$$\frac{Qddx + Pddy}{Qdx + Pdx} = \frac{dxddx + dyddy}{dt^2 + dx^2 + dy^2},$$

where t, x, y are rectangular coordinates in three-dimensional space, and the functions P and Q are determined from the differential equation of the surface $Pdx = Qdy + Rdt$. Euler returned to the problem of geodesics many times. In the second volume of his *Mechanics* (Mechanica. Petersburg) *[177, v. 2, p. 426]* he showed that, "in the absence of forces," the path of a point on a surface is a geodesic (an assumption used earlier by Bernoulli). In this connection, Euler showed that the *principal normal of a geodesic* (a straight line in the osculating plane of that curve passing through the point of contact and perpendicular to the tangent) always coincides with the normal to the surface.

---

[3] Many of Euler's papers deal with the determination of geodesics. The first was published in 1728 *[176, vol. 25, pp. 1–12]*, and the last was published posthumously *[176, vol. 25, pp. 269–279]*. Euler called geodesics *shortest curves*. The term *geodesic* first appeared in Laplace's *Celestial Mechanics* (Paris, 1799). Later it was applied to all quadrics. After the appearance of Liouville's paper (1814) it was applied to all surfaces.

We note that in the cartography paper *On the representation of the surface of a sphere in the plane* Euler compared the arc length elements of the plane and the sphere and proved the impossibility of an isometric mapping of a sphere to a plane. Also, he posed the question about the three mappings of the sphere to the plane that are of greatest importance in cartography, namely, the mapping in which the meridians and parallels are mapped onto an orthogonal system of lines, the mapping that preserves angles between curves (conformal mapping), and the mapping that preserves areas (equiareal mapping).

Independently of Euler, Monge considered developable surfaces in his *Memoir on evolutes, radii of curvature and various kinds of inflection of curves with twofold curvature* (Mémoire sur les développées, des rayons de courbure et les differents genres d'inflexion des courbes à double courbure. Paris, 1785) *[374]*. We note that Monge's book *Applications of analysis to geometry* (Applications de l'analyse à la géométrie. Paris, 1807) *[373]* contained the first systematic exposition of the theory of surfaces.

Intrinsic Geometry of Surfaces in the Work of Gauss

The general theory of the intrinsic geometry of a surface was formulated by Carl Friedrich Gauss in his *General investigations of curved surfaces* (Disquisitiones generales circa superficies curvas. Göttingen, 1828) *[196, vol. 4, pp. 217–258]*. Gauss's paper was the result of the assignment, given to him in 1820, to produce a cartographic survey of the kingdom of Hanover. This assignment made him reflect on problems of geodesy. In turn, this brought him to the theory of surfaces.

Gauss's theory unified the surface theories of Euler and Monge and the theory of quadratic forms developed by him in his *Arithmetical investigations* (Disquisitiones arithmeticae. Göttingen, 1801) *[196, vol. 1]*. In *Investigations of curved surfaces* Gauss introduced curvilinear coordinates p, q of points of the surface and defined the functions

$$a = \frac{dx}{dp}, \qquad b = \frac{dy}{dp}, \qquad c = \frac{dz}{dp}, \qquad a' = \frac{dx}{dq}, \qquad b' = \frac{dy}{dq},$$

$$c' = \frac{dz}{dq}; \qquad bc' - cb' = A, \qquad ca' - ac' = B', \qquad ab' - ba' = C;$$

$$\frac{ddx}{dp^2} = \alpha, \qquad \frac{ddx}{dpdq} = \beta, \qquad \frac{ddx}{dq^2} = \gamma, \qquad \frac{ddy}{dp^2} = \alpha',$$

$$\frac{ddy}{dpdq} = \beta', \qquad \frac{ddy}{dq^2} = \gamma', \qquad \frac{ddz}{dp^2} = \alpha'', \qquad \frac{ddz}{dpdq} = \beta'', \qquad \frac{ddz}{dq^2} = \gamma''.$$

In modern terms, the vectors $\{a, b, c\}$ and $\{a', b', c'\}$ are the partial derivatives of the radius vector of a point on the surface with respect to p and q

(Gauss denoted ordinary and partial derivatives the same way); the vector $\{A, B, C\}$ is the cross product of $\{a, b, c\}$ and $\{a', b', c'\}$ and its direction is that of the normal to the surface; and $\{\alpha, \beta, \gamma\}$, $\{\alpha', \beta', \gamma'\}$, and $\{\alpha'', \beta'', \gamma''\}$ are the second partial derivatives of the radius vector of a point on the surface with respect to p and q.

Further, Gauss introduced the quadratic forms

$$ds^2 = Edp^2 + 2Fdpdq + Gdq^2$$

and

$$Ddp^2 + D'dpdq + D''dq^2,$$

where

$$aa + bb + cc = E, \quad aa' + bb' + cc' = F, \quad a'a' + b'b' + c'c' = G,$$

$$A\alpha + B\beta + C\gamma = D, \quad A\alpha' + B\beta' + C\gamma' = D', \quad A\alpha'' + B\beta'' + C\gamma'' = D''.$$

The first of these forms, the so-called first fundamental form, gives the square of an arc length element of the surface, that is, of an element of length of an arc of a curve on the surface, and the second differs from the modern second fundamental form only by the multiplier $AA + BB + CC = EG - FF$.

Gauss introduced the all-important concept of "measure of curvature" now known as the *Gaussian curvature* of a surface. Making use of the spherical image of the surface, that is, the mapping that associates to a point P on the surface, a point P' on the unit sphere, such that the radius OP' is parallel to the normal to the surface at P (in modern terms, the end of the unit normal to the surface with beginning at a fixed point), Gauss defined the concepts of total curvature and "measure of curvature" as follows:

> We shall say that a part of a curved surface bounded by a given contour has *total curvature* given by the area of the corresponding figure on the surface of the sphere. One must draw a clear distinction between the total curvature and a kind of specific curvature that we shall call the *measure of curvature*. The latter pertains to a point on the surface and is the fraction obtained by dividing the total curvature of an element of the surface adjacent to the point by the area of that element, and thus gives the ratio of corresponding infinitesimal areas on the sphere and on the curved surface. We hope that our subsequent exposition will fully explain the utility of these new concepts" *[196, vol. 4, p. 226]*.

Gauss goes on to show that

> the "measure of curvature" at a point of the surface is equal to a fraction whose numerator is 1 and whose denominator is the product of the two principal curvatures of the normal sections.
>
> It is clear that the measure of curvature is positive for convex-convex or concave-concave surfaces (this is a trivial distinction) and negative for convex-concave ones. If the surface is made up of parts of both

kinds, then on their boundary the measure of curvature must vanish *[196, vol. 4, pp. 231]*.

Then Gauss obtains further expressions for the "measure of curvature" of which the most important are the expression of the "measure of curvature" k in terms of the coefficients of his two forms,

$$k = \frac{DD'' - D'D'}{EG - FF},$$

and the expression in terms of the coefficients of the first form alone and their derivatives with respect to p and q:

$$\begin{aligned} 4(EG - FF)^2 k = {} & E\left(\frac{dE}{dq}\frac{dG}{dq} - 2\frac{dF}{dp}\frac{dG}{dq} + \left(\frac{dG}{dp}\right)^2\right) + \\ & + F\left(\frac{dE}{dp}\frac{dG}{dq} - \frac{dE}{dq}\frac{dG}{dp} - 2\frac{dE}{dq}\frac{dF}{dq} + \frac{dF}{dp}\frac{dF}{dq} - \right. \\ & \left. - 2\frac{dF}{dp}\frac{dG}{dp}\right) + G\left(\frac{dE}{dp}\frac{dG}{dp} - \frac{dE}{dp}\frac{dF}{dq} + \left(\frac{dE}{dq}\right)^2\right) - \\ & - 2(EG - FF)\left(\frac{ddE}{dq^2} - 2\frac{ddF}{dpdq} + \frac{ddG}{dp^2}\right). \end{aligned}$$

In connection with the last formula Gauss makes the following comment:

> The formula in the last section leads, of itself, to the following remarkable
>
> *Theorem*. If a curved surface is applied to any other surface then the measure of curvature at each of its points remains unchanged.
>
> Also, it is clear that every finite part of a curved surface will, after application to another surface, retain its total curvature.
>
> The special case to which geometers have until now limited their investigations is the case of surfaces applicable to a plane. Our theory readily shows that the measure of curvature of such surfaces at any point is zero. . . .
>
> What we have set forth in the previous section involves a special approach to the investigation of surfaces worthy of the close attention of geometers. Namely, when a surface is regarded not as the boundary of a solid but as a solid with one vanishing dimension, flexible but not stretchable, then the properties of the surface are partly dependent on the form to which it has been reduced and in which it is being studied, and partly independent [of it in the sense that] they remain invariant regardless of its form under bending. The latter properties, whose investigation opens a new and fruitful area of geometry, include the measure of curvature and total curvature as defined by us. They also include the study of geodesic curves, as well as many other matters to be discussed in the sequel. When this approach is adopted, then the plane, and surfaces applicable to a plane, such as cylindrical and conical surfaces,

> are regarded as essentially the same, and the general method of characterizing a surface studied in this manner is based on the formula $\sqrt{Edp^2 + 2Fdpdq + Gdq^2}$ that expresses the connection of the line element of the surface with two variables p and q *[196, vol. 4, pp. 237–238]*.

Gauss is defining the *intrinsic geometry* of a surface invariant under bending and application to another surface. Some of the properties studied in intrinsic geometry are the lengths of curves on the surface, the angles between curves, and what Gauss calls *geodesic curves*, that is, geodesics. Gauss's theorem, called by him a *remarkable theorem* (Theorema Egregium), asserts that the *measure of curvature* is a property that belongs to intrinsic geometry.

Further, Gauss considers the total curvature of a geodesic triangle (that is, a triangle whose sides are arcs of geodesics). The total curvature of such a triangle is given by $\int k d\sigma$, where $d\sigma$ is an element of the surface of the triangle. He finds that

> the total curvature of a triangle is equal to the part of the spherical surface that corresponds to the triangle taken with a plus or minus sign according as the surface on which the triangle lies is concave-concave or concave-convex; as the unit of area we take a square with side one (the radius of the sphere); then the area of the sphere is 4π. It follows that the [surface of the] part of the sphere corresponding to the triangle is to the surface of the sphere as $\pm(A + B + C - \pi)$ to 4π. This theorem, that undoubtedly belongs with the most beautiful theorems of the theory of surfaces, can be stated as follows:
>
> *The excess above* 180° *of the sum of the angles of a triangle formed by geodesic curves on a curved concave-concave surface and the defect below* 180° *of the sum of the angles of a triangle formed by geodesic curves on a concave-convex surface are each measured by the area of the part of the spherical surface that corresponds to the given triangle via normal directions, provided that the whole surface* (*of the sphere*) *is taken as* 720 *degrees [196, vol. 4, pp. 245–246]*.

This theorem of Gauss implies that the Gaussian curvature at a point is equal to the limit of the ratio of the angular excess $A + B + C - \pi$ of a geodesic triangle ABC on the surface to its area as the triangle shrinks to the given point.

Minding's Theory of Surfaces of Constant Curvature

Gauss's work on the intrinsic geometry of surfaces was continued by Ferdinand Minding (1806–1885), who worked in Dorpat (now Tartu). In his *Remark on the development of curved lines on surfaces* (Bemerkung über die Abwickelung krummer Linien auf Flächen. Berlin, 1830) *[366]*, Minding introduced the fundamental concept of *geodesic curvature* of a curve on a surface, defined as the limit of the ratio of the angle between tangent geodesics at the endpoints of an arc of the curve to the arc length as the arc shrinks to a point, and showed that this limit is invariant under bending. In the paper *How to decide whether two surfaces are mutually applicable; including remarks on surfaces of constant measure of curvature* (Wie sich entscheiden lässt ob zwei gegebene krumme Flächen auf einander abwickelbar sind, nebst Bemerkungen über die Flächen von unveränderlicher Krümmungsweise. Berlin, 1839) *[367]* Minding expressed the line element of a surface with constant "measure of curvature" as

$$ds^2 = dp^2 + \left(\frac{1}{\sqrt{k}} \sin p\sqrt{k}\right)^2 dq^2$$

and concluded that

> two surfaces of equal constant measure of curvature can be applied to each other in infinitely many ways, since any two points of one can be associated to two arbitrary points of the other provided that the lengths of the shortest curves between the points of each pair are equal. This implies the following consequences:
>
> Every surface whose measure of curvature is zero [results from] the bending of a plane—this much is well known.
>
> Every surface whose measure of curvature (k) is constant and positive can be applied to a sphere of radius $1/\sqrt{k}$ *[367, pp. 375–376]*.

Further, Minding discovered helical surfaces and, in particular, surfaces of constant negative curvature. One such surface is given by the parametric equations

$$r = \sqrt{x^2 + y^2} = \frac{1}{\cosh\varphi}, \qquad z = \varphi - \tanh\varphi.$$

Minding comments that

> This surface is the result of rotating a curve like ... *CBE* ... (Figure 102) about the zz-axis which it approaches asymptotically *[367, p. 380]*.

The curve *CBE*, which is characterized by the constancy of the length of the segment of the tangent between the point of tangency and the zz-axis, is called a *tractrix*, and the surface of revolution referred to by Minding is called a *pseudosphere*.

In *Contributions to the theory of shortest curves on curved surfaces* (Beiträge zur Theorie der kürzesten Linien auf krummen Flächen. Berlin, 1840) *[368]* Minding established the trigonometric relations in geodesic triangles on such surfaces and noted that these formulas could be obtained from the corresponding formulas of spherical geometry on a sphere of radius r by multiplying r by the complex number i.

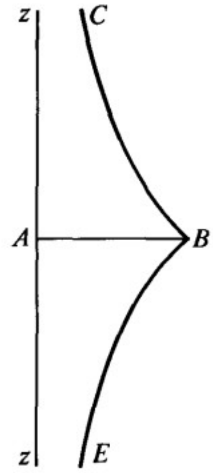

Figure 102

Interpretation of the Lobačevskian Plane on a Pseudosphere

In spite of the fact that Minding's paper appeared in the same journal (*Crelle's*) as Lobačevskiĭ's *Imaginary geometry*, neither of them noticed that the trigonometric formulas of the hyperbolic plane coincide with the trigonometric formulas of a surface of constant negative curvature.[4]

The person who *did* notice the sameness of these formulas was E. Beltrami, who considered the matter in *An attempt at an interpretation of non-Euclidean geometry [42, pp. 374–405]*. Beltrami constructed a model of the hyperbolic plane in a circle and associated to the points of the hyperbolic plane of curvature $-1/R^2$ the coordinates u, v of the corresponding points of the circle. He found that in this coordinate system the line element is given by

$$ds^2 = R^2\frac{(a^2-u^2)du^2+2uv\,du\,dv+(a^2-v^2)dv^2}{a^2-u^2-v^2}.$$

Beltrami computed the total curvature of a surface with this line element and noticed that the Gaussian curvature of the hyperbolic plane is everywhere equal to the same number $-1/R^2$; that is, the hyperbolic plane can be viewed as a surface of constant negative curvature.

Thus, speaking of surfaces of constant negative curvature, Beltrami concluded that

---

[4] Lobačevskiĭ's paper appeared in vol. 17 (1837) of *Crelle's Journal* and Minding's paper in vol. 20 (1840) of that journal. B. L. Laptev *[265, p. 20]* explains that Lobačevskiĭ did not borrow the latter volume from the library of Kazan University.

> the theorems of non-Euclidean planimetry apply to them. Further, most of these theorems can be thought of concretely only if we refer them to such surfaces and not to the plane *[42, p. 381]*.

That is why Beltrami suggested that all surfaces of constant negative curvature be called *pseudospherical* surfaces.

Beltrami also showed that each of the sheets of Minding's pseudosphere is isometric to the part of the hyperbolic plane enclosed between two parallel lines and a horocycle perpendicular to them. He also found parts of the hyperbolic plane isometric to other surfaces of revolution of constant negative curvature determined by Minding.

Riemannian Geometry

In the paper *On the hypotheses which lie at the foundations of geometry [122, pp. 55–71]* Riemann introduced a notion of an n-*ply extended manifold* broader than either of the similar notions introduced by Grassmann and Schläfli. After defining this manifold Riemann posed the question of the "measure-relations of which such a manifold is capable" and of the possibility "to express geometrically the calculated results." After noting that the foundations of these two parts of the question are established in Gauss's celebrated memoir *Disquisitiones generales circa superficies curvas [122, pp. 59–60]*, Riemann writes:

> Position-fixing being reduced to quantity-fixings, and the position of a point in the n-ply extended manifold being consequently expressed by means of n variables $x_1, x_2, x_3, \ldots x_n$, the determination of a line comes to the giving of these quantities as functions of one variable. The problem consists then in establishing a mathematical expression for the length of a line, and to this end we must consider the quantities x as expressible in terms of certain units. I shall treat this problem only under certain restrictions, and I shall confine myself in the first place to lines in which the ratios of the increments dx of the respective variables vary continuously. We may then conceive these lines broken up into elements, within which the ratios of the quantities dx may be regarded as constant; and the problem is then reduced to establishing for each point a general expression for the linear element ds starting from that point, an expression which will thus contain the quantities x and the quantities dx. I shall suppose, secondly, that the length of the linear element, to the first order, is unaltered when all the points of this element undergo the same infinitesimal displacement, which implies at the same time that if all the quantities dx are increased in the same ratio, the linear element will vary also in the same ratio. On these suppositions, the linear element may be any homogeneous function of the first degree of the quantities

> dx, which is unchanged when we change the signs of all the dx, and in which the arbitrary constants are continuous functions of the quantities x. To find the simplest cases, I shall seek first an expression for manifoldness of $n - 1$ dimensions which are everywhere equidistant from the origin of the linear element; that is, I shall seek a continuous function of position whose values distinguish them from one another. In going outwords from the origin, this must either increase in all directions or decrease in all directions; I assume that it increases in all directions, and therefore has a minimum at that point. If, then, the first and second differential coefficients of this function are finite, its first differential must vanish, and the second differential cannot become negative; I assume that it is always positive. This differential expression, then, of the second order remains constant when ds remains constant, and increases in the duplicate ratio when the dx, and therefore also ds, increase in the same ratio; it must therefore be ds^2 multiplied by a constant, and consequently ds is the square root of an always positive integral homogeneous function of the second order of the quantities dx, in which the coefficients are continuous functions of the quantities x. For Space, when the position of points is expressed by rectilinear co-ordinates, $ds = \sqrt{\sum (dx)^2}$ *[122, pp. 60–61]*.

(In Clifford's translation we changed his term n-*dimensional manifoldedness* to Riemann's n-ply extended manifold). By *Space* Riemann means three-dimensional Euclidean space. After considering various possible cases of the dependence of ds on the differentials dx, Riemann restricts himself to "manifolds for which the line element is given by the square root of a differential expression of the second degree," that is,

$$ds^2 = \sum_i \sum_j g_{ij} dx_i dx_j, \tag{8.2}$$

where $g_{ij} = g_{ji}$ are functions of the variables x_i.

Riemann's requirement guarantees that his n-dimensional space is locally Euclidean. The quadratic form (8.2) is assumed to be positive definite, that is, for all dx_i not simultaneously zero $ds^2 > 0$. Hence each pair of points with infinitesimally different coordinates x_i and $x_i + dx_i$ are a definite distance ds apart. By integrating this distance along different lines we determine their length. Among the different lines we can find the shortest (geodesic) lines $x_i = x_i(t)$ that are solutions of the differential equations

$$\frac{d^2 x_i}{ds^2} + \sum_j \sum_k \Gamma^i_{jk} \frac{dx_j}{ds} \frac{dx_k}{ds} = 0, \tag{8.3}$$

where the Γ^i_{jk} are point functions expressed in terms of the coefficients g_{ij} by means of the relations

$$\sum_i g_{il} \Gamma^l_{jk} = \frac{1}{2}\left(\frac{\partial g_{lk}}{\partial x_j} + \frac{\partial g_{il}}{\partial x_k} - \frac{\partial g_{jk}}{\partial x_l}\right). \tag{8.4}$$

The spaces defined in this way are called *Riemannian spaces*. Surfaces in ordinary space are particular Riemannian spaces for $n = 2$; in this case, an instance of a geometry of the kind defined by Riemann is the so-called intrinsic geometry of a surface, elaborated by Gauss in the work *General investigations of curved surfaces* alluded to by Riemann. Clearly, Euclidean space is a special case of a Riemannian space whose geodesics are Euclidean straight lines.

A more general example of a Riemannian space is a hypersurface in $(n + 1)$-dimensional Euclidean space and, in particular, a hypersphere in this space. The geodesics of a hypersphere are its great circles—sections by two-dimensional planes passing through its center. Elliptic space, obtained from a sphere by identifying antipodal points, and Lobačevskian space are also examples of Riemannian spaces.

One of the most important concepts of Riemannian geometry is the *curvature of a space*. The curvature is defined at every point in every two-dimensional direction passing through this point. To determine the curvature of a Riemannian space at a point one considers a geodesic triangle, that is, a curvilinear triangle bounded by arcs of three geodesics, one of whose vertices is at the given point and two of whose sides issuing from this vertex are tangent to the given two-dimensional direction. For this triangle ABC one computes the angular excess $A + B + C - \pi$ (as defined, the angular excess can be positive, zero, or negative), as well as the area, and forms the ratio of the angular excess over the area of the triangle. Now one lets the triangle shrink to the given vertex but insists that the sides issuing from it continue to be tangent to the given two-dimensional direction. It is obvious that in this limiting process the area of the geodesic triangle tends to zero. Since the geometry of the two-dimensional surface in which the passage to the limit is taking place is locally Euclidean and the angular excess of a Euclidean plane is zero, it follows that the angular excess of the geodesic triangle also tends to zero. But the ratio of the angular excess over the area of the triangle tends to a definite limit called the *curvature of the Riemannian space* at the given point in the given two-dimensional direction.

The curvature of n-dimensional Euclidean space, regarded as a special case of a Riemannian space, is equal to zero at all of its points; that is why a Euclidean space is called Riemannian space of *zero curvature* and Riemannian spaces different from Euclidean space are called *curved spaces*.

Riemann defined the curvature of his space in the following manner; in a neighborhood of the point at which he wanted to define curvature he introduced coordinates x_i equal to zero at the point and such that distance s of points in the neighborhood of this point was given in terms of the coordinates by the relation $s^2 = \sum_i x_i^2$. Riemann writes:

> When we introduce these quantities, the square of the line-element is Σdx^2 for infinitesimal values of the x, but the term of next order in it is equal to a homogeneous function of the second order of the $\frac{1}{2}n(n - 1)$ quantities $(x_1 dx_2 - x_2 dx_1)$, $(x_1 dx_3 - x_3 dx_1)$ ... an infinitesimal, there-

> fore, of the fourth order; so that we obtain a finite quantity on dividing this by the square of the infinitesimal triangle, whose vertices are $(0,0,0,\dots)$, $(x_1,x_2,x_3,\dots)$, $(dx_1,dx_2,dx_3,\dots)$. This quantity retains the same value so long as the x and the dx are included in the same binary linear form, or so long as the two geodesics from 0 to x and from 0 to dx remain in the same surface-element; it depends therefore only on place and direction. It is obviously zero when the manifold represented is flat, i.e., when the squared line-element is reducible to $\Sigma\, dr^2$, and may therefore be regarded as the measure of the deviation of the manifold from flatness at the given point in the given surface-direction. Multiplied by $-\frac{3}{4}$ it becomes equal to the quantity which Privy Councillor Gauss has called the total curvature of a surface *[122, pp. 62–63]*.

In view of Riemann's choice of coordinates, the expansion of the square of the line element ds^2 in the neighborhood of the point he considered is given by

$$ds^2 = \sum_i dx_i^2 + \sum_i \sum_j \sum_k c_{ij,k} x_k dx_i dx_j + \sum_i \sum_j \sum_k \sum_l c_{ij,kl} x_k x_l dx_i dx_j + \dots,$$

where $c_{ij,k}$ and $2c_{ij,kl}$ are the values of the derivatives $\dfrac{\partial g_{ij}}{\partial x_k}$ and $\dfrac{\partial^2 g_{ij}}{\partial x_k \partial x_l}$ at the point under consideration. In the first place, Riemann notes that there is no linear term in this expansion, that is, that $c_{ij,k} = 0$. The reason for this is that his coordinate lines are geodesics satisfying equation (8.3), where the coefficients Γ^i_{jk} are expressed in terms of g_{ij} by formulas (8.4). Then Riemann claims that the second-order terms in the expansion of ds^2 form a quadratic form in the $x_i dx_j - x_j dx_i$. If for the sake of uniformity we denote the infinitesimals x_i by δx_i then the latter magnitudes can be written as $\Delta x_{ij} = \delta x_i dx_j - \delta x_j dx_i$. These quantities determine a parallelogram on the vectors $\{dx_i\}$ and $\{\delta x_i\}$, so that the quadratic terms in the expansion can be written as

$$\Delta\sigma^2 = \sum_i \sum_j \sum_k \sum_l R_{ij,kl} \Delta x_{ij} \Delta x_{kl}.$$

The quantity obtained by Riemann, which he calls the fraction from the division of $\Delta\sigma^2$ by the area of the triangle on the vectors $\{dx_i\}$ and $\{\delta x_i\}$, is actually the limit of this fraction as the triangle in question shrinks to the point. Nowadays, a quantity proportional to that defined by Riemann (with a proportionality factor such that in the case of a surface it coincides with the Gaussian curvature) is called the *Riemannian curvature* of the space at a given point in a given two-dimensional direction. Riemann goes on to give our earlier geometric interpretation of the curvature he defined. He notes that on surfaces in ordinary space "the difference between the angle sum of an infinitesimal triangle and two right angles is proportional to the area of the triangle" and writes:

> To give an intelligible meaning to the curvature of an *n*-fold manifold at a given point and in a given surface-direction through it, we must start from the fact that a geodesic proceeding from a point is entirely determined when its initial direction is given. According to this we obtain a determinate surface if we prolong all the geodesics proceeding from the given point and lying initially in the given surface-direction; this surface has at the given point a definite curvature, which is also the curvature of the *n*-fold continuum at the given point in the given surface-direction *[122, p. 64]*.

Riemannian geometry was applied by Riemann to the theory of differential equations in *A mathematical work containing an attempt to answer the question proposed by the most illustrious Paris Academy: To determine the heat state of a homogeneous solid so that a system of isothermal curves given at a certain moment in time remains a system of isothermal curves at an arbitrary moment in time and so that the temperature at a point is expressed as a function of time and two more independent variables* (Commentatio mathematica qua respondere tentatur questioni ab Ill$^{\text{ma}}$ Academia Parisensi proposita: Trouver quel doit être l'état calorifique d'un corps solide homogène pour qu'une système de courbes isothermes, à un instant donné, restent isothermes après un temps quelconque, de telle sorte que la température d'un point puisse s'exprimer en fonction du temps et de deux autres variables indépendentes), written in 1861 and published in his collected works (Leipzig, 1876) *[454, pp. 391–404]*. In this paper Riemann solved the problem of reducing the differential equation of heat conduction

$$\sum_i \frac{\partial}{\partial s_i}\left(\sum_j b_{ij}\frac{\partial u}{\partial s_j}\right) = h\frac{\partial u}{\partial t}$$

to simplest form— a problem equivalent to that of transforming the quadratic form $\sum_i \sum_j b_{ij} ds_i ds_j$ to a sum of squares. Riemann found that this can be done if and only if the expression

$$K = \frac{1}{2}\frac{\sum\limits_i \sum\limits_j \sum\limits_k \sum\limits_l (ij, kl)(ds_i\delta s_j - ds_j\delta s_i)(ds_k\delta s_l - ds_l\delta s_k)}{\left(\sum\limits_i \sum\limits_j b_{ij} ds_i ds_j\right)\left(\sum\limits_i \sum\limits_j b_{ij}\delta s_i\delta s_j\right) - \left(\sum\limits_i \sum\limits_j b_{ij} ds_i\delta s_j\right)^2},$$

that is invariant under a change of variables, vanishes. Of this expression, he denotes by (111), Riemann says:

> The expression $\sqrt{\sum_i \sum_j b_{ij} ds_i ds_j}$ can be regarded as a line element of an *n*-tuply extended space that is outside the bounds of our intuition. If we lead from point $(s_1, s_2, \ldots, s_n)$ in this space all possible geodesics whose initial directions are characterized by the ratios $\alpha ds_1 + \beta\delta s_1 : \alpha ds_2 + \beta\delta s_2 : \ldots : \alpha ds_n + \beta\delta s_n$ (where α and β are arbitrary quantities) then these lines form a certain surface which we can think of as located in the

> ordinary space of our intuition. Then expression (111) is the curvature of this surface at the point $(s_1, s_2, \ldots, s_n)$ *[454, p. 403]*.

The quantities (ij, kl), the so-called four-index Riemann symbols, are the same quantities that we denoted earlier by $R_{ij,kl}$. We note that the quantities $R_{ij,kl}$ can be expressed in terms of the coefficients g_{ij} and their derivatives, using the quantities Γ^i_{jk} (expressed in terms of the g_{ij} and their derivatives by formulas (8.4)), by means of the formula

$$R_{ij,kl} = \left(\frac{\partial \Gamma^h_{jk}}{\partial x_i} - \frac{\partial \Gamma^h_{ik}}{\partial x_j} + \Gamma^h_{ir}\Gamma^r_{jk} - \Gamma^h_{jr}\Gamma^r_{ik}\right) g_{hl}.$$

In the paper mentioned previously Riemann also used the quantities Γ^i_{jk} but denoted them as p_{ijk}.

Riemann's investigations were continued by Elwin Bruno Christoffel (1829–1900) in the paper *On the transformation of homogeneous differential expression of second degree* (Über die Transformation der homogenen Differentialausdrücke zweiten Grades, Berlin, 1869) *[114, vol. 1, pp. 368–377]*, in which he posed the question of the conditions under which the geometry determined by a form $\sum_i \sum_j g_{ij} dx_i dx_j$ coincides with the geometry determined by a form $\sum_i \sum_j h_{ij} dy_i dy_j$. Just as Riemann's intention was to develop Gauss's theory of surfaces, so Christoffel's intention was to generalize the problem of superposition of surfaces. Christoffel's necessary condition for the coincidence of geometries turned out to be the coincidence of the differential forms $\sum_i \sum_j \sum_k \sum_l R_{ij,kl} dx_i dx_k \delta x_j \delta x_l$, computed for the two given forms. Christoffel denoted the quantities Γ^i_{jk} by $\left\{ {jk \atop i} \right\}$ and the quantities $\sum_l g_{il} \Gamma^l_{jk}$ by $\left[{jk \atop i} \right]$. That is why these quantities are often called *Christoffel symbols of the first and second kind*, respectively.

Riemannian Spaces of Constant Curvature

After defining Riemannian spaces of variable curvature and noting that Euclidean spaces are spaces of zero curvature Riemann dwelled at length on spaces of constant nonzero curvature:

> Manifolds whose curvature is constantly zero may be treated as a special case of those whose curvature is constant. The common character of these continua whose curvature is constant may be also expressed thus, that figures may be moved in them without stretching. For clearly figures could not be arbitrarily shifted and turned round in them if the curvature at each point were not the same in all directions. On the other hand, however, the measure-relations of the manifold are entirely determined by the curvature; they are therefore exactly the same in all directions at one point as at another, and consequently the same constructions can be made from it: whence it follows that in aggregates with

> constant curvature figures may have any arbitrary position given them. The measure-relations of these manifolds depend only on the value of the curvature, and in relation to the analytic expression it may be remarked that if this value is denoted by α, the expression for the line-element may be written
>
> $$\frac{1}{1+\frac{1}{4}\alpha\sum x^2}\sqrt{\sum dx^2}$$
>
> *[122, p. 65].*

The latter expression generalizes the previously mentioned expression, obtained by Minding, of the line element of a surface of constant curvature in terms of its Gaussian curvature.

The simplest example of a Riemannian space of constant positive curvature is a sphere in $(n + 1)$-dimensional Euclidean space; the Riemannian curvature of a sphere of radius r, of any dimension, in all two-dimensional directions is equal to $1/r^2$, for the area of any spherical triangle is the product of r^2 and the angular excess of the triangle.

An example of an n-dimensional Riemannian space of constant negative curvature is n-dimensional Lobačevskian space, first defined by Beltrami in the paper *Fundamental theory of spaces of constant curvature* (Teoria fondamentale degli spazî di curvatura costante. Milan, 1869) *[42, pp. 406–429]* published in the same year as his previously discussed paper. This space can also be viewed as one of the sheets of a sphere of radius qi in $(n + 1)$-dimensional pseudo-Euclidean space. The Riemannian curvature of such a sphere in all two-dimensional directions is $-1/q^2$ since the area of an arbitrary spherical triangle on this sphere is the product of its angular defect by $-q^2$.

We wish to mention here a remarkable theorem of F. Schur established in the paper *On the connection between spaces of constant curvature and projective spaces* (Über dem Zusammenhang der Räume constanten Krümmungmasses mit den projectiven Räumen. Leipzig, 1886) *[517]* which asserts that, on a Riemannian manifold, the constancy of the Riemannian curvature in all two-dimensional directions at each point implies the constancy of the Riemannian curvature at all points. Schur's proof is purely geometric and is based on a projective mapping of the bundle of linear elements at one point onto a similar bundle at another point. An analytic proof of this result was given by Luigi Bianchi (1856–1928) in the paper *On four-index symbols and on Riemannian curvature* (Sui simboli a quatro indici e sulla curvatura di Riemann. Rome, 1902) *[56]*.

Elliptic Geometry

Another form of n-dimensional Riemannian space of constant positive curvature is a sphere in $(n + 1)$-dimensional Euclidean space with identified antipodal points called n-dimensional *elliptic space* or *non-Euclidean space of Riemann.* When $(n + 1)$-dimensional Euclidean space is completed to $(n + 1)$-dimensional projective space, pairs of antipodal points of a sphere in $(n + 1)$-dimensional Euclidean space are projected from its center onto the points of its plane at infinity. Since this plane is an n-dimensional projective space, elliptic space can be viewed as a metrized projective space. The details are as follows.

An arbitrary sphere of $(n + 1)$-dimensional Euclidean space is given by an equation of the form

$$A \sum_i x_i^2 + 2 \sum_i b_i x_i + c = 0,$$

which can be written in homogeneous coordinates as

$$A \sum_i x_i^2 + 2 \sum_i b_i x_i x_0 + c(x_0)^2 = 0.$$

The latter equation shows that our sphere intersects the plane at infinity, $x_0 = 0$, in the imaginary quadric $\sum_i x_i^2 = 0$. Hence an elliptic space can be described as a projective space with a given imaginary conic. The distance ω between two points X and Y of an elliptic space of curvature $1/r^2$ is connected with the angle φ between the corresponding diameters of the sphere by the relation $\omega = \varphi r$. On the other hand, Edmond Laguerre (1834–1886) showed in the paper *On the theory of foci* (Sur la theorie des foyers. Paris, 1853) *[298, vol. 2, pp. 6–15]* that the angle φ between two straight lines in Euclidean space can be expressed in terms of the cross ratio (ij, xy) of the straight lines x, y and two *isotropic straight lines* i, j, that is, imaginary lines of zero length that lie in the plane of x and y and pass through the point of intersection of x and y, by means of the relation

$$\varphi = \frac{1}{2i} \ln(ij, xy). \tag{8.5}$$

Since the imaginary lines i, j that join the center of the sphere to the points I, J of the imaginary quadric $\sum_i x_i^2 = 0$ in the plane at infinity are, in view of the equation of the quadric, isotropic, Laguerre's formula (8.5) yields an expression for the distance ω between points X, Y of elliptic space in terms of the cross ratio (IJ, XY) of these points and the two points of intersection of the straight line XY and the imaginary quadric:

$$\omega = \frac{r}{2i} \ln(IJ, XY). \tag{8.6}$$

An elliptic metric in the projective plane was defined in 1859 by Cayley in the *Sixth memoir upon quantics [103, vol. 2, pp. 561–592]*. An elliptic metric in space, and the term *elliptic geometry*, were introduced by Klein in 1871 in the paper *On the so-called non-Euclidean geometry [282, vol. 1, pp. 254–305]*, in which he wrote that

> The basis of a general projective metric in space is provided by an arbitrary *fundamental surface of the second order.*
>
> To define the distance between two points one joins them by a straight line. It intersects the fundamental surface in two new points that are in a definite cross ratio with the two given points. *The logarithm of this cross ratio multiplied by an arbitrary constant c yields what one should call the distance between the two given points [282, vol. 1, p. 300].*

Klein gave a similar definition of the angle between two planes (see p. 238). Further Klein wrote:

> By a *motion* is meant the totality of linear transformations that leave the fundamental surface invariant.
>
> By *spheres* one means quadric surfaces that meet the fundamental surface along a plane curve. The center of the sphere is the pole of the plane that contains the osculating curve....
>
> If the fundamental surface is *imaginary* then all straight lines have finite length and each pencil of planes has finite angle sum. *Elliptic* geometry comes under this case (provided that the constant c' in the definition of angles is taken as $\sqrt{-1}/2$, so that the sum of the angles in a pencil of planes is π).
>
> We do not investigate the case when the fundamental surface is *real* and *ruled* (like a hyperboloid of one sheet) for this case is no way connected with the three geometries (elliptic, hyperbolic, parabolic) considered here.
>
> Finally, if the fundamental surface is *real* and *nonruled* then for the interior points of the surface we obtain a metric that includes the metric of hyperbolic geometry provided that we again take the constant c' to be $\sqrt{-1}/2$.
>
> *Parabolic* geometry is included as a special case of the general metric; this case arises if the fundamental surface specializes (degenerates) into an imaginary conic section. The fundamental conic section of parabolic geometry is the so-called imaginary circle at infinity *[282, vol. 1, p. 301].*

Klein's *fundamental surface* is now called by Cayley's term *the absolute*. We note that Klein's *linear transformations* are collineations, his *hyperbolic geometry* is Lobačevskian geometry, and his *parabolic geometry* is Euclidean geometry; the *imaginary circle at infinity* is the imaginary circle $\sum_i x_i^2 = 0$ in the plane at infinity of Euclidean space that plays the role of the absolute of this space. Klein did not investigate the geometry of the exterior of an oval (nonruled) quadric and the geometry of a ruled quadric. The reason for this is that, unlike elliptic geometry and Lobačevskian geometry, the geometry of these spaces is locally not Euclidean but pseudo-Euclidean.

We also note that the only difference between formula (8.6) and formula (6.27) for Lobačevskian space is that in one case we have the pure imaginary constant r/i and in the other the real constant q.

Clifford Parallels and Surfaces

The geometry of elliptic space was significantly developed by William Kingdon Clifford (1845–1879) in his *Preliminary sketch of biquaternions* (London, 1879) *[122, pp. 181–200]*.

After defining elliptic, hyperbolic, and parabolic geometries whose absolutes are, respectively, an imaginary quadric, a real (oval) quadric, and an imaginary conic in a real plane, Clifford investigates *elliptic geometry*. After defining poles and polar planes and mutually polar straight lines with respect to an absolute and pointing out that two points that are polar conjugates with respect to the absolute "are a *quadrant* apart," that is, are $(\pi/2)r$ apart, or, if $r = 1$, are $\pi/2$ apart, Clifford notes that

> Through an arbitrary point can in general be drawn *one* line perpendicular to a given plane; namely, the line joining the point to the pole of the plane. If, however, the point *is* the pole of the plane, every line through it is perpendicular to the plane. Similarly, from a point not on the polar of a given line can be drawn one and only one perpendicular to the line; namely, the line through the point which meets the given line and its polar *[122, p. 192]*.

and further:

> *In general, two lines can be drawn so that each meets two given lines at right angles, and these are polars of one another*. One line may therefore be converted into another by rotation about two polar axes. These axes are determined as the lines which meet the two given lines and their polars. If we travel continuously along one of these lines and draw perpendiculars on the other, one of these axes determines the shortest distance between the lines, and the other the longest. If then these two are equal, the lines are equidistant along their whole length. Thus *there is a case of exception in which two lines and their polars belong to the same set of generators of a hyperboloid; the lines are then equidistant along their whole length, and meet the same two generators of one system of the absolute*. I shall use the word *parallel* to denote two lines so situated; and they shall be called *right* parallel or *left* parallel according as one is converted into the other by a right-handed or left-handed twist. Through an arbitrary point can be drawn one right parallel and one left parallel to a given line; the angle between them is twice the distance of the point from the line. There are many points of analogy between the *parallels* here defined and those of parabolic geometry. Thus, if a line meets two parallel lines, it makes equal angles with them; and a series of parallel lines meeting a given line constitute a ruled surface of zero curvature. The geometry of this surface is the same as that of a finite parallelogram whose opposite sides are regarded as identical *[122, pp. 192–193]*.

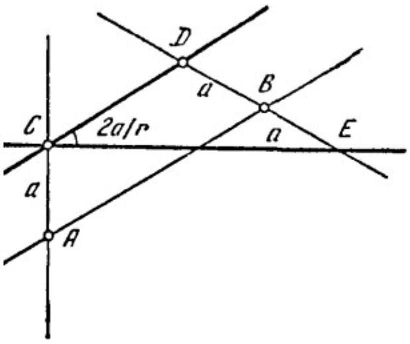

Figure 103

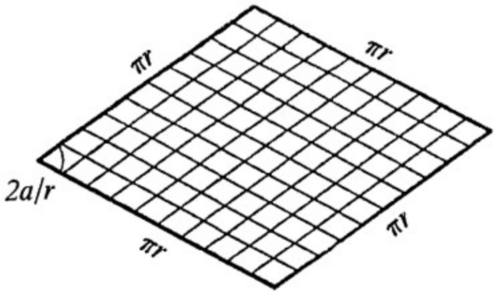

Figure 104

The parallels defined by Clifford are now called *paratactic straight lines*;[5] one must bear in mind that, unlike parallels in Euclidean (*parabolic*) geometry, Clifford parallels are skew straight lines. Figure 103 illustrates the construction of a right, CD, and left, CE, Clifford parallel through a point C to a straight line AB. From the point C one drops the perpendicular CA to the straight line AB and constructs its polar DBE. On the latter one lays off on either side of the point B segments BD and BE equal to the segment $CA = a$. The required parallels are the straight lines CD and CE; the angle DCE is measured in terms of the segment $DE = 2a$ and is equal to $2a/r$. The surface constructed by Clifford is now known as a *Clifford surface*. It is a ruled quadric obtained by rotating one of two paratactic straight lines about the other; its rectilinear generators in both families are paratactic to the axes; at the same time it is also a surface of revolution about the polar of the first axis. The geometry of a Clifford surface is Euclidean. Its area is finite and equal to $\pi^2 r^2 \sin 2a/r$, for it is isometric to a rhombus with sides πr and acute angle $2a/r$ (Figure 104) with sides in each pair of opposite sides glued together. To prove that the geometry of this surface is Euclidean it suffices to write down its parametric equations in homogeneous coordinates whose basis points are located on the axes of the surface,

$$x_0 = \cos\frac{a}{r}\cos u, \qquad x_1 = \cos\frac{a}{r}\sin u,$$

$$x_2 = \sin\frac{a}{r}\cos v, \qquad x_3 = \sin\frac{a}{r}\sin v,$$

and to compute the line element

$$ds^2 = \sum_i dx_i^2 = r^2\left(\cos^2\frac{a}{r}\,du^2 + \sin^2\frac{a}{r}\,dv^2\right).$$

---

[5] This term was introduced by E. Study in the paper *[568]*.

If in the latter we put

$$U = r\cos\frac{a}{r}\cdot u, \qquad V = r\sin\frac{a}{r}\cdot v,$$

then we have $ds^2 = dU^2 + dV^2$.

If one eliminates from the parametric equations of the Clifford surface the parameters u and v then one obtains its equation in the form

$$\sin^2\frac{a}{r}(x_0^2 + x_1^2) - \cos^2\frac{a}{r}(x_2^2 + x_3^2) = 0.$$

A Clifford surface is the simplest solution of the Clifford-Klein problem of finding spaces with a Euclidean metric that are not isometric to Euclidean space in the large.

Clifford's Idea of the Geometrization of Physics

W. K. Clifford was also interested in questions of the philosophy of space. In his philosophical work *Philosophy of pure science* (London, 1873) there are his famous words on Lobačevskian geometry!

> What Vesalius was to Galen, what Copernicus was to Ptolemy, that was Lobatchewsky to Euclid. There is, indeed, a somewhat instructive parallel between the last two cases. Copernicus and Lobatchewsky were both of Slavic origin. Each of them has brought about a revolution in scientific ideas so great that it can only be compared with that wrought by the other. And the reason of the transcendent importance of these two changes is that they are changes in the conception of the Cosmos *[123, vol. 1, p. 356]*.

What Clifford is saying here is that Lobačevskiĭ's discovery that Euclidean geometry is not the only conceivable geometry is just as revolutionary as Vesalius' shattering of the myth of the exclusive position of man in the animal kingdom and Copernicus' discovery that the Earth is just one of the planets.

Clifford expressed his interesting thoughts on space in his posthumously published *The Common sense of the exact sciences* (London, 1885) *[121]*. Clifford begins the chapter on space with the words

> Geometry is a physical science *[121, p. 43]*,

and at the end of the chapter on position he writes:

> We may conceive our space to have everywhere a nearly uniform curvature, but that slight variations of the curvature may occur from point to point, and themselves vary with the time. These variations of the curvature with the time may produce effects which we not unnaturally attribute to physical causes independent of the geometry of our space.

> We might even go so far as to assign to this variation of the curvature of space "what really happens" in that phenomenon which we term the motion of matter *[121, pp. 202–203]*.

Clifford developed these ideas in greater detail in his report *On the space theory of matter* (Cambridge, 1876). First he paraphrases Riemann:

> Riemann has shewn that as there are different kinds of lines and surfaces, so there are different kinds of space of three dimensions; and that we can only find out by experience to which of these kinds the space in which we live belongs. In particular, the axioms of plane geometry are true within the limits of experiment on the surface of a sheet of paper, and yet we know that the sheet is really covered with a number of small ridges and furrows, upon which (the total curvature not being zero) these axioms are not true. Similarly, he says although the axioms of solid geometry are true within the limits of experiment for finite portions of our space, yet we have no reason to conclude that they are true for very small portions; and if any help can be got thereby for the explanation of physical phenomena, we may have reason to conclude that they are not true for very small portions of space *[122, p. 21]*.

Then he states the following four principles:

> (1) That small portions of space *are* in fact of a nature analogous to little hills on a surface which is on the average flat; namely, that the ordinary laws of geometry are not valid in them.
> (2) That this property of being curved or distorted is continually being passed on from one portion of space to another after the manner of a wave.
> (3) That this variation of the curvature of space is what really happens in that phenomenon which we call the *motion of matter*, whether ponderable or etherial.
> (4) That in the physical world nothing else takes place but this variation, subject (possibly) to the law of continuity *[122, pp. 21–22]*

These principles form a program of geometrization of physics.

Riemann's Topology

In addition to the theory of Riemannian spaces Riemann also founded topology—one of the most important disciplines that significantly broadened our notions of space.

We have already pointed out that Euler interpreted Leibniz's term *geometry of position* in a topological sense, whereas Carnot and Grassmann gave it narrower interpretations. Euler's interpretation of the term was developed by the German physicist Johann Benedict Listing (1808–1862), who suggested the now generally accepted term *topology* in his *Preliminary studies on topology* (Vorstudien zur Topologie. Göttingen, 1847) *[329]*. Listing's term comes from replacing Leibniz's Latin *situs* (place) with its Greek counterpart *topos*. Listing studied

> *linear complections, that is, lines or curves or sets of such, located on a surface, such as a plane or a sphere, or arbitrarily disposed in space [329, p. 867].*

He investigated knots, chains, plaits, and other forms of mutual disposition of linear complections - later he called them *linear complexes*—with numerous examples drawn from biology and technology. Listing's work *The census of spatial complexes or a generalization of Euler's therorem on polyhedra* Der Census räumlicher Komplexe oder Verallgemeinerung des Euler'schen Satzes von den Polyedern. Göttingen, 1862) *[330]* dealt with more general *spatial complexes*.

Gauss interpreted Leibniz's ideas in the same topological sense. Gauss devoted to topological investigations, as to non-Euclidean geometry, a number of rough notes and letters (see *[196, vol. 8, pp. 407–410]* and the study of Jean Claude Pont *[435a, pp. 31–38]*). When he founded the topology of two-dimensional manifolds and laid the foundations of multidimensional manifolds Riemann also interpreted Leibniz's ideas in the same way. Riemann laid the foundations of two-dimensional topology in his *Theory of Abelian functions* (1857) *[454, pp. 82–142]*, mentioned earlier. In this work he wrote, with reference to Leibniz, that

> For the study of functions which arise as integrals of exact differentials, some theorems belonging to *analysis situs* are nearly indispensable *[454, p. 91]*.

Riemann associates to algebraic functions $f(x, y)$ in the complex variables x and y multisheeted surfaces now called *Riemann surfaces*. He divides these surfaces into

> simply connected ones, in which every closed curve bounds a region of the surface - as, for example, a disk—and multiply connected ones, for which this does not happen—as, for example, an annulus bounded by two concentric circles *[454, p. 22]*.

and points out that by means of a system of cuts it is possible to make a multiply connected surface into a simply connected one. Riemann introduces the characteristic p of a plane algebraic curve (later called by Clebsch *[119]* the genus of the curve) which he defines as half the number of cuts needed to make the corresponding multiply connected Riemann surface into a simply connected one. The number p is now called the *genus of the surface*. We note that, as S. L'Huillier showed *[323]*, for polyhedra the genus p is connected with the Euler characteristic $\chi = N_0 - N_1 + N_2$ of a polyhedron by means of the relation $\chi = 2 - 2p$. For a sphere $p = 0$, for a torus $p = 1$, and for a sphere with p handles it is equal to p. Riemann showed that for a Riemann surface the genus p, the number n of its sheets, and the number w of its branch points are connected by the relation $w - 2n = 2p - 2$.

In a survey that is a supplement to the article *On the hypotheses that lie at the foundations of geometry* Riemann adds a remark in connection with the first chapter of the article *Notion of an n-ply extended magnitude*:

> Chapter 1 is at once an introduction to investigations on *analysis situs* *[454, p. 286]*.

Fragments dealing with *analysis situs* were published in 1876 in an edition of Riemann's collected works *[454, pp. 479–482]*. In these fragments Riemann generalized the topological properties of a two-dimensional surface to an n-dimensional manifold, here called an *n-stretch* (*n-Streck*). Here Riemann defines what are now called *homologous* n-stretches:

> an n-stretch A is said to be transformable into an n-stretch B if A and parts of B together form the complete boundary of an interior $(n + 1)$-stretch *[454, p. 479]*.

Then he gives the extremely important definition:

> If in the interior of a continuously extended manifold it is possible to make every unbounded n-stretch bounding by means of m definite parts of nonbounding n-stretches then this manifold has $(m + 1)$-tuple connection of the n-th dimension.
>
> A continuously extended manifold is called *simply connected* if the connection of every dimension is simple *[454, p. 479]*.

It is easy to verify that for a two-dimensional manifold of genus p Riemann's *connection* is $(2p + 1)$-ple. Then Riemann explains the dependence of the connection of the boundary of a manifold on the connection of the manifold itself.

These ideas of Riemann were set forth by his friend Enrico Betti in the previously mentioned paper *On spaces of an arbitrary number of dimensions [55, vol. 2, pp. 273–290]*. By "spaces" Betti meant manifolds in multidimensional Euclidean spaces. He wrote:

> If in an n-dimensional space R, bounded by one or more $(n - 1)$-dimensional spaces, every closed m-dimensional space, $m < n$, is the boundary of a part of a linear connected $(m + 1)$-dimensional space, entirely contained in R, then we shall have a connection in $m + 1$ dimensions and we shall say that R has a *simple* connection of the m-th species. If a space R has only simple connections, then we shall say that it is simply connected. If, however, one can imagine in R a number p_m of closed m-dimensional spaces which cannot form the boundary of a linear connected part of an $(m + 1)$-dimensional space, entirely contained in R, and such that every other closed m-dimensional space forms

> by itself or with some or all of these spaces the boundary of a linear connected part of an $(m + 1)$-dimensional space, entirely contained in R, then we shall say that R has a connection of $(p_m + 1)$-th order of the m-th species *[55, vol. 2, p. 278]*.

These ideas were further developed by Poincaré. Already in the memoir *On curves defined by differential equations* (Sur les courbes defines par les équations differentielles. Paris, 1881–1885) *[431, vol. 1, pp. 90–161]* he made extensive use of topological properties of curves to give qualitative descriptions of solutions of differential equations. Poincaré devoted to the topology of multidimensional manifolds the large memoir *Analysis situs* (the title is taken over from Riemann) (Paris, 1895) *[431, vol. 6, pp. 193–288]* and five supplements to it (Palermo-London-Paris, 1899 1904).

Poincaré determined $(n - p)$-dimensional manifold in n-dimensional space by means of p equations and q inequalities between the n coordinates. Then he defined the boundary of a manifold, homomorphism between manifolds, and homology—the fundamental concept of combinatorial topology. Using this concept he defined the *Betti numbers* of a manifold, that is, Betti's *orders of connection* (in the twenties of this century Solomon Lefschetz (1884–1972) and James Alexander (1888–1971) proposed to call *Betti numbers* numbers b_i one less than Poincaré's *Betti numbers*; cf. *[308]*). Poincaré extended Euler's theorem to polyhedra with arbitrary Betti numbers by showing that

$$N_0 - N_1 + N_2 - \cdots + (-1)^n N_{n-1} = b_0 - b_1 + b_2 - \cdots - (-1)^n b_{n-1}.$$

The polynomial $\sum b_i t^i$ is called the *Poincaré polynomial.* In the same paper Poincaré also laid the foundation for the homotopic theory of manifolds in which a leading role is played by the noncommutative *Poincaré group* introduced by him.

Topological Spaces

At the beginning of the 20th century, in connection with the spread of the group-theoretic viewpoint, mathematicians began to study *abstract spaces* together with the study of topological invariants of manifolds that are submanifolds of Euclidean spaces or are obtained from such manifolds by identification of points (as in the case of obtaining the projective plane from a sphere) or by splitting them into points of various sheets (as in the case of constructing the Riemann surface of an algebraic function out of its domain of definition in the complex plane). One of the first works in this direction was the paper *On certain points of the functional calculus* (Sur quelques points du calcul fonctionelles. Palermo, 1906) *[184]* of the French mathematician Maurice Fréchet (1878–1973). In this paper Fréchet defines for the first time an *abstract metric space* exemplified by a space of functions or curves. To construct an abstract space Fréchet found it necessary

> to generalize, first of all, the theory of linear sets that has brought about so much progress in the theory of functions of a single variable,

by which theory he meant the, by that time, extensively developed theory of sets of points of the real line. Fréchet goes on to say:

> If we assume this preliminary investigation of sets then there arises a difficulty. The first generalization that seems natural is that of the notion of a continuous function. But if one wishes to consider operations where the variable is an element of arbitrary nature, then we must first know what is to be meant by neighboring elements or by the limit of a sequence of elements. This seems impossible: usually one gives a special definition of limit for each category of elements under study— points, curves, and so on. I circumvented this difficulty by a method similar to that which allows one to reason in the theory of abstract groups about a composition of explicitly indeterminate form.
>
> Now I note that almost all (but not all) classical definitions of limit can be formulated as follows: in the given category of elements one can associate to each pair of elements a number $\rho(A, B)$ whose properties are very close to the properties of distance of two points, namely that A coincides with B if $\rho(A, B) = 0$ and A tends to B if $\rho(A, B)$ tends to zero. If we accept this hypothesis, less general but nevertheless very broad, then we obtain numerous more specific results.
>
> The approach just outlined leads to the generalizing of almost all theorems about linear sets and about continuous functions (at least those that can be formulated independently of the nature of the investigated sets) *[184, pp. 1–2]*.

When mentioning abstract groups Fréchet emphasizes that he is applying the same methods of creating abstract mathematical concepts that have hitherto been used only in algebra, where, together with the abstract theory of groups, founded in the seventies of the 19th century, there also appeared Dedekind's abstract ring theory.

Developing his program, Fréchet defines a general metric space, which he calls *class* (V), as

> a set of elements of arbitrary nature such that we know how to determine whether two given elements are identical or not and, in addition, such that to any two of them, A, B, we can associate a number $(A, B) = (B, A)$ with the following two properties:
>
> 1′ The necessary and sufficient condition that (A, B) is zero is the identity of A and B.
>
> 2′ There exists a completely determined positive function $f(\varepsilon)$ such that the inequalities $(A, B) \leq \varepsilon$ and $(B, C) \leq \varepsilon$ imply $(A, C) \leq f(\varepsilon)$ for all elements A, B, C. In other words, for (A, C) to be small it suffices that (A, B) and (B, C) are small *[184, p. 18]*.

At present, metric spaces are defined by means of three axioms: the *identity axiom* that coincides with Frechet's axiom 1′; the *symmetry axiom* $(A, B) = (B, A)$ that Frechet regards as part of the definition of distance; and the *triangle inequality axiom* $(A, B) + (B, C) \geq (A, C)$ that replaces Fréchet's axiom 2′.

Fréchet goes on to consider sets in metric spaces, limits of sequences, and limit points of sets. All limit points of a set form its *derived set*. Sets that contain all their limit points are called *closed*, and complements of closed sets with respect to the whole space are called *open* sets. The intersection of all closed sets containing a given set M is called the *closure* $\bar{M}$ of the set M. Then, after defining the Cauchy criterion for a sequence of elements $A_1, A_2, \ldots$ of the metric space as the possibility of associating to every $\varepsilon > 0$ an integer n with the property that the inequality $(A_n, A_{n+p}) > \varepsilon$ is satisfied for every p, Fréchet defines a *complete* metric space as a metric space in which every sequence satisfying the Cauchy criterion has a, necessarily unique, limit.

Fréchet restricts himself to spaces that can be regarded in at least one way as the derived sets of countable sets of their elements. He considers metric spaces of functions with different definitions of distance.

The definition of limit points and closed sets made it possible to introduce continuous mappings and homeomorphisms of the metric spaces considered by Fréchet. Fréchet's paper became the starting point for the development of a general theory of abstract spaces and for the development of the basic concepts of functional analysis.

Since distance is not needed for the study of topological properties of abstract spaces, just as it is not needed for the study of topological properties of lines and surfaces, soon after the appearance of abstract spaces Felix Hausdorff (1868–1942) in his *Foundations of set theory* (Grundzüge der Mengenlehre. Leipzig, 1914) *[217; 218]* defined an *abstract topological space*. Hausdorff defined a topological space as any collection of elements, called *points*, with a distinguished collection of subsets $\{U\}$, such that to each point x there are associated some, and, at the very least, one of the sets of the system $\{U\}$, called *neighborhoods* $U(x)$ of x; the intersection of any two neighborhoods $U_1(x)$ and $U_2(x)$ contains a neighborhood $U_3(x)$ of this point, and if y is a point of a neighborhood $U(x)$ then there exists a neighborhood $U(y)$ of y contained in $U(x)$. Prescribing neighborhoods makes it possible to define limit points of any set M as points x such that every neighborhood of x contains at least one point of M other than x. Just as in Fréchet spaces so too in a topological (Hausdorff) space one defines derived, closed, and open sets. It is easy to see that all neighborhoods are open sets.

Every Fréchet metric space is a topological space. In fact, one can take as neighborhoods the sets of points whose distances from the points of a (fixed) countable set, whose derived set is the whole space, are less than some rational numbers. It is easy to see that the number of such neighborhoods is countable, or, as one says, the space has a *countable basis*.

A further development of the Hausdorff definition is the definition of a topological space proposed by the Polish mathematician Kazimierz Kuratowski (1896–1980) in the paper *The operation $\bar{A}$ of analysis situs* (L'operation $\bar{A}$ de l'analysis situs. Warsaw, 1922) *[296]*. By *operation $\bar{A}$* Kuratowski means the transition from a set A to its closure $\bar{A}$. According to Kuratowski, a topological space is a collection of elements of arbitrary nature, called *points*, on whose subsets A there is defined an operation of *closure* satisfying the following axioms:

1′ for the union $A + B$ of two sets A and B we have $\overline{A + B} = \bar{A} + \bar{B}$;
2′ a set A is contained in its closure, $A \subset \bar{A}$;
3′ the closure of the empty set $\varnothing$ coincides with it, $\overline{\varnothing} = \varnothing$;
4′ the closure of the closure coincides with the closure, $\bar{\bar{A}} = \bar{A}$.

If for every set there is defined its closure $\bar{A}$ then the points of $\bar{A}$ not in A are called the *limit points of A*; the sets A that coincide with their closures A are called the *closed sets*, and their complements relative to the whole space are called the *open sets*.

The Soviet mathematician Pavel Sergeevič Aleksandrov [Alexandroff] (1896–1983) proposed in the paper *On the foundation of* n*-dimensional topology* (Zur Begründung der *n*-dimensionalen Topologie. Leipzig, 1925) *[14]* a more symmetric form of Kuratowski's definition:

1. A topological space is a set of elements of arbitrary nature, called *points*, in which certain subsets, called *open sets*, have been singled out such that:
   1′ the whole space is an open set;
   2′ the null set is an open set;
   3′ the intersection of finitely many open sets is an open set;
   4′ every union of open sets is an open set.
2. A topological space is a set of elements of arbitrary nature, called points, in which certain subsets, called *closed sets*, have been singled out such that:
   1′ the whole space is a closed set;
   2′ the null set is a closed set;
   3′ every union of closed sets is a closed set;
   4′ the intersection of finitely many closed sets is a closed set.

In the first case a closed set is defined as the complement of an open set and in the second case an open set is defined as the complement of a closed set. Neighborhoods can be defined as subsystems of open sets such that an arbitrary open set can be represented as the union of sets of this subsystem (see *[218, p. 258]*).

To different systems of closed or open subsets in the same set of points there correspond different topologies on this set. For example, our axiom systems are satisfied if

(A) the only closed (and open) sets are the whole space and the null set;
(B) the closed (and open) sets are all sets of points of the space.

In case (A) the closures of all nonempty sets, including single points, coincide with the whole space. In case (B) the closure of each set coincides with this set, and a minimal system of neighborhoods is a system in which the neighborhood of each point is that point alone. Then the space has no limit points and is called *discrete*; the space of case (A) is called *trivial*.

Hausdorff ruled out case (A) by means of the following axiom: for any two points of the space there are disjoint neighborhoods *[218, p. 260]*. Sometimes Hausdorff's axiom is replaced with a weaker one due to Frigyes Riesz, that the closures of all single points of the space are the points themselves *[456, vol. 1, pp. 155 169]*—or by an even weaker axiom introduced by the Soviet mathematician Andreĭ Nikolaevič Kolmogorov (1903 1987), that any two points of the space have different closures *[15, p. 58]*.

A very important class of topological spaces is the class of *compact spaces* such that every covering of the space by means of open sets contains a finite subcovering. The Soviet mathematicians P. S. Aleksandrov and Pavel Samuilovič Uryson [Urysohn] (1898–1924) studied such spaces in the case when the minimal cardinality of a system of neighborhoods is greater than the cardinality of a countable set and called them *bicompact [16]*. For these spaces P. S. Aleksandrov developed a homology theory analogous to the homology theory of manifolds in Euclidean spaces. By now mathematicians have found a great many topological invariants of the most varied topological spaces.

One of the most obvious topological invariants is the dimension of a topological space. Whereas it is possible to have a one-to-one correspondence between manifolds of different dimensions, a one-to-one bicontinuous correspondence can only be established between manifolds of the same dimension. If the points of a topological space have neighborhoods homeomorphic to n-dimensional Euclidean space then it is natural to say that the dimension of the space is n. In more complicated cases dimension was defined by the Dutch mathematician Luitzen Egbertus Jan Brouwer (1882–1966) in the paper *Proof of the invariance of the dimension number* (Beweis der Invarianz der Dimensionzahl. Leipzig, 1911) *[80]*. The ideas of Brouwer were developed by Urysohn in *A memoir on Cantor manifolds* (Memuar o kantorovyh mnogoobraziyah. 1928) *[599]* and by the German mathematician Karl Menger (b. 1902) in *Dimension theory* (Dimensionstheorie. Leipzig, 1932) *[362]*. They defined dimension by induction on the dimension number, beginning with the dimension -1 which they assigned to the empty set.

Urysohn and Menger also proposed another definition of dimension, equivalent to the preceding for the most important topological spaces: a nonempty space is n-dimensional if every finite covering of the space has a finite subdivision of order $\leq n$ and there exists a finite covering of the space without finite subdivisions of order $< n$. A nonempty space is infinite-dimensional if it is not n-dimensional for any nonnegative n. The dimension of the null set is again taken to be -1.

In the previously mentioned paper Brouwer proved his famous *fixed-point* *theorem*: every continuous mapping of an n-dimensional simplex into itself has at least one fixed point. This theorem was first proved by the Latvian mathematician Piers Bohl (1865–1921), who worked in Riga, in the paper *On the motion of a mechanical system near an equilibrium position* (Über die Bewegung eines mechanischen Systems in der Nähe einer Gleichgewichtlage. Berlin, 1904) *[64, pp. 79–125]*. The Bohl-Brouwer theorem was extended to infinite-dimensional analogues of an n-dimensional simplex by the Soviet mathematician Andrei Nikolaevič Tihonov [Tychonoff] (b. 1906) *[597]*. Bohl came to the fixed-point theorem in connection with the problem of proving the existence of a solution of a system of differential equations connected with the notion of certain mechanical systems he investigated. The Bohl-Brouwer theorem was later used to prove the existence of solutions of finite systems of ordinary differential equations, and the Tihonov theorem was used to prove the existence of solutions of infinite systems of differential equations.

The Influence of the General Theory of Relativity

We have already pointed out the importance of Einstein's discovery of the special theory of relativity for the elaboration of the concept of pseudo-Euclidean geometry. For example, the appearance of Weyl's book *Space, time, matter [626]* in which, among other matters, he set forth his axiomatization of n-dimensional Euclidean space, was connected with the general theory of relativity. But the importance of the general theory of relativity for the development of geometry is far broader and deeper. Whereas in the special theory of relativity spacetime was viewed as a pseudo-Euclidean space, in the general theory it is viewed as an analogue of a Riemannian space that stands in the same relation to such a space as pseudo-Euclidean space to Euclidean space. Such a space is now called a *pseudo-Riemannian* or *general Riemannian space*. Just as in a Riemannian space, so too at each point of this space there is given the square of a line element

$$ds^2 = \sum_i \sum_j g_{ij} dx^i dx^j,$$

where the g_{ij} are point functions and, although the quadratic form is no longer positive definite, it can be reduced at each point to the form

$$ds^2 = -(dx^0)^2 + (dx^1)^2 + (dx^2)^2 + (dx^3)^2.$$

The first sketch of the general theory of relativity was set forth by Einstein together with the German mathematician Marcel Grossmann (1878–1936) in *Outline of a generalized theory of relativity and theory of gravitation* (Entwurf einer verallgemeinerten Relativitätstheorie und Theorie der Gravitation. Leipzig, 1913), and the final theory was presented in *Foundations of the general theory of relativity* (Grundlagen der allgemeinen Relativitätstheorie. Leipzig, 1916) *[340, pp. 109–164]*.

Already in the 1913 paper Einstein and Grossmann used the *tensor calculus* created by the Italian geometer Gregorio Ricci-Curbastro (1853–1925) in *Principles of a theory of differential quadratic forms* (Principii di una theoria delle forme differenziale quadratiche. Milan, 1884) *[453, vol. 1, pp. 138–171]* and subsequently developed together with Tullio Levi-Civita (1873–1941) in *Methods of the absolute differential calculus and their applications* (Méthodes du calcul différentiel absolu et leurs applications. Leipzig, 1901) *[453, vol. 2, pp. 185–271]*. Ricci gave the name *covariant system of the first order* to the functions a_i of the coordinates x^i that change as a result of a coordinate transformation $x^{i'} = x^{i'}(x^1, \ldots, x^n)$ in accordance with the rule

$$a_{i'} = \sum_i a_i \frac{\partial x^i}{\partial x^{i'}}, \tag{8.7}$$

exemplified by the law of transformation of partial derivatives $\frac{\partial \varphi}{\partial x^i}$, and the name *contravariant system of the first order* to functions a^i of the coordinates x^i that transform in accordance with the opposite rule

$$a^{i'} = \sum_i a^i \frac{\partial x^{i'}}{\partial x^i}, \tag{8.8}$$

exemplified by the law of transformation of the differentials dx^i of the coordinates. Ricci considered scalars as systems of zero order.

Ricci called the functions a_{ij}, a^{ij}, and a^i_j that transform in accordance with the respective rules

$$a_{i'j'} = \sum_i \sum_j a_{ij} \frac{\partial x^i}{\partial x^{i'}} \frac{\partial x^j}{\partial x^{j'}}, \quad a^{i'j'} = \sum_i \sum_j a^{ij} \frac{\partial x^{i'}}{\partial x^i} \frac{\partial x^{j'}}{\partial x^j}, \quad a^{i'}_{j'} = \sum_i \sum_j a^i_j \frac{\partial x^{i'}}{\partial x^i} \frac{\partial x^j}{\partial x^{j'}}, \tag{8.9}$$

twice covariant, *twice contravariant*, and *mixed* systems of the second order.

Ricci defined in a similar way systems of higher order. Contravariant systems of the first order at a point can be regarded as coordinates of vectors; covariant systems of the first order at the same point can be regarded as coefficients of linear forms defined on these vectors; twice covariant systems of the second order can be regarded as coefficients of bilinear forms defined on these vectors, and mixed systems of the second order can be regarded as matrices of linear transformations defined on these vectors. Einstein and Grossmann proposed that Ricci's "systems" be called *tensors* (and thus extended to them the term *elastic tensor* and that the "orders" of the systems be called *ranks*. The Dutch geometer Jan Arnoldus Schouten (1883–1971) in his *Ricci calculus* (Der Ricci-Kalkül. Berlin, 1924) *[510]* called Ricci's systems *affinors* and thereby extended to them a term used by F. Jung for linear operators; he called "orders" of the systems *valences*, borrowing this term from chemistry.

Most mathematicians now use the term *tensor* in the sense of Einstein and *valence* in the sense of Schouten. Following Einstein's suggestion, in the tensor calculus one omits the summation sign when summing with respect to covariant and contravariant indices. We will follow this rule in the following.

The coefficients of the quadratic form that defines the metric of a Riemannian space form a twice covariant tensor g_{ij}; the quadratic form is written in tensor notation as

$$ds^2 = g_{ij}dx^i dx^j, \tag{8.10}$$

and the equation of the geodesics is written as

$$\frac{d^2x^i}{dt^2} + \Gamma^i_{jk}\frac{dx^j}{dt}\frac{dx^k}{dt} = 0. \tag{8.11}$$

The Christoffel symbols Γ^i_{jk} do not form a tensor and transform under coordinate transformations in accordance with a more involved law. But the four-index Riemann symbols, now written as $R_{ij,k}^{\cdot\cdot\,\cdot l}$, do form a tensor of valence four called the *curvature tensor*.

Covariant differentiation as defined by Ricci associates to every tensor field in a Riemannian space—that is, to every function that defines a tensor at every point of a region in a Riemannian space—the field of a new tensor that has one additional covariant valence. The covariant derivative $\nabla_i\varphi$ of a scalar is its partial derivative $\frac{\partial\varphi}{\partial x^i}$ with respect to the coordinate x^i. The covariant derivatives $\nabla_j a^i$ and $\nabla_j a_i$ of vectors a^i and a_i are given by

$$\nabla_j a^i = \frac{\partial a^i}{\partial x^j} + \Gamma^i_{jk}a^k, \qquad \nabla_j a_i = \frac{\partial a_i}{\partial x^j} - \Gamma^k_{ji}a_k. \tag{8.12}$$

The covariant derivatives $\nabla_k a_{ij}$ and $\nabla_k a^i_j$ of the tensors a_{ij} and a^i_j have the form

$$\nabla_k a_{ij} = \frac{\partial a_{ij}}{\partial x^k} - \Gamma^l_{ki}a_{lj} - \Gamma^l_{kj}a_{il}, \qquad \nabla_k a^i_j = \frac{\partial a^i_j}{\partial x^k} + \Gamma^i_{kl}a^l_j - \Gamma^l_{kj}a^i_l. \tag{8.13}$$

The Geometry of the General Theory of Relativity

Einstein formulated the principle of general relativity in *The foundations of the general theory of relativity* as follows:

> The general laws of nature are to be expressed by equations which hold good for all systems of co-ordinates, that is, are covariant with respect to any substitutions whatever (generally covariant) *[340, p. 117]*.

The most important element of the general relativity theory is the geometric interpretation of gravity. In this theory gravitation is linked to the curvature of space, whose definition in a pseudo-Riemannian space is the same as that in a Riemannian space; the greater the density of matter in a certain region, and thus the intensity of the gravitational field, the greater the curvature of pseudo-Riemannian spacetime. A mass point subject to gravitational forces alone moves along a geodesic which satisfies the same equations as in Riemannian space.

Light rays, too, propagate along geodesics of pseudo-Riemannian spacetime. The deflection of the trajectories of material particles and of light rays from straight lines represents the attraction of particles of matter and of light by the heavy masses that gives rise to the gravitational field. In this connection we quote from Einstein's paper *On the ether* (Über den Aether. Zürich, 1924) *[166]*:

> General relativity theory sets aside one other shortcoming of classical dynamics: in the latter, inertia and weight appear as phenomena that are completely independent from one another in spite of the fact that both are conditioned by the same material constant -- mass. Relativity theory surmounts this shortcoming by establishing for the dynamical behavior of an electrically neutral particle the law of geodesics in which the interaction of inertia and gravitation is already inseparable. This interaction imparts to the ether a metric that varies from point to point and properties that determine the dynamical behavior of material points. In turn, these are determined by physical factors, namely the distribution of mass or energy. Thus the ether of general relativity differs from the ether of classical mechanics in that it is no longer "absolute" but is determined in the sense of its properties, that vary in space, by the distribution of weighted matter. This definition is complete provided that the world is spatially finite and closed *[166, p. 89]*.

Here the word *ether* is used in the sense of curved space whose geometric properties are determined by matter; in other papers Einstein replaces this term by the term *space-time continuum*. Einstein's reference to the finite and closed character of the universe reflects his original view that the curvature of space implies that space is finite and closed. (Cf. the paper *[649]* of Yakov Borisovič Zel'dovič (1914–1988).)

General relativity theory has given a physical interpretation to the curvature of pseudo-Riemannian spacetime. Light rays propagate along the isotropic geodesics of this spacetime. The deviation of the trajectories of material points and light rays from geodesics represents the attraction of material points and light by the heavy masses that give rise to the gravitational field.

The primary connection between non-Euclidean geometry and general relativity is that the discovery of non-Euclidean geometry extended the range of conceivable spaces and thus prepared the ground for the discovery of spaces of variable curvature, both Riemannian and pseudo-Riemannian; the latter represents the mathematical apparatus of general relativity. However, there is also a direct link between general relativity and non-Euclidean

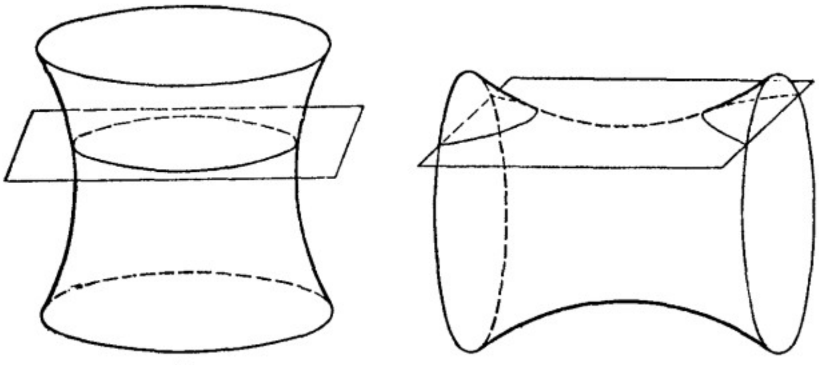

Figure 105

geometry, but what is involved is a four-dimensional rather than a three-dimensional space as in the case of special relativity. The geometry in question describes the spacetime of general relativity "in the mean," under the assumption of the uniform distribution of matter. This view was presented by Einstein already in the paper *Cosmological considerations linked to the general relativity theory* (Kosmologische Betrachtungen zur allgemeinen Relativitätstheorie. Berlin, 1917) *[340, pp. 175–189]*. Here Einstein considered a uniform distribution of matter in space alone, regarding space itself as a sphere in four-dimensional Euclidean space and spacetime as a cylinder in five-dimensional space. However, if we proceed from the assumption that we are dealing with a uniform distribution of matter throughout the spacetime continuum then spacetime is a sphere of real or imaginary radius in five-dimensional pseudo-Euclidean spaces of indices 4 and 3, respectively. If we assume, for simplicity, that the hypersurfaces $t =$ const. are parallel hyperplanes, then, in time, the "space section" of the world decreases or increases, depending on the position of the cutting hyperplane. In the first case the curvature of the "space section" is constant and positive, whereas in the second case it is constant and negative (Figures 105a and 105b), in full agreement with astronomical observations. This confirmation shows that real spacetime, that is, a pseudo-Riemannian space of variable curvature, corresponds in the mean to the picture just outlined; the theory of an expanding universe of constant negative curvature was proposed by A. A. Friedmann in the paper *On the possibility of a world of constant negative curvature* (Über die Möglichkeit einer Welt mit konstanter negativer Krümmung des Raumes. Leipzig, 1924) *[188]*.

The view of spacetime as a four-dimensional pseudo-Riemannian space of index 3 with positive curvature was proposed by the Belgian astronomer Willem de Sitter (1872 1934) in the paper *On Einstein's theory of gravitation and its astronomical consequences* (Brussels, 1917) *[541]*. In the paper *Geometrical note on de Sitter's world* (London, 1924) *[158]* Patrick du Val showed that "de Sitter's world" is a Lobačevskian space of positive curvature, that is, a sphere of real radius in five-dimensional pseudo-Euclidean space of index 4 with identified antipodal points (see also *[129a]*).

Einstein's Philosophy of Space

The discovery of the general theory of relativity was a brilliant concretization of the connection between matter and space and time, which are an existence form of matter— an issue often addressed by the classics of Marxism.

Einstein dealt with the philosophical questions of space in many of his papers. One relevant passage is the preceding quotation from his paper *On the ether*. The following quotation is from the paper *Geometry and experience* (Geometrie und Erfahrung. Berlin, 1921) *[165]*:

> Of all sciences mathematics is held in especially high esteem, for its theorems are absolutely true and indisputable while the areas of other sciences are to some extent debatable and there is always the danger of their results being overturned by new discoveries. But it is not fitting for a researcher working in some other area of science to envy mathematics, for the propositions of mathematics rest not on real objects but exclusively on objects of our imagination. In fact, it is little wonder that one attains logical agreement of deductions if one earlier reached agreement concerning the principal propositions (axioms) as well as the methods to be employed for deriving from the principal propositions other propositions. At the same time, the deep esteem for mathematics has another basis, which is that mathematics is that which gives to the exact sciences a measure of confidence which they could not otherwise attain.
>
> In this connection there arises a riddle that has worried researchers of all times. Whence the remarkable correspondence between mathematics and real things if mathematics is just a product of human thought unrelated to any experience? Can the human mind understand the properties of real things without any experience, just by way of reflection?
>
> To my mind, a concise answer to this question is this: to the extent to which the theorems of mathematics can be applied to reflect the real world they are not exact; they are exact to the extent to which they do not refer to reality. It seems to me that complete clarity in this matter can be achieved only by following the kind of mathematics known as axiomatics. The progress achieved through axiomatics consists in the fact that it sharply separated its formal-logical content from its objective and intuitive content. By point, straight line, and so on, in axiomatic geometry one should mean only contentless ideas. That which gives them content lies outside mathematics.
>
> On the other hand, however, it is true that mathematics in general and geometry in particular owe to their origins the necessity of learning

> a little about the behavior of objects existing in reality. This is shown by the very word "geometry" which means "measurement of the earth" *[165, pp. 3–5]*.

In this paper Einstein arrives

> at the viewpoint held by as original and deep a thinker as Henri Poincaré: Euclidean geometry differs from all conceivably possible axiomatic geometries by its simplicity. And since axiomatic geometry contains no statements about actual reality and can make such statements only in conjunction with physical laws, it seems possible and reasonable to adhere to Euclidean geometry regardless of the properties of reality. On the other hand, in case of an observed disagreement between theory and experience, it is easier to agree to change physical laws than axiomatic Euclidean geometry. If one forgets all about the connection between a practically rigid body and geometry, then it is not easy to refuse to admit that Euclidean geometry must be viewed as simplest.
>
> Why did Poincaré and other researchers reject the equivalence that thrusts itself upon one between a practically rigid body of real experience and a geometric body? Simply because, when one considers them more closely, real rigid bodies in nature turn out not to be rigid at all, since their geometric behavior, that is, their possible mutual disposition, depends on temperature, external forces, and so on. Thus the initial direct connection between geometry and physical reality is destroyed and we are forced to shift to the following more general position characteristic of Poincaré's viewpoint. Geometry (G) tells us nothing about the behavior of real objects; this behavior is described only by geometry together with the totality of physical laws (Ph). In symbolic terms we can say that only the sum (G) + (Ph) lends itself to experimental verification. Thus one can choose arbitrarily (G) as well as different parts of (Ph); all of these laws represent agreements. To avoid contradictions it is necessary to choose the rest of (Ph) so that (G) and all (Ph) are experimentally verifiable *[165, pp. 7–8]*.

We see that Einstein refers here to the philosophical works of Poincaré mentioned earlier but, unlike Poincaré, who treated "objective reality" and "laws of nature" in the spirit of Mach, Einstein proceeds from "physical reality" and the possibility of "choosing arbitrarily" (G), that is, geometric axioms which, together with (Ph), that is, physical laws, must confront experience. Thus Einstein interprets Poincaré's position in materialistic terms and, like Lobačevskiĭ, believes that the question of which of the conceivable geometric systems corresponds to the geometry of the real world must be decided experimentally.

It should be pointed out that Einstein frequently refers to Mach, whom he regards as one of his predecessors. In the obituary *Ernst Mach* (Ernst Mach. Leipzig, 1916) Einstein considered Mach's critique of Newton's mechanics and wrote:

> The quoted lines show that Mach clearly understood the weak points of classical mechanics and came close to discovering the general relativity theory. And that half a century before its creation! *[167]*.

Einstein regarded Mach's idea that the inertia of a body is explainable by its interaction with other bodies—what Einstein called *Mach's principle*—as one of the factors in the preparation of the general relativity theory. Mach's idea that "space and time cannot be completely separated from one another" *[347, p. 350]* is very close to the ideas of special relativity theory.

Undoubtedly, Einstein's famous *thought experiments* were influenced by Mach. At the same time Einstein did not agree with Mach's doctrine of sensations as elements of the world. He not only interpreted the terms *sensations* and *experience* in a materialist spirit but also ascribed his viewpoint to Mach when he said (apropos Mach's use of the term *sensations*) that

> frequently, as a result of insufficient familiarity with his, that is, Mach's, works, some persons tend to confuse them with the terminology of philosophical idealism and solipsism *[167]*.

Here Einstein's opinion was based on the fact that he took Mach's materialist terminology literally and throught it inconceivable that a serious physicist could be a subjective idealist. Later Einstein changed his opinion about Mach's philosophy and during a meeting of the French philosophical society, while answering a question from Emile Meyerson, he referred to Mach as a "deplorable philosopher" (*un déplorable philosophe*) and accused him of a "myopic view of science that led him to reject the existence of atoms" *[364, p. 62]*.

Parallel Displacement

The heightened interest in Riemannian geometry brought about by general relativity theory resulted in an extremely important discovery in this geometry, a concept known as *parallel displacement of vectors*. The discovery was made by Levi-Civita in the paper *The notion of parallelism in an arbitrary manifold and the geometric characterization of Riemannian curvature implied by it* (Nozione di parallelismo in una varieta qualunque e consequente specificazione geometrica della curvatura Riemannina. Palermo, 1917) *[320]*.

If a vector a^i is defined at a point A of a Riemannian space then the result of its displacement to a point B of the line $x^i(t)$ is a solution of the differential equation

$$\frac{da^i}{dt} + \Gamma^i_{jk} a^j \frac{dx^k}{dt} = 0, \tag{8.14}$$

that can be written with the help of the covariant derivative as

$$\nabla_k a^i \frac{dx^k}{dt} = 0. \tag{8.15}$$

It follows that if one defines along a coordinate line a vector field of vectors obtained by parallel displacement of a given vector then at all points of this line the covariant derivative with respect to the corresponding coordinate is equal to zero. Parallel displacement of vectors admits of a visual geometric definition. Parallel displacement of vectors from a point A of the space to an infinitely near point B is generated by mapping a neighborhood of the point A onto a neighborhood of the point B that is the result of applying first a reflection (along geodesics) in the point A in the neighborhood of A, and then a reflection in C, the midpoint of the geodesic arc from A to B, in a neighborhood of C that contains the neighborhood of A. Under this neighborhood mapping the increments of the coordinates of the point A map to the increments of the coordinates of the point B and, consequently, the differentials of the coordinates of A, that is, the vectors at A, map to the differentials of the coordinates of B, that is, the vectors at B. The name *parallel displacement* is due to the fact that the product of two reflections in two points in ordinary space is a translation of this space. Levi-Civita showed that the curvature of a Riemannian space, at a given point, in a two-dimensional direction is the limit of the ratio of the angle by which a vector is rotated as a result of parallel displacement along a closed contour passing through the given point to the area of the surface bounded by this contour when the contour shrinks to the given point (this is Levi-Civita's *geometric characterization of Riemannian curvature*).

The Problem of a Unified Field Theory
